A diagnosis can also be based on positive cultures of stool, urine, rose spots, bone marrow, and gastric or intestinal secretions. Unlike blood cultures, bone marrow cultures remain highly (90%) sensitive despite ≤5 days of antibiotic therapy. Culture of intestinal secretions (best obtained by a noninvasive duodenal string test) can be positive despite a negative bone marrow culture. If blood, bone marrow, and intestinal secretions are all cultured, the yield of a positive culture is >90%. Stool cultures, while negative in 60 to 70% of cases during the first week, can become positive during the third week of infection in untreated patients. Although the majority of patients (90%) clear bacteria from the stool by the eighth week, a small percentage become chronic carriers and continue to have positive stool cultures for at least 1 year.

Several serologic tests, including the classic Widal test for “febrile agglutinins,” are available; however, given high rates of false-positivity and false-negativity, these tests are not clinically useful. Polymerase chain reaction and DNA probe assays are being developed.

![FIGURE 137-1](https://example.com/rose_spots.png) "Rose spots," the rash of enteric fever due to \textit{S. typhi} or \textit{S. paratyphi}.

**TREATMENT**

In the preantibiotic era, the mortality rate from typhoid fever was as high as 15%. The introduction of treatment with chloramphenicol in 1948 greatly altered the disease course, decreasing mortality to <1% and the duration of fever from 14–28 days to 3–5 days. Chloramphenicol remained the standard treatment for enteric fever until the emergence of plasmid-mediated resistance to this drug in the 1970s. Given the increased mortality associated with resistance to chloramphenicol and the rare chloramphenicol-induced bone marrow toxicity, ampicillin (1 g orally every 6 h) and trimethoprim-sulfamethoxazole (TMP-SMX; one double-strength tablet twice daily) became the mainstays of treatment.

In 1989, MDR \textit{S. typhi} emerged. These bacteria are resistant to chloramphenicol, ampicillin, trimethoprim, streptomycin, sulfonamides, and tetracycline. Like chloramphenicol resistance, resistance to ampicillin and trimethoprim is plasmid-encoded. In 1994, 12% of \textit{S. typhi} isolates in the United States were MDR. Thus either quinolones or third-generation cephalosporins are currently recommended for empirical antibiotic treatment (Table 137-1). Despite efficient in vitro killing of \textit{Salmonella}, first- and second-generation cephalosporins as well as aminoglycosides are ineffective in treating clinical infections.

Quinolones are the only available oral antibiotics for the treatment of MDR \textit{S. typhi} infections. The greatest experience has been gained for ciprofloxacin (500 mg orally twice a day for 10 days). Shorter courses of ofloxacin (10 to 15 mg/kg in divided doses twice daily for 2 to 3 days) have also been successful. Limited data suggest that treatment with fluoroquinolones is associated with fewer treatment failures.
and more rapid resolution of symptoms than treatment with β-lactam agents. However, quinolone resistance is emerging. In 1993, an outbreak of nalidixic acid-resistant S. typhi (NARST) infections in Vietnam was linked to chromosomal mutations in the gene encoding DNA gyrase (the target of the quinolones). NARST strains have also been isolated in India. Thus, all strains of S. typhi must be screened for resistance to nalidixic acid and tested for sensitivity to a clinically appropriate quinolone. Patients infected with NARST strains need to be treated with higher doses of ciprofloxacin (10 mg/kg twice a day for 10 days) or longer courses of ofloxacin (10 to 15 mg/kg in divided doses twice daily for 7 to 10 days) or with other antibiotics to which the strains are sensitive.

Ceftriaxone (1 to 2 g intravenously or intramuscularly) for 10 to 14 days is equivalent to oral or intravenous chloramphenicol in the treatment of susceptible strains. An alternative agent shown to be effective in an open-label study for the treatment of NARST strains is azithromycin (1 g orally once a day for 5 days or 1 g orally on day 1 followed by 500 mg orally for 6 days).

In cases of severe typhoid fever (fever; an abnormal state of consciousness—i.e., delirium, obtundation, stupor, or coma—or septic shock; and a positive culture for S. typhi or S. paratyphi A), dexamethasone treatment should be considered. In a single trial in Jakarta in the early 1980s in chloramphenicol-treated patients, treatment with dexamethasone (a single dose of 3 mg/kg followed by eight doses of 1 mg/kg, given every 6 h) decreased the mortality rate from 56% to 10%.

The 1 to 4% of patients who develop chronic carriage of Salmonella can be treated for 6 weeks with an appropriate antibiotic. Treatment with oral amoxicillin, TMP-SMX, ciprofloxacin, or norfloxacin has been shown to be ~80% effective in eradicating chronic carriage of susceptible organisms. However, in cases of anatomical abnormality (e.g., biliary or kidney stones), eradication of the infection often cannot be achieved by antibiotic therapy alone and requires surgical correction of the abnormalities.

PREVENTION AND CONTROL Theoretically, it is possible to eliminate salmonellae that cause enteric fever since the bacteria survive only in human hosts and are spread by contaminated food and water. However, given the high prevalence of the disease in developing countries that lack good facilities for sewage disposal and water treatment, this goal is currently unrealistic. Thus, travelers to developing countries should be advised to monitor their food and water intake carefully and to consider vaccination.

Three vaccine alternatives are currently available: (1) a heat-killed, phenol-extracted, whole-cell vaccine (two parenteral doses); (2) Ty21a, an attenuated S. typhi vaccine (four oral doses); and (3) ViCPS, consisting of purified Vi polysaccharide from the bacterial capsule (one parenteral dose). In addition, an acetone-killed whole-cell vaccine is available only for use by the U.S. military. The minimal ages for vaccination with the Ty21a, ViCPS, and Vi-rEPA (see below) vaccines are 6 years, 2 years, and 6 months, respectively. A large-scale meta-analysis of vaccine trials comparing the whole-cell vaccine, Ty21a, and ViCPS in populations of endemic areas indicates that, while all three vaccines have similar efficacy for the first year, the 3-year cumulative efficacy of the whole-cell vaccine (73%) exceeds that of both Ty21a (51%) and purified Vi (55%). In addition, the heat-killed whole-cell vaccine maintains its efficacy for 5 years, while Ty21a and ViCPS most likely maintain their efficacy for 4 and 2 years, respectively. However, the whole-cell vaccine is associated with a much higher incidence of side effects than the other two vaccines; 16% of whole-cell vaccine recipients develop fever and 10% miss a day of work or school, while only 1 to 2% of persons receiving the alternative vaccines have any fever. A fourth vaccine, Vi-rEPA, has been developed. This vaccine consists of Vi polysaccharide bound to a nontoxic recombinant protein that is identical to Pseudomonas aeruginosa exotoxin A; two parenteral doses are given. Coupling of the Vi polysaccharide to exotoxin A results in impressive T cell responses. In a trial in 2- to 5-year-old children, the vaccine provided 90% efficacy and was very well tolerated, with no evidence of adverse reactions. Trials of this vaccine in adults and infants are under way.

Although data on typhoid vaccines in travelers are limited, some evidence suggests that efficacy may be substantially lower than that for populations in endemic areas. The Centers for Disease Control and Prevention (CDC) currently recommends vaccination for persons traveling to developing countries who will have prolonged exposure to contaminated food and water or close contact with indigenous populations in rural areas. The only recommendations for domestic vaccination include people who have intimate or household contact with a chronic carrier or laboratory workers who frequently work with S. typhi. Given their decreased incidence of side effects and their similar short-term efficacy, the current bias is toward the use of Ty21a or ViCPS for vaccination of travelers.

Enteric fever is a reportable disease in the United States. Individual health departments have their own guidelines for allowing food handlers or health care workers to return to work. The reporting system enables public health departments to track down potential source patients and thus to identify and treat chronic carriers in order to prevent further outbreaks. In addition, since 1 to 4% of patients with S. typhi infection become chronic carriers, it is important to monitor patients (especially those employed in child care or food handling) for chronic carriage and to treat this condition if indicated.

NONTYPHOIDAL SALMONELLOSIS

Epidemiology The incidence of nontyphoidal salmonellosis has doubled in the United States over the past two decades. Currently, the CDC estimates that there are 2 million cases annually, with 500 to 2000 deaths. Although more than 200 serovars of Salmonella are considered to be human pathogens, the majority of the reported cases in the United States are caused by S. typhimurium or S. enteritidis. The incidence of salmonellosis is highest during the rainy season in tropical climates and during the warmer months in temperate climates, coinciding with the peak in food-borne outbreaks. Morbidity and mortality associated with salmonellosis are highest among the elderly, infants, and immunocompromised individuals, including those with hemoglobinopathies and those infected with HIV or with pathogens that cause blockade of the reticuloendothelial system (e.g., patients with bartonellosis, malaria, schistosomiasis, or histoplasmosis).

Unlike S. typhi and S. paratyphi, whose only reservoir is humans, nontyphoidal salmonellosis is acquired from multiple animal reservoirs. The main mode of transmission is from food products contaminated with animal products or waste—most commonly eggs and poultry but also undercooked meat, unpasteurized dairy products, seafood, and fresh produce. S. enteritidis associated with chicken eggs is emerging as a major cause of food-borne disease. S. enteritidis causes infection of the ovaries and upper oviduct tissue of hens, resulting in contamination of the contents of eggs prior to shell deposition. Approximately 1 in 20,000 eggs is thought to be infected with S. enteritidis. Between 1974 and 1994, there was a fivefold increase (from 5% to 25%) in the isolation of S. enteritidis from eggs in the United States; in 1998, the U.S. Department of Agriculture estimated that 80% of all salmonellosis cases were caused by infected eggs. Eradication of S. enteritidis from hens has proved difficult, given that infection is spread to egg-laying...
hens both vertically from breeding flocks and horizontally through contact with rodents and manure. Transmission via contaminated eggs can be prevented by cooking of eggs such that the liquid yolk is solidified or through pasteurization of egg products.

Another factor in the increasing incidence of nontyphoidal salmonellosis in developed countries, including the United States, is related to the centralization of food processing and widespread distribution. For example, a 1994 outbreak of ≈250,000 cases was linked to a pasteurized ice-cream premix most likely contaminated in tanker trucks that had previously carried unpasteurized eggs. Similar outbreaks have been traced to manufactured foods including pasteurized milk, infant formula, powder-milk products, paprika-powdered potato chips, and a ready-to-eat savory snack. In addition, large outbreaks have been linked to fresh produce, including alfalfa sprouts, cantaloupe, fresh-squeezed orange juice, and sliced tomatoes, contaminated by manure or water at a single site and then broadly distributed.

A less common source of nontyphoidal Salmonella infections is exposure to pets, especially reptiles. Fecal carriage rates in reptiles can be >90%. In the 1970s, 14% of cases of salmonellosis were attributed to small turtles; the U.S. Food and Drug Administration subsequently prohibited the distribution of these pets, with a resultant decline in rates of reptile-associated salmonellosis. However, since 1986, an increase in the popularity of nonbanned reptiles, including iguanas, has been followed by increases in rates of Salmonella infections. Other pets, including African hedgehogs, snakes, birds, rodents, baby chicks, ducklings, dogs, and cats, can also serve as potential vectors.

Antibiotic resistance is an increasing phenomenon among nontyphoidal Salmonella serovars. In particular, S. typhimurium of definitive phage type 104 (DT104)—a serotype resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracyclines—has become prominent in the United Kingdom. This serotype is associated with greater mortality and morbidity than other nontyphoidal Salmonella serotypes. Its acquisition is associated with exposure to ill farm animals and to a variety of meat products. The prevalence of S. typhimurium DT104 in the United States increased from 0.6% in 1979–1980 to 34% in 1996. Of concern is the isolation in the United Kingdom in 1996 of S. typhimurium DT104 strains resistant to ciprofloxacin (14%) or trimethoprim (24%).

Also of concern is the recent increase in ceftriaxone- and fluoroquinolone-resistant nontyphoidal Salmonella strains in the United States. The CDC reported that the prevalence of ceftriaxone-resistant strains increased from 0 to 0.5% from 1995 to 1998. Each resistant strain appears to be an independent isolate. The majority of resistant strains have been isolated from children, where the clinical use of fluoroquinolones is limited. The likely source of resistant strains appears to be cattle and chickens treated with ceftriaxone, since 2% of S. typhimurium strains isolated from these livestock in the United States are also resistant to ceftriaxone. In addition, at least two outbreaks of fluoroquinolone-resistant S. typhimurium have been reported in this country. In each instance, the index case presumably originated in the Philippines. Fluoroquinolone-resistant S. choleraesuis has also been documented in Taiwan. One outbreak was associated with fluoroquinolone-treated swine; thus the source of these resistant strains also appears to be livestock treated with antibiotics.

**CLINICAL MANIFESTATIONS**

**Gastroenteritis** Infection with nontyphoidal Salmonella most often results in gastroenteritis indistinguishable from that caused by other bacterial and viral pathogens. Nausea, vomiting, and diarrhea occur 6 to 48 h after the ingestion of contaminated food or water. Patients often experience abdominal cramping and fever (38° to 39°C, or 100.5° to 102.2°F). The diarrhea is usually characterized as loose, nonbloody stools of moderate volume. However, large-volume watery stools, bloody stools, or symptoms of dysentery do not rule out the diagnosis. Rarely, Salmonella causes a syndrome of pseudoappendicitis or an illness that mimics inflammatory bowel disease. Gastroenteritis caused by nontyphoidal Salmonella is usually self-limited. Diarrhea resolves within 3 to 7 days and fever within 72 h. Stool cultures remain positive for 4 to 5 weeks after infection and—in rare cases of chronic carriage (<1%)—remain positive for >1 year. Antibiotic treatment usually is not recommended and in some studies has prolonged carriage of Salmonella. Neonates, the elderly, and the immunosuppressed (e.g., HIV-infected patients) with nontyphoidal Salmonella gastroenteritis are especially susceptible to dehydration and dissemination and may require hospitalization and antibiotic therapy.

**Bacteremia and Endovascular Infections** Up to 5% of patients with nontyphoidal Salmonella gastroenteritis have positive blood cultures, and 5 to 10% of these bacteremic persons develop localized infections. Bacteremia is particularly common and persistent among infants, the elderly, and patients with severe underlying infection or immunosuppression (e.g., transplant recipients, HIV-infected patients). Salmonellae have a propensity for infection of vascular sites; if >50% of three or more blood cultures are positive, an endovascular infection should be suspected. Preexisting valvular heart disease is a strong risk factor for the development of endocarditis, while atherosclerotic plaque, prosthetic grafts, and aortic aneurysms are associated with arteritis. Arteritis should be suspected in elderly patients who have a history of prolonged fever with associated back, chest, or abdominal pain preceded by gastroenteritis. Endocarditis and arteritis are rare (<1% of cases) but are associated with potentially morbid complications. Endocarditis can be complicated by cardiac valve perforation or by ring or septal abscesses, while arteritis can be associated with mycotic aneurysms, ruptured aneurysms, or vertebral osteomyelitis.

Unlike most nontyphoidal Salmonella serotypes, S. choleraesuis and S. dublin are frequently associated with sustained bacteremia and fever, often in the absence of a history of gastroenteritis. Similarly, these serotypes appear to be especially invasive and are often associated with metastatic infection.

**Localized Infections**

**Intraabdominal Infections** Intraabdominal infections due to nontyphoidal Salmonella are rare and usually manifest as hepatic or splenic abscesses or as cholecystitis. Involvement of the pancreas and adrenals and even an infected pheochromocytoma have been reported. Risk factors include anatomical abnormalities of the hepatobiliary system, including gallstones; abdominal malignancy; and sickle cell disease (especially with splenic abscesses). Eradication of the infection often requires surgical correction of anatomical abnormalities and drainage of abscesses.

**Central Nervous System Infections** Salmonella infections of the central nervous system usually manifest as meningitis, although cerebral abscesses have been found. Meningitis is usually seen in neonates (<4 months old) and is associated with severe sequelae, including residual seizures, hydrocephalus, ventriculitis, abscess formation, subdural empyema, and permanent disability (e.g., mental retardation and paralysis).

**Pulmonary Infections** Nontyphoidal Salmonella pulmonary infections usually present as lobar pneumonia, sometimes complicated by lung abscesses, empyemas, pleural effusions, and bronchopleural fistulas. The majority of cases occur in patients with a preexisting abnormality of lung or pleura, including malignancy. Additional risk factors include sickle cell disease and glucocorticoid use. It is important to determine whether the pulmonary infection is in fact due to Salmonella or whether it is a secondary infection.

**Urinary and Genital Tract Infections** Urinary tract infections caused by nontyphoidal salmonellae present as either cystitis or pyelonephritis, usually in association with malignancy, urethritis, structural abnormalities, or immunosuppression (HIV infection, renal transplantation). Genital infections due to these bacteria are rare and present as ovarian and testicular abscesses, prostatitis, or epididymitis. Like other focal infections, both genital and urinary tract infections can be complicated by abscess formation.

**Bone, Joint, and Soft Tissue Infections** Salmonella osteomyelitis most commonly affects the femur, tibia, humerus, or lumbar vertebrae and...
is most often seen in association with sickle cell disease, hemoglobinopathies, or preexisting bone disease (e.g., fractures). Prolonged antibiotic treatment is recommended to decrease the incidence of relapse and chronic osteomyelitis. Septic arthritis occurs in the same patient population as osteomyelitis and usually presents in the knee, hip, or shoulder joints. Reactive arthritis (Reiter’s syndrome) can follow Salmonella gastroenteritis and is seen most frequently in persons with the HLA-B27 histocompatibility antigen. Salmonella can cause rare soft tissue infections, usually at sites of local trauma in immunosuppressed patients.

**DIAGNOSIS**

Nontyphoidal Salmonella gastroenteritis is diagnosed when Salmonella is cultured from stool. All salmonellae isolated in clinical laboratories should be sent to local public health departments. In cases where there is concern about bacteremia (i.e., those including prolonged or recurrent fever), blood cultures are indicated. Once bacteremia is documented, it is important to determine whether it is high-grade (>50% of three or more blood cultures positive); if so, endovascular infection is possible and further evaluation to identify the source is indicated. In addition, depending on clinical symptoms and on whether metastatic disease is suspected, other body fluids, such as joint fluid or cerebrospinal fluid, should be cultured.

**TREATMENT**

Antibiotic treatment is not generally recommended for Salmonella gastroenteritis. The symptoms are usually self-limited and have not been demonstrated to be altered by short courses of antibiotics. In addition, in case-control and double-blinded placebo-controlled trials, antibiotic treatment has been associated with increased rates of relapse and prolonged gastrointestinal carriage. Dehydration secondary to diarrhea should be treated with fluid and electrolyte replacement.

However, preemptive antibiotic treatment should be considered in patients at increased risk for metastatic infection. These patients include neonates (probably up to 3 months of age); persons >50 years old (because of the high risk of atherosclerotic plaque or aneurysm); transplant recipients; and patients with lymphoproliferative disease, HIV infection, prosthetic joints, vascular grafts, significant joint disease, or underlying sickle cell disease. This group should receive a course of oral or intravenous antibiotics lasting for 2 or 3 days or until defervescence in immunologically normal patients. Limited data exist regarding the treatment of highly immunocompromised individuals; however, these individuals may require a longer course of therapy—perhaps 7 to 14 days, depending on the clinical scenario. Rare cases of chronic nontyphoidal Salmonella carriage should be treated with a prolonged antibiotic course, as described above for chronic carriage of S. typhi.

Focal infections or life-threatening bacteremia with nontyphoidal Salmonella should be treated with antibiotics (at the same doses used for enteric fever). Given the increasing prevalence of antibiotic resistance, empirical therapy should include a third-generation cephalosporin or a quinolone. If the bacteremia is low-grade (<50% of blood cultures positive), the patient should be treated for 7 to 14 days. Patients with AIDS and Salmonella bacteremia should receive 1 to 2 weeks of intravenous antibiotic therapy followed by 4 weeks of oral therapy with quinolones. Patients who relapse after this regimen should receive long-term suppressive therapy with a quinolone or TMP-SMX, as indicated by bacterial sensitivities.

If the patient has an endovascular infection or endocarditis, treatment for 6 weeks with intravenous β-lactam antibiotics is indicated. Chloramphenicol treatment has been associated with high failure rates and is not recommended. Limited case reports have described the successful treatment of Salmonella endovascular infections with quinolones, which may prove an alternative approach in cases caused by sensitive strains. However, concern remains about the development of quinolone resistance during prolonged therapy. Surgical resection of infected aneurysms or other infected endovascular sites is often required. If surgical resection is not possible, lifelong suppressive antibiotic therapy may be indicated. For extraintestinal nonvascular infections, 2 to 4 weeks of antibiotic therapy (depending on the site) are usually recommended. In cases of chronic osteomyelitis, abscesses, and urinary or biliary tract abnormality, surgical interventions may be required in addition to prolonged antibiotic therapy to eradicate infection.

**PREVENTION AND CONTROL**

The incidence of nontyphoidal salmonellosis continues to rise along with rates of emergence of antibiotic-resistant strains. The increased centralization of food production plays a prominent role in the growing incidence, as one oversight can result in rapid, widespread distribution of contaminated food. Thus, it is important to monitor every step of food production, from handling of raw products to preparation of finished foods. In particular, with the increasing prevalence of S. enteritidis in egg-laying hens, it is recommended that pasteurized eggs be substituted for bulk-pooled eggs at all nursing homes, hospitals, and commercial food-service establishments. All cases of nontyphoidal salmonellosis should be reported to public health departments, since tracking and monitoring of these cases result in the identification of the sources of local outbreaks and help authorities anticipate large-scale international outbreaks. Lastly, the prudent use of antimicrobial agents in both humans and animals is necessary to minimize the further emergence of antibiotic-resistant strains.

**FURTHER READING**

**ETIOLOGIC AGENT**

Shigellae are small, gram-negative, nonmotile bacilli and are members of the family Enterobacteriaceae and the tribe Escherichiae. They are so closely related to Escherichia coli that the two genera cannot be distinguished by DNA hybridization methods. In fact, shigellae are now thought to be differentiated pathogenic E. coli. The four Shigella species (S. dysenteriae, S. flexneri, S. boydii, and S. sonnei) are defined on the basis of somatic O antigens and carbohydrate fermentation patterns. Overall, there are 43 O serotypes of Shigella; S. sonnei is the only species that exists as a single serotype. Because acquired immunity is serotype-specific, an individual can be infected multiple times by different serotypes. Shigellae are...
Shigella infection and recurrent disease among HIV-infected individuals greatly exceed those in the HIV-uninfected population (Chap. 173). Shigellosis is associated with a high rate of secondary household transmission. As many as 40% of children and 20% of adults who are household contacts of a case (generally a preschool child) develop Shigella infection. The infection is often symptomatic in children but asymptomatic in adults, presumably because of acquired immunity in adults. In contrast, epidemic disease due to newly introduced strains affects all ages, with severe and fatal cases occurring primarily in the very young and the very old. Prolonged asymptomatic carriage of Shigella in humans is uncommon; unless there is underlying malnutrition, the organisms are generally cleared rapidly. However, veterinary reports suggest that long-term asymptomatic carriage of Shigella by non-human primates is not uncommon.

PATHOGENESIS AND PATHOLOGY Shigellae enter the host via the mouth. Because they are genetically equipped to survive low pH, they readily pass the gastric acid barrier. An essential step in pathogenesis is invasion of the colonic mucosa and cell-to-cell spread of infection. It was originally thought that shigellae invade the host across the absorptive epithelial cells. However, the luminal surface of colonic cells appears to be resistant to invasion. More recent experimental studies show that Shigella uptake occurs primarily through the antigen-sampling M cells, resulting in initial limited penetration of the lamina propria, where the organisms encounter and are ingested by resident macrophages. Shigellae multiply within and trigger apoptosis of the infected macrophage, but not before initiating the production of the proinflammatory cytokine interleukin (IL) 1β. Viable shigellae released from dead macrophages then invade the basolateral surface of the colonic epithelium, spread from cell to cell via a novel host actin-based propulsion mechanism, and provoke the synthesis of IL-8 from the epithelium. IL-8 is a chemokine that induces the migration of polymorphonuclear neutrophils (PMNs) through the epithelial cell layer into the intestinal lumen; the tight junctions are damaged as the PMNs traverse the mucosa, and this damage allows further Shigella invasion and exacerbates inflammation. The consequences are mucosal ulcerations and characteristic dysenteric small-volume stools consisting of mucus, cellular debris, neutrophil exudates, and blood. The host inflammatory response is essential to disease pathogenesis, and its blockade by any number of interventions interrupts the cascade from invasion to illness.

After attaching to the colonic epithelium, shigellae induce their own uptake via a host endocytic mechanism (i.e., a phagocytosis-like process) in which the bacteria are initially engulfed within plasma membrane–enclosed endosomes. Subsequently, the bacteria dissolve the endosomal vacuole and are released into the nutrient-rich cytoplasm—a step that is essential for their intracellular replication. This intracellular existence also provides the organism with a means to evade extracellular host defenses, to move within the cell to the plasma membrane, and to spread directly from cell to cell via protrusions it creates at the interface between adjacent cells.

Many of the microbial virulence features as well as the host cell biologic responses occurring during pathogenesis have been defined during the past decade, and this information has led to the following understanding of this complex process: Virulence requires the function of multiple genes and regulatory elements encoded both on the chromosome and on a large (180- to 210-kilobase pair) plasmid present in all virulent shigellae as well as in enteroinvasive E. coli (EIEC, which causes a Shigella-like disease). Some of these gene products convey acid resistance, some mediate the endocytic cell invasion process, others underlie the subsequent escape from the endosomal vacuole, and still others underlie the movement of the organism to the plasma membrane, leading to cell-to-cell transfer. The plasmid-borne invasion genes encode a type III bacterial secretion system that, upon contact with the host cell, injects invasion effectors into that cell via needle-like macromolecular structures. These effectors cause an actin-dependent re-arrangement of the local plasma membrane, which engulfs the attached bacterium into a plasma membrane–bound endosome.
Shigellae lack flagella and are nonmotile. To move within the cell, they have evolved a novel mechanism involving the formation of a growing tail of polymerized host actin created by the microbial protein IcsA (an ATPase) localized to one pole of the bacterium. Actin polymerization and cross-linking at one end of the bacterium propel it randomly through the cytosol. Some organisms reach the plasma membrane, where they form protrusions into the adjacent cell. When these protrusions are pinched off and the resulting double host-cell membrane surrounding the organism is lysed, the bacterium lies within the cytoplasm of the newly invaded cell, and the process is repeated. Inactivation of IcsA by host phosphorylases may serve as a molecular host-defense mechanism to modulate virulence by limiting microbial spread.

Another important host protein essential for cell-to-cell spread is the cadherin L-CAM. Mutations in L-CAM alter the long finger-like protrusions induced by shigellae at the plasma membrane and impair their subsequent fusion with the adjacent cell. Once a single Shigella organism has invaded a host epithelial cell, the entire process of bacterial escape from the endosome into the host cell’s cytoplasm, multiplication, and cell-to-cell spread can take place without exposure of the bacterium to the extracellular milieu and host immune defenses. Invaded host epithelial cells ultimately die.

Another property of apparent importance in the virulence of S. dysenteriae type 1 (which causes the most clinically severe form of shigellosis) is the ability to produce Shiga toxin, a protein encoded by the iron-regulated chromosomal gene stx. Related members of this toxin family are produced by some strains of E. coli, including serotype O157:H7. Such strains, designated Shiga toxin-producing E. coli (STEC), cause hemorrhagic colitis and hemolytic-uremic syndrome (HUS). Shiga toxins are composed of two distinct peptide subunits, each with highly conserved active regions. The first, located on the larger A subunit, is an N-glycosidase that hydrolyzes adenosine from specific sites of ribosomal RNA of the mammalian 60S ribosomal subunit, irreversibly inhibiting protein synthesis. The second conserved region is a binding site on the B subunit that recognizes the receptor glycolipid Gb3 on host cells. Receptor specificity is determined by a terminal galactose α1→4-galactose disaccharide. Wild-type toxigenic S. dysenteriae causes more severe illness than does an isogenic toxin-negative mutant in an experimental monkey model. The related Shiga toxins all target endothelial cells and appear to play a role in the pathogenesis of the microangiopathic complications associated with toxin-producing shigellae and E. coli: HUS and thrombotic thrombocytopenic purpura (TTP). Two other Shigella enterotoxins, ShET-1 and -2, have been described; the former is restricted almost exclusively to S. flexneri 2a, whereas the latter is distributed more widely (e.g., in the physiologically similar EIEC).

These two enterotoxins, encoded by chromosomal and plasmid-encoded genes, respectively, alter electrolyte transport by gut segments in vitro and cause net fluid secretion in ligated rabbit ileal loops in vivo. Although both toxins induce antibody in infected humans, their role (if any) in the pathogenesis of the watery-diarrhea phase of shigellosis remains uncertain.

The characteristic pathology of human bacillary dysentery is extensive ulceration of the epithelial surface of the colonic mucosa, with an exudate consisting of desquamated colonic cells, PMNs, and erythrocytes that may resemble a pseudomembrane in severely affected areas. Marked mucus depletion and increased mitotic activity are evident in the crypt regions and presumably reflect a response to the loss of surface colonic cells. The lamina propria is edematous and hemorrhagic and is infiltrated by neutrophils and plasma cells. There is also swelling of capillary and venular endothelial cells, with margination of neutrophils. At the ultrastructural level, intraepithelial-cell bacteria can be seen within endosomes as well as free in the cytoplasm. Histologic examination of colon from dysenteric humans shows an alteration of mucosal endothelial cells similar to that induced by endothelial toxin (ETEC). Mild diarrhea is also a frequent feature of patients with persistent and severe shigellosis, which is characterized by fecal urgency and tenesmus with passage of mucus and dark stools. Severe dysentery occurs less commonly with S. flexneri and is least likely with S. sonnei or S. boydii. Patients with mild disease generally recover without specific therapy in a few days to a week. Severe shigellosis can progress to toxic dilatation and colonic perforation, either of which may be fatal. In developing countries, shigellosis almost doubles the risk of persistent diarrhea; the mortality rate increases by tenfold when persistent Shigella diarrhea develops.

Endoscopy shows the mucosa to be hemorrhagic, with mucous discharge and focal ulcerations and sometimes an overlying exudate resembling a pseudomembrane. The majority of lesions are in the distal colon, with progressively fewer in the more proximal segments of the large bowel. Mild diarrhea is common among patients with watery diarrhea; severe dehydration is very rare. With extensive colonic involvement, protein-losing enteropathy can occur and can have impor-

tions of HUS usually develop toward the end of the first week of

shigellosis, when dysentery is already resolving. Oliguria and a

marked drop in hematocrit (by as much as 10% within 24 h) are the

first signs and may progress to anuria with renal failure and to severe

anemia with congestive heart failure, respectively. Even with advanced

therapy, 5 to 10% of patients with HUS die of the acute illness. In

addition, renal damage progresses slowly over several decades in sur-

vivors, some of whom will develop significant renal failure and require

long-term dialysis or renal transplantation for survival. Leukemoid

reactions, with leukocyte counts of <50,000/µL, usually accompany

HUS; thrombocytopenia, with 30,000 to 100,000 platelets/µL, is com-

mon and in adults can lead to TTP, which is part of the spectrum of

the toxin-mediated microangiopathy. Profound hypotenreemia and se-

vere hypoglycemia are also encountered, especially in developing

countries, and may underline central nervous system abnormalities such

as seizures and altered consciousness. S. flexneri is associated with a

rare toxic encephalopathy that is manifested by bizarre posturing and

lethal cerebral edema.

Reactive arthritis is a less common extraintestinal manifestation

that is usually associated with S. flexneri strains. In patients expressing

histocompatibility antigen HLA-B27, the full triad of Reiter’s syn-
drome sometimes develops weeks to months after diarrheal illness

(Chap. 305). Pneumonia, meningitis, vaginitis (in prepubertal girls),

keratoconjunctivitis, and “rose spot” rashes are rare events.

DIAGNOSIS AND LABORATORY FINDINGS Shigellosis is the principal bac-
terial cause of dysentery and should be considered whenever a patient

presents with bloody diarrhea. However, in the United States, because

S. typhimurium is the most common infecting Shigella species, most patients

present with fever and nonbloody watery diarrhea that are indistin-
guishable from the signs caused by other bacterial or viral agents of

mild to moderate diarrhea. In this country, many patients with bloody

diarrhea have STEC or Campylobacter jejuni identified as the cause.

The specific diagnosis is based on culture of Shigella from the stool;
sensitive and specific diagnostic methods based on the polymerase

chain reaction have been developed but are not yet widely available.

A commercial enzyme immunoassay to detect Shiga-family toxins in

stool can identify most patients infected with S. dysenteriae type 1

(rare in the United States) or STEC within 3 h. The yield of Shigella

in culture is increased if the patient has fecal leukocytes or bloody

diarrhea. The organism is very labile and must be transferred quickly

to plates or holding media (such as buffered glycerol saline) if it is to

be isolated. Stool samples are preferable to swabs; when the latter are

used, a rectal sample should be obtained. More than one differential

selective medium should be used for culture—i.e., MacConkey and

one other medium, such as Hektoen enteric or xylose-lysine-deoxy-

cholate. Stool cultures to diagnose nonbloody watery diarrhea have a

very low yield of positives and are not considered to be cost-effective

in the United States. A rapid test can be performed, since antibodies to somatic an-
tigens develop early in the acute phase of disease. However, the re-

agents for such tests generally are not available, even in the United

States, and serologic assessments are usually used only for epidemi-

ologic studies.

The differential diagnosis includes inflammatory colitis due to other microbial agents: STEC, EIEC, C. jejuni, Salmonella enteritidis, Yersinia enterocolitica, Clostridium difficile, and the protozoan Ent-
amoeba histolytica. Ulcerative colitis and Crohn’s colitis are among the “noninfectious” conditions that should be considered (Chap. 276). All these infections except that due to E. histolytica are associated with the presence of large numbers of fecal leukocytes. Amebiasis can be diagnosed by the detection of phagocytic trofozoites in the stool or by immunoassay (Chap. 194).

Other laboratory studies are nonspecific and may disclose neutro-

philic leukocytosis, anemia due to blood loss with hemorrhagic diarrhea,

prerenal azotemia, or (if watery diarrhea has been pronounced)

hyperchloremic acidosis. Laboratory findings in shigellosis compli-

cated by HUS are discussed above.

TREATMENT

The mild to moderate dehydration in shigellosis is readily corrected

with oral rehydration solutions (Chap. 140). The role of antibiotic

therapy depends on the bacterial species involved and the severity of
disease. Since S. sonnei infection is usually self-limited, culture results
generally do not become available until the patient is better and there

is little clinical need for further therapy. The use of antibiotics in severe

cases with bloody diarrhea or dysentery reduces the duration of illness

and can shorten the carriage state. Resistance to sulfonamides, strep-
tomycin, chloramphenicol, and tetracyclines is almost universal, and

many shigellae are now resistant to ampicillin and trimethoprim-sul-

famethazoxole (TMP-SMX) as well. Knowledge of the pattern of resis-
tance in a given population, which can change with time, is

essential. In the United States, multiresistant strains are most likely to be

acquired during travel abroad; therefore, for domestically acquired infection, either ampicillin or TMP-SMX remains the drug of choice unless resistance is known to be prevalent in particular communities (Table 138-1). Amoxicillin should not be substituted for ampicillin; it is ineffective because it is too well absorbed proximally and does not reach bacteria in the colonic lumen. Similarly, nonabsorbable antibi-

otics are ineffective because they do not reach the mucosal bacterial population. Short courses of treatment (1 or 3 days) or even single doses of a fluoroquinolone such as ciprofloxacin or the macrolide

azithromycin have been employed with success. In developing coun-

doms, where resistance to ampicillin and TMP-SMX is commonplace,

the drug of choice for the treatment of multiresistant S. dysenteriae

type 1 infections is naldixic acid; however, resistance to the latter
drug is increasing in prevalence with its increasing use. The fluoro-

quinolones (e.g., ciprofloxacin, ofloxacin) are highly effective against

all strains (Chap. 118) but are currently too costly for use in the de-
veloping world and are not yet approved for use in children <17 years

old in the United States; these drugs have caused cartilage damage in

young rodents during toxicity tests, although there is no evidence for

a similar effect at therapeutic doses in humans. Alternative drugs shown to be effective include oral pivamidocinicol (aminocillin, pi-

voxil, pivmecillinam; still not available in the United States), azith-

romycin, and intravenous ceftriaxone (50 mg/kg per day for 5 days).

In small-scale clinical trials, 2 to 5 days of cefixime treatment resulted

in the resolution of clinical symptoms due to S. sonnei, but the relapse

rate was 20 to 24%. (Cefixime is not currently available in the United

States.) Single doses of ceftriaxone may be effective, but more clinical

data are needed. No antibiotic treatment is recommended for the con-

valescent carrier state, which usually lasts no more than a few weeks—

i.e., for a much shorter period than is seen with nontyphoidal Salmo-

nella or Salmonella typhi. Patients with AIDS can develop chronic

carriage of Shigella and may be subject to relapsing infection with

bacteremia (Chap. 173). This cycle can be interrupted by several weeks

treatment with a quinolone.

The role of antimotility agents such as atropine sulfate and di-
Agents are contraindicated for use in the dysenteric phase of disease. Increasing the likelihood of complicating toxic megacolon. Therefore, mechanisms and facilitating further invasion of the mucosa, potentially in- of enhancing the severity of disease by delaying excretion of orga-

Diarrhea volume and in one study was highly effective in combination with shigellosis is controversial. Loperamide, in particular, may reduce phenoxylate (Lomotil) and loperamide (Imodium) in the early phases of treatment. Nutritional support should begin during the acute illness and is required for months thereafter (Chap. 63). Considerable effort is being directed toward the development of a safe and effective vaccine. Direct-contact transmission of shigellosis can be prevented by appropriate environmental and personal hygiene. Hand washing with soap and water when caring for infected infants, handling diapers, or preparing food is effective, and efficacy can be enhanced by the use of a triclosan antibacterial soap. Safe water supplies and sanitary latrines or toilets significantly reduce the primary spread of the organism, which is facilitated by the fecal-oral route.

Hand washing with soap and water when caring for infected infants, handling diapers, or preparing food is effective, and efficacy can be enhanced by the use of a triclosan antibacterial soap. Safe water supplies and sanitary latrines or toilets significantly reduce the primary spread of the organism, which is facilitated by the fecal-oral route.

Treatment of complications of shigellosis often differs in developed and developing countries. For example, antibiotic-unresponsive toxic megacolon, with or without perforation, is often managed by colectomy and ileostomy in the United States. Surgery is less often employed in developing countries because of a lack of surgical services and limited availability of medical instruments (such as stethoscopes) after each contact with an infected patient. In the United States, cohorting of asymptomatic infected children, use of antibiotics to reduce infectiousness, and scrupulous attention to hygiene are usually successful in nosocomial outbreaks. Children in day care must be kept at home while clinically ill and ideally should have one negative stool culture before returning to the day-care facility. Likewise, food handlers who develop shigellosis should be culture-negative before returning to work. Antibiotic treatment is not indicated for the asymptomatic carrier state.

**PREVENTION** There are no licensed vaccines against Shigella, although considerable effort is being directed toward the development of a safe and effective vaccine. Direct-contact transmission of shigellosis can be prevented by appropriate environmental and personal hygiene. Hand washing with soap and water when caring for infected infants, handling diapers, or preparing food is effective, and efficacy can be enhanced by the use of a triclosan antibacterial soap. Safe water supplies and sanitary latrines or toilets significantly reduce the primary spread of the organism, which is facilitated by the fecal-oral route.

DEFINITION Bacteria of the genus *Campylobacter* and of the related genera *Arcobacter* and *Helicobacter* (Chap. 135) cause a variety of inflammatory conditions. Although acute diarrheal illnesses are most common, these organisms may cause infections in virtually all parts of the body, especially in compromised hosts, and these infections may have late nonsuppurative sequelae. The designation *Campylobacter* comes from the Greek for “curved rod” and refers to the organism’s vibrio-like morphology.

ETIOLOGY Campylobacters are motile, non-spore-forming, curved gram-negative rods. Originally known as *Vibrio fetus*, these bacilli were reclassified as a new genus in 1973, after it was recognized that they were quite dissimilar to other vibrios. Since then, >15 species have been identified. These species are currently divided into three genera: *Campylobacter*, *Arcobacter*, and *Helicobacter*. Not all of the species are pathogens of humans. The human pathogens can be divided into two major groups: those that primarily cause diarrheal disease and those that cause extraintestinal infection. The principal diarrheal pathogen is *C. jejuni*, which accounts for 80 to 90% of all cases of recognized illness due to campylobacters. Other organisms that cause diarrheal disease include *C. coli*, *C. upsaliensis*, *C. lari*, and *C. fetus*. The major species causing extraintestinal illnesses is *C. fetus*; however, any of the diarrheal agents may cause systemic or localized infection as well. Neither aerobes nor strict anaerobes, these microaerophilic organisms are adapted for survival in the gastrointestinal mucosal layer. This chapter will focus on *C. jejuni* and *C. fetus* as the major pathogens and prototypes for their groups; the key features of infection are listed by species (excluding *C. jejuni*, described in detail in the text below) in Table 139-1.

Epidemiology Campylobacters are found in the gastrointestinal tract of many animals used for food (including poultry, cattle, sheep, and swine) and of many household pets (including birds, dogs, and cats). These microorganisms usually do not cause illness in their animal hosts. In most cases, campylobacters are transmitted to humans in raw or undercooked food products or through direct contact with infected animals. In the United States and other developed countries, ingestion of contaminated poultry that has not been sufficiently cooked is the most common means of acquiring infection (50 to 70% of cases). Other modes of transmission include ingestion of raw (unpasteurized) milk or untreated water, contact with infected household pets, travel to developing countries (campylobacters being among the causes of traveler’s diarrhea; Chap. 113), oral-anal sexual contact, and (occasionally) contact with an index case who is incontinent of stool.

Campylobacter infections are common. Several studies indicate that, in the United States, diarrheal disease due to campylobacters is more common than that due to *Salmonella* and *Shigella* combined. Infections occur throughout the year, but their incidence peaks during summer and early autumn. Persons of all ages are affected; however, attack rates for *C. jejuni* are highest among young children and young adults, while those for *C. fetus* are highest at the extremes of age. Systemic infections due to *C. fetus* (and to other *Campylobacter* and related species) are most common in compromised hosts. Persons at increased risk include those with AIDS, hypogammaglobulinemia, neoplasia, liver disease, diabetes mellitus, and generalized atherosclerosis as well as neonates and pregnant women. However, apparently healthy nonpregnant persons occasionally develop transient *Campylobacter* bacteremia as part of a gastrointestinal illness.

In developing countries, *C. jejuni* infections are hyperendemic, with the highest rates among children <2 years old. Infection rates fall with age, as does the illness-to-infection ratio; these observations suggest that frequent exposure to *C. jejuni* leads to the acquisition of immunity.

Pathology and Pathogenesis Many *C. jejuni* infections are subclinical, especially in hosts in developing countries who have had multiple prior infections and thus are partially immune. Most illnesses occur within 2 to 4 days (range, 1 to 7 days) of exposure to the organism in food or water. The sites of tissue injury include the jejunum, ileum, and colon. Biopsies show an acute nonspecific inflammatory reaction, with neutrophils, monocytes, and eosinophils in the lamina propria, as

well as damage to the epithelium, including loss of mucus, glandular degeneration, and crypt abscesses. Biopsy findings may be consistent with Crohn’s disease or ulcerative colitis, but these “idiopathic” chronic inflammatory diseases should not be diagnosed unless infectious colitis, specifically including that due to infection with Campylobacter species and related organisms, has been ruled out.

The high frequency of C. jejuni infections and their severity and recurrence among hypogammaglobulinemic patients suggest that antibodies are important in protective immunity. The pathogenesis of infection is uncertain. Both the motility of the strain and its capacity to adhere to host tissues appear to favor disease, but classic enterotoxins and cytotoxins (although described and including cytolysin discluding toxin, or CLDT) appear not to play any substantial role in tissue injury or disease production. The organisms have been visualized in the epithelium, albeit in low numbers. The documentation of a significant tissue response and occasionally of C. jejuni bacteremia further suggests that tissue invasion is clinically significant.

The pathogenesis of C. fetus infections is better defined. Virtually all clinical isolates of C. fetus possess a proteinaceous capsule-like structure (an S-layer) that renders the organism resistant to complement-mediated killing and opsonization. As a result, C. fetus can cause bacteremia and can seed sites beyond the intestinal tract. The ability of the organism to switch the S-layer proteins expressed, a phenomenon that results in antigenic variability, may contribute to the chronicity and high rate of recurrence of these infections in compromised hosts.

CLINICAL MANIFESTATIONS OF C. JEJUNI AND C. FETUS INFECTIONS

The clinical features of infections due to all of the Campylobacter and related species causing enteric disease appear to be highly similar. There is often a prorome, with fever, diarrhea, myalgia, and/or malaise, 12 to 48 h before the onset of diarrheal symptoms. The most common signs and symptoms of the intestinal phase are diarrhea, abdominal pain, and fever. The degree of diarrhea varies from several loose stools to grossly bloody stools; most patients presenting for medical attention have 10 or more bowel movements on the worst day of illness. Abdominal pain usually consists of cramping and may be the most prominent symptom. Pain is usually generalized but may become localized; C. jejuni infection may cause pseudoappendicitis. Fever may be the only initial manifestation of C. jejuni infection, a situation mimicking the early stages of typhoid fever. Febrile young children may develop convulsions. Campylobacter enteritis is generally self-limited; however, symptoms persist for >1 week in 10 to 20% of patients seeking medical attention, and relapses occur in 5 to 10% of untreated patients.

C. fetus may cause a diarrheal illness similar to that due to C. jejuni, especially in normal hosts, or may cause either intermittent diarrhea or nonspecific abdominal pain without localizing signs. Sequelae are uncommon, and outcome is benign. C. fetus may also cause a prolonged relapsing systemic illness (with fever, chills, and myalgias) that has no obvious primary source; this manifestation is especially common in compromised hosts. Secondary seeding of an organ (e.g., meninges, brain, bone, urinary tract, or soft tissue) complicates the course, which may be fulminant. C. fetus infections have a tropism for vascular sites: endocarditis, mycotic aneurysm, and septic thrombophlebitis may all occur. Infection during pregnancy often leads to fetal death. H. cinaedi causes recurrent cellulitis with fever and bacteremia in immunocompromised hosts.

COMPLICATIONS

Except in the case of infection with C. fetus, bacteremia is uncommon, developing most often in immunocompromised hosts and at the extremes of age. Three patterns of extraintestinal infection have been noted: (1) transient bacteremia in a normal host with enteritis (benign course, no specific treatment needed); (2) sustained bacteremia or focal infection in a normal host (bacteremia originating from enteritis, with patients responding well to antimicrobial therapy); and (3) sustained bacteremia or focal infection in a compromised host. Enteritis may not be clinically apparent. Antimicrobial therapy, possibly prolonged, is necessary for suppression or cure of the infection.

Campylobacter infections in patients with AIDS or hypogammaglobulinemia may be severe, persistent, and extraintestinal; relapse after cessation of therapy is common. Hypogammaglobulinemic patients may also develop osteomyelitis and an erysipelas-like rash.

Local suppurrative complications of infection include cholecystitis, pancreatitis, and cystitis; distant complications include meningitis, endocarditis, arthritis, peritonitis, cellulitis, and septic abortion. All are rare. Hepatitis, interstitial nephritis, and the hemolytic-uremic syndrome occasionally complicate acute infection. Reactive arthritis and other rheumatologic complaints may develop several weeks after infection, especially in persons with the HLA-B27 phenotype. Guillain-Barré syndrome follows Campylobacter infections uncommonly (i.e., in 1 of every 1000 to 2000 cases). For certain C. jejuni serotypes, such as O19, Guillain-Barré syndrome may occur once following 100 or 200 cases. Because of their high incidence, it is now estimated that Campylobacter infections may trigger 20 to 40% of all cases of Guillain-Barré syndrome.

DIAGNOSIS

In patients with Campylobacter enteritis, peripheral leukocyte counts reflect the severity of the inflammatory process. However, stools from nearly all Campylobacter-infected patients presenting for medical attention in the United States contain leukocytes or erythrocytes. Fecal smears should be treated with Gram’s or Wright’s stain and examined in all suspected cases. When the diagnosis of Campylobacter enteritis is suspected on the basis of findings indicating inflammatory diarrhea (fever, fecal leukocytes), clinicians can ask the laboratory to attempt the visualization of organisms with characteristic vibrioid morphology by direct microscopic examination of stools with Gram’s staining or to use phase-contrast or dark-field microscopy to identify the organisms’ characteristic “darting” motility. Confirmation of the diagnosis of Campylobacter infection is based on identification of an isolate from cultures of stool, blood, or another site. Campylobacter-specific media should be used to culture stools from all patients with inflammatory or bloody diarrhea. Since all Campylobacter species are fastidious, they will not be isolated unless selective media or other selective techniques are used. Not all media are equally useful for isolation of the broad array of campylobacters; therefore, failure to isolate campylobacters from stool does not entirely rule out their presence. The detection of the organisms in stool almost always implies infection; there is a brief period of postconvalescent fecal carriage and no commensalism in humans. In contrast, C. spirochenum and related organisms found in the oral cavity are commensals with rare pathogenic significance.

DIFFERENTIAL DIAGNOSIS

The symptoms of Campylobacter enteritis are not sufficiently unusual to distinguish this illness from that due to Salmonella, Shigella, or Yersinia, among other pathogens. The combination of fever and fecal leukocytes or erythrocytes is indicative of inflammatory diarrhea, and definitive diagnosis is based on culture or demonstration of the characteristic organisms on stained fecal smears. Similarly, extraintestinal Campylobacter infection is diagnosed by culture. Infection due to Campylobacter should be suspected in the setting of septic abortion and that due to C. fetus specifically in the setting of septic thrombophlebitis. It is important to reiterate that the presentation of Campylobacter enteritis may mimic that of ulcerative colitis or Crohn’s disease, that Campylobacter enteritis is much more common than either of the latter (especially among young adults), and that biopsy may not be able to distinguish among these entities. Thus a diagnosis of inflammatory bowel disease should not be made until Campylobacter infection has been ruled out, especially in persons with a history of foreign travel, significant animal contact, immunodeficiency, or exposure incurring a high risk of transmission.

TREATMENT

Fluid and electrolyte replacement is central to the treatment of diarrheal illnesses (Chap. 113). Even among patients presenting for medical attention with Campylobacter enteritis, fewer than half will clearly benefit from specific antimicrobial therapy. Indications for such therapy include high fever, bloody diarrhea, severe diarrhea, persistence
for >1 week, and worsening of symptoms. A 5- to 7-day course of erythromycin (250 mg orally four times daily or— for children —30 to 50 mg/kg per day, in divided doses) is the regimen of choice. Although no relevant clinical trials have been conducted, the in vitro susceptibility of *Campylobacter* species to macrolides such as clarithromycin and azithromycin suggests that these antibiotics would also be useful therapeutic agents. An alternative regimen for adults is ciprofloxacin (500 mg orally twice daily) or another fluoroquinolone for 5 to 7 days, but resistance to this class of agents is increasing. Other alternatives include tetracycline and furazolidone. Use of antimotility agents, which may prolong the duration of symptoms and has been associated with toxic megacolon and with death, is not recommended.

For systemic infections, treatment with gentamicin (1.7 mg/kg intravenously every 8 h after a loading dose of 2 mg/kg), imipenem (500 mg intravenously every 6 h), or chloramphenicol (50 mg/kg intravenously each day in three or four divided doses) should be started empirically, but susceptibility testing should then be performed. Ciprofloxacin and amoxicillin/clavulanate are alternative agents for susceptible strains. In the absence of immunocompromise or endovascular infections, therapy should be administered for 14 days. For immunocompromised patients with systemic infections due to *C. fetus* and for patients with endovascular infections, prolonged therapy (for up to 4 weeks) is usually necessary.

**CHOLERA**

**DEFINITION**

Cholera is an acute diarrheal disease that can, in a matter of hours, result in profound, rapidly progressive dehydration and death. Accordingly, *cholera* gravis (the severe form of cholera) is a much-feared disease, particularly in its epidemic presentation. Fortunately, prompt aggressive fluid repletion and supportive care can obviate the high mortality that cholera has historically wrought. While the term *cholera* has occasionally been applied to any severely dehydrating secretory diarrheal illness, whether infectious in etiology or not, it has generally referred to disease caused by *V. cholerae* serogroup O1. In 1992, however, a new serogroup (O139) that causes epidemic cholera emerged on the Indian subcontinent and has since killed thousands of people.

**MICROBIOLOGY AND EPIDEMIOLOGY**

The species *V. cholerae* comprises a host of organisms classified on the basis of the carbohydrate determinants of their lipopolysaccharide (LPS) O antigens. Some 200 serogroups have now been recognized. They are divided into those that agglutinate in antisera to the O1 group antigen (*V. cholerae* O1) and those that do not (non-O1 *V. cholerae*). Although some non-O1 *V. cholerae* serogroups have occasionally caused sporadic outbreaks of diarrhea, serogroup O1 was, until the emergence of serogroup O139, the exclusive cause of epidemic cholera.

Two biotypes of *V. cholerae* O1, *classical* and *El Tor*, are distinguished. Each biotype is further subdivided into two serotypes, termed *Inaba* and *Ogawa*.

The natural habitat of *V. cholerae* is coastal salt water and brackish estuaries, where the organism lives in close relation to plankton and where it may survive in a viable but nonculturable form. Humans become infected incidentally but, once infected, can act as vehicles for spread. Ingestion of water contaminated by human feces is the most common means of acquisition of *V. cholerae*. Consumption of contaminated food can also contribute to spread. There is no known animal reservoir. While the infectious dose is relatively high, it is markedly reduced in hypochlorhydric persons, in those using antacids, and when gastric acidity is buffered by a meal. Cholera is predominantly a pediatric disease in endemic areas, but it affects adults and children equally when newly introduced into a population. In endemic areas, the disease is more common in the summer and fall months. While this seasonality has not been explained fully, it may be due to environmental conditions that affect the multiplication of vibrios or to seasonal alterations in human behavior that affect contact with water. In endemic areas, children <2 years of age are less likely to develop severe cholera than are older children, perhaps because of passive immunity acquired from breast milk. For unexplained reasons, susceptibility to cholera is significantly influenced by ABO blood group status; those with type O blood are at greatest risk, while those with type AB are at least risk.

Cholera is native to the Ganges delta in the Indian subcontinent. Since 1817, seven global pandemics have occurred. The current (seventh) pandemic—the first due to the El Tor biotype—began in Indonesia in 1961 and spread throughout Asia as *V. cholerae* El Tor displaced the endemic classical strain in many areas. In the early 1970s, El Tor cholera exploded in Africa, causing major epidemics before becoming a persistent endemic problem. Its recent history in Africa has been punctuated by severe outbreaks, often fed by the chaos of war and genocide. Such was the case in the camps for Rwandan refugees set up in 1994 around Goma, Zaire. Tens of thousands of cases occurred and mortality was high. In 1995, the occurrence of hundreds of cases in Romania and the Black Sea states of the former Soviet Union demonstrated the potential of this organism to cause epidemics whenever public health measures break down.
Since 1973, sporadic endemic infections due to vibrios related to the seventh-pandemic strain have been recognized along the U.S. Gulf Coast of Louisiana and Texas. These infections are typically associated with the consumption of contaminated, locally harvested shellfish. Occasionally, cases in U.S. locations remote from the Gulf Coast have been linked to shipped-in Gulf Coast seafood.

It was not until 1991 that the current cholera pandemic reached Latin America. Beginning along the Peruvian coast in January 1991, the disease spread in an explosive epidemic to virtually all of South and Central America and to Mexico (Fig. 140-1). About 400,000 cases were reported in the first year of the outbreak, and &gt;1 million had been reported by the end of 1994. While the cumulative mortality rate has been &lt;1%, the mortality rate approached 30% in the communities first affected, where a lack of familiarity with the disease led initially to the deployment of ineffective treatment. Intensive education of health care providers and of the community at large has enhanced awareness of the disease and its appropriate management and has greatly diminished mortality. As it did in Africa two decades earlier, the epidemic El Tor strain proved capable of establishing itself in inland waters rather than in its classic niche of coastal salt waters; the organism has already become endemic in many of the Latin American countries into which it was recently introduced. Cases linked to the Latin American epidemic have occurred (via importation of contaminated seafood) in the United States. Although secondary spread of this strain has not taken place in the United States, these events underscore the need for vigilance among health care professionals, even in locations remote from an epidemic.

In October 1992, a large-scale outbreak of clinical cholera occurred in southeastern India. The etiologic agent proved to be a novel strain of *V. cholerae* belonging neither to the O1 serogroup that typically causes epidemic cholera nor to any of the 137 other serogroups known at the time. This strain spread rapidly up and down the coast of the Bay of Bengal, reaching Bangladesh in December 1992. There alone, it caused more than 100,000 cases of cholera in the first 3 months of 1993. It subsequently spread across the Indian subcontinent and to neighboring countries, affecting Pakistan, Nepal, western China, Thailand, and Malaysia by the end of 1994 (Fig. 140-2). The organism has since been designated *V. cholerae* O139 Bengal in recognition of its novel O antigen and its geographic origin. The clinical manifestations and epidemiologic features of the disease caused by *V. cholerae* O139 Bengal are indistinguishable from those of O1 cholera. Immunity to the latter, however, is not protective against the former. Because naturally acquired immunity to *V. cholerae* O1 does not cross-protect against *V. cholerae* O139 Bengal, vaccines being developed against the former are unlikely to be effective against the latter.

Some authorities believed that the emergence of *V. cholerae* O139 signaled the beginning of the eighth global cholera pandemic. Indeed, just as O1 El Tor replaced the classical biotype that preceded it, O139 Bengal in 1993 rapidly replaced O1 El Tor as the most common environmental isolate and the predominant cause of clinical cholera in the areas in which it had appeared. However, by the beginning of 1994, O1 El Tor resumed its dominance in Bangladesh. Currently, in most regions of Southeast Asia, O1 *V. cholerae* remains dominant; in others, O139 periodically reemerges.

**PATHOGENESIS** In the final analysis, cholera is a toxin-mediated disease. Its characteristic watery diarrhea is due to the action of cholera toxin (CT), a potent protein enterotoxin elaborated by the organism following its colonization of the small intestine. For *V. cholerae* to colonize the small intestine and produce CT, it must first recognize, contend with, and traverse several hostile environments. The first of these is the acidic milieu of the stomach. To elude the bactericidal effects of gastric acidity, *V. cholerae* relies, at least in part, on a relatively large inoculum size (compared to that needed for colonization by *Shigella*, for instance). The organism must next traverse the mucous layer lining the small bowel. *V. cholerae* chemotaxis and motility and a variety of proteases may allow the organism to traverse this gel covering the intestinal epithelium. Adherence to the intestinal epithelium is believed to be mediated by the toxin-coregulated pilus (TCP), so named because its synthesis is regulated in parallel with that of CT. CT, TCP, and several other virulence factors are coordinately regulated by the toxR gene product. The ToxR protein modulates the expression of virulence genes in response to environmental signals via a cascade of regulatory proteins. Additional regulatory processes, including the density of the bacterial population (in a phenomenon known as quorum sensing), control the virulence of *V. cholerae*.

Once established in the human small bowel, the organism produces CT, which consists of a monomeric enzymatic moiety (the A subunit) and a pentameric binding moiety (the B subunit). The B pentamer binds to G<sub>42704</sub> ganglioside, a glycolipid on the surface of epithelial cells that serves as the toxin receptor and makes possible the delivery of...
the A subunit to its cytosolic target. The activated A subunit (A1) irreversibly transfers ADP-ribose from nicotinamide adenine dinucleotide to its specific target protein, the GTP-binding regulatory component of adenylate cyclase in intestinal epithelial cells. The ADP-ribosylated G protein upregulates the activity of adenylate cyclase; the result is the intracellular accumulation of high levels of cyclic AMP. In intestinal epithelial cells, cyclic AMP inhibits the absorptive sodium transport system in villus cells and activates the secretory chloride transport system in crypt cells, and these events lead to the accumulation of sodium chloride in the intestinal lumen. Since water moves passively to maintain osmolality, isotonic fluid accumulates in the lumen. When the volume of that fluid exceeds the capacity of the rest of the gut to resorb it, watery diarrhea results. Unless the wasted fluid and electrolytes are adequately replaced, shock (due to profound dehydration) and acidosis (due to loss of bicarbonate) follow. Although perturbation of the adenylate cyclase pathway is the primary mechanism by which CT causes excess fluid secretion, it is not the only one. Increasing evidence indicates that CT also enhances intestinal secretion via prostaglandin and/or neural histamine receptors.

The genes encoding CT (ctxAB) are part of the genome of a bacteriophage designated CTXΦ. The receptor for this phage on the V. cholerae surface is the essential V. cholerae intestinal colonization factor TCP. After the infection of TCP+ ctxAB− V. cholerae cells, the CTXΦ genome stably integrates at a specific site on the V. cholerae chromosome. Since ctxAB is part of a mobile genetic element (CTXΦ), horizontal transfer of this bacteriophage may account for the emergence of new toxigenic V. cholerae serogroups. Many of the other genes important for V. cholerae pathogenicity, including the genes encoding the biosynthesis of TCP, those encoding accessory colonization factors, and those regulating virulence gene expression, are clustered together in the V. cholerae pathogenicity island. Similar clustering of virulence genes is found in other bacterial pathogens. It is believed that pathogenicity islands are acquired by horizontal gene transfer.

V. cholerae O139 Bengal is closely related to the O1 El Tor strains of the seventh pandemic and seems to have arisen from them by horizontal gene transfer. It shares the virulence attributes and general pathogenic mechanisms of O1 vibrios. V. cholerae O139 Bengal is in fact virtually identical to the seventh-pandemic strains of V. cholerae O1 El Tor except for two important differences: production of the novel O139 LPS and of an immunologically related O-antigen polysaccharide capsule. The ability to produce the O139 LPS is due to a replacement of a 22-kb DNA segment encoding O1 antigen biosynthesis with a 35-kb segment containing the genes encoding O139 LPS and capsule biosynthesis. Encapsulation is not a feature of O1 strains and may explain the resistance of O139 strains to human serum in vitro as well as the occasional development of O139 bacteremia.

CLINICAL MANIFESTATIONS After a 24- to 48-h incubation period, cholera begins with the sudden onset of painless watery diarrhea that may quickly become voluminous and is often followed shortly by vomiting. In severe cases, stool volume can exceed 250 mL/kg in the first 24 h. If fluids and electrolytes are not replaced, hypovolemic shock and death ensue. Fever is usually absent. Muscle cramps due to electrolyte disturbances are common. The stool has a characteristic appearance: a nonbilious, gray, slightly cloudy fluid with flecks of mucus, no blood, and a somewhat sweet, inoffensive odor. It has been called “rice-water” stool because of its resemblance to the water in which rice has been washed. Clinical symptoms parallel volume contraction: At losses of 3 to 5% of normal body weight, thirst develops; at 5 to 8%, postural hypotension, weakness, tachycardia, and decreased skin turgor are documented; and at >10%, oliguria, weak or absent pulses, sunken eyes (and, in infants, sunken fontanelles), wrinkled (“washerwoman”) skin, somnolence, and coma are characteristic. Complications derive exclusively from the effects of volume and electrolyte depletion and include renal failure due to acute tubular necrosis. Thus, if the patient is adequately treated with fluid and electrolytes, complications are averted and the process is self-limited, resolving in a few days.

Laboratory data usually reveal an elevated hematocrit (due to hemoconcentration) in nonanemic patients; mild neutrophilic leukocytosis; elevated levels of blood urea nitrogen and creatinine consistent with prerenal azotemia; normal sodium, potassium, and chloride levels; a markedly reduced bicarbonate level (<15 mmol/L); and an elevated anion gap (due to increases in serum lactate, protein, and phosphate). Arterial pH is usually low (about 7.2).

DIAGNOSIS The clinical suspicion of cholera can be confirmed by the identification of V. cholerae in stool; however, the organism must be specifically sought. With experience, it can be detected directly by dark-field microscopy on a wet mount of fresh stool, and its serotype can be discerned by immobilization with Inaba- or Ogawa-specific antisera. Laboratory isolation of the organism requires the use of a selective medium. The best of these is thiosulfate–citrate–bile salts–sucrose (TCBS) agar, on which the organism grows as a flat yellow colony. If a delay in sample processing is expected, Carey-Blair transport medium and/or alkaline-peptone water-enrichment medium should be inoculated as well. In endemic areas there is little need for biochemical confirmation and characterization, although these tasks may be worthwhile in places where V. cholerae is an uncommon isolate. Standard microbiologic biochemical testing for Enterobacteriaceae will suffice for identification of V. cholerae. All vibrios are oxidase-positive.

The yield of stool cultures for the diagnosis of V. cholerae infection declines late in the course of the illness or when effective antibacterial therapy is initiated. Although not generally performed in clinical laboratories, measurement of serum vibrioiodial antibody titers can be used to confirm the diagnosis in non-cholera-endemic regions of the world. Monoclonal antibody–based diagnostic kits and methods based on the polymerase chain reaction and on DNA probes have also been developed for detection of V. cholerae O1 and O139.

**TREATMENT**

Cholera is simple to treat; only the rapid and adequate replacement of fluids, electrolytes, and base is required. The mortality rate for appropriately treated disease is usually <1%. However, analysis of a large outbreak of cholera among airline travelers from an endemic country to the United States revealed frequent misdiagnoses by U.S. health professionals and poor appreciation on their part of the principles of management. It has been proved conclusively that fluid may be given orally. This approach takes advantage of the hexose-Na+ cotransport mechanism to move Na+ across the gut mucosa together with an actively transported molecule such as glucose. Since Na+ losses in the stool are high, a fluid containing Na+ at 90 mmol/L has been recommended by the World Health Organization (WHO) (Table 140-1). This amount of Na+ is higher than that needed to treat diarrhea due to most other causes. The solution is safe, even for infants, if its intake is alternated with the consumption of sodium-free fluids such as breast milk or water. For the sake of simplicity, WHO advises routine use of

8 Contains (per package, to be added to 1 L of drinking water): NaCl, 3.5 g; Na2HCO3·H2O, 2.9 g; and glucose, 20 g.
9 If prepackaged ORS is unavailable, a simple homemade alternative can be prepared by combining 5 g NaCl (about 1 level teaspoon) with either 50 g precooked rice cereal or 40 g sucrose in 1 L of drinking water. In that case, potassium must be supplied separately (e.g., in orange juice or coconut water).
10 mmol citrate per liter, which supplies 30 mmol HCO3/L.
This single solution for diarrheal disease rather than attempts to choose among multiple formulations according to etiology.

Cereal-based formulations are receiving increased attention as alternative oral rehydration solutions. Because of their lower osmolality, they may reduce stool output. A mixture with a lower sugar and salt content has also been evaluated in cholera patients, with favorable results. However, concerns have been raised over the safety of its use—in particular, whether it could cause significant hyponatremia in patients with moderate or severe diarrhea. Because commercial oral rehydration solutions also contain concentrations of glucose and sodium lower than those of the WHO formulation, they should not yet be used routinely to treat cholera.

For initial management of severely dehydrated patients, intravenous fluid replacement is preferable, if available. Because profound acidosis (pH < 7.2) is common in this group, Ringer’s lactate is the best choice among commercial products (Table 140-2). It must be used with additional potassium supplements, preferably given by mouth. The total fluid deficit in severely dehydrated patients (≥10% of body weight) can be replaced safely within the first 4 h of therapy, half within the first hour. Thereafter, oral therapy can usually be initiated, with the goal of maintaining fluid intake equal to fluid output. However, patients with continued large-volume diarrhea may require prolonged intravenous treatment to keep up with gastrointestinal fluid losses. Severe hypokalemia can develop but will respond to potassium given either intravenously or orally. In the absence of adequate staff to monitor the patient’s progress, the oral route of rehydration and potassium replacement is safer than the intravenous route.

Although not necessary for cure, the use of an antibiotic to which the organism is susceptible will diminish the duration and volume of fluid loss and will hasten clearance of the organism from the stool. Single-dose tetracycline (2 g) or doxycycline (300 mg) is effective in adults but is not recommended for children <8 years of age because of possible deposition in bone and developing teeth. Emerging drug resistance is an ever-present concern. For adults with cholera in areas where tetracycline resistance is prevalent, ciprofloxacin—or erythromycin (a total of 40 mg/kg daily in three divided doses for 3 days)—is a clinically effective substitute. Both drugs are highly effective in reducing total stool output, and each is significantly better than trimethoprim-sulfamethoxazole. Because of the high cost of quinolones, WHO recommends erythromycin as the first alternative to tetracycline. For children, furazolidone has been the recommended agent and trimethoprim-sulfamethoxazole the second choice. Because of cost and/or toxicity issues related to the other drugs, erythromycin is a good choice for pediatric cholera.

**Control** In outbreaks, efforts should first be made to identify case contacts and to treat incubating carriers. Next, epidemiologic studies should be undertaken to establish the modes of transmission in order to define the best strategy to interrupt them. Both the establishment of rehydration centers and instruction in rehydration techniques are essential to the reduction of mortality.

* Potassium supplements, preferably administered by mouth, are required to replace the usual potassium losses from stool.

**Prevention** Provision of safe water and facilities for sanitary disposal of feces, improved nutrition, and attention to food preparation and storage in the household could significantly reduce the incidence of cholera. Much effort has been devoted to the development of an effective cholera vaccine over the past two decades, with a particular focus on oral vaccine strains. Traditional killed cholera vaccine given intramuscularly provides little protection to nonimmune subjects and predictably causes adverse effects, including pain at the injection site, malaise, and fever. The vaccine’s limited efficacy is at least partially due to its failure to induce a local immune response at the intestinal mucosal surface.

Two types of oral cholera vaccines are under development. The first is a killed whole-cell (WC) vaccine. Two formulations of the killed WC vaccine have been prepared—one that also contains the nontoxic B subunit of CT (WC/BS) and one composed solely of killed bacteria. In field trials in Bangladesh, both of the killed vaccines were compared with placebo and conferred ~50% protection over a 3-year evaluation period. The protective efficacy of WC/BS was superior to that of WC during the initial 8 months of follow-up (69 versus 41%) but equivalent or inferior thereafter. Immunity was relatively sustained in persons vaccinated at an age of >5 years but was not well sustained in younger vaccinees. The WC/BS vaccine is now available in Europe but not in the United States.

The second approach is that of a live attenuated vaccine strain developed, for example, by the isolation or creation of mutants lacking the genes encoding CT. Strain CVD 103-HgR, an oral live cholera vaccine licensed for immunization of travelers in Europe, is derived from a classical biotype strain of *V. cholerae* and contains a deletion of the CT A subunit gene. This strain has been extensively tested in volunteers; although it is poorly excreted in the stool of humancase-vaccinees, a single dose produces a significant increase in the titer of vibriocidal antibody in ~75% of recipients, including children between the ages of 2 and 4 years, with almost no side effects. Unfortunately, in a large field trial in Indonesian children, this vaccine failed to induce protection against clinical cholera. Other live attenuated vaccine candidate strains have been prepared from El Tor and O139 *V. cholerae* and are now undergoing clinical trials. Because of the minimal efficacy of existing parenteral vaccines, cholera immunization is recommended for U.S. travelers only if it is mandated by the countries they plan to visit.

**Other Vibrio Species**

The genus *Vibrio* includes several human pathogens that do not cause clinical cholera. Abundant in coastal waters throughout the world, noncholera vibrios can reach high concentrations in the tissues of filter-feeding mollusks. As a result, human infection commonly follows the ingestion of seawater or of raw or undercooked shellfish (Table 140-3). Most noncholera vibrios can be cultured on blood or MacConkey agar, which contains enough salt to support the growth of these halophilic species. In the microbiology laboratory, the species of noncholera vibrios are distinguished by standard biochemical tests. The most important of these organisms are *V. parahaemolyticus* and *V. vulnificus*.

The two major types of syndromes for which these species are responsible are gastrointestinal illness (due to *V. parahaemolyticus*, non-O1 *V. cholerae*, *V. mimicus*, *V. fluvialis*, *V. hollisae*, and *V. furnissii*) and soft tissue infections (due to *V. vulnificus*, *V. alginolyticus*, and *V. damselae*). *V. vulnificus* is also a cause of primary sepsis in some compromised individuals. *V. parahaemolyticus* causes rare cases of wound infection and otitis and very rare cases of sepsis.

**Species Associated Primarily with Gastrointestinal Illness**

*V. parahaemolyticus* Widespread in marine environments, *V. parahaemolyticus* grows in saline concentrations up to 8 to 10%. This species was originally implicated in enteritis in Japan in 1953, accounting for 24% of reported cases in one study—a rate that presumably was due to the common practice of eating raw seafood in that country. *V. parahaemolyticus* has since been identified as a significant intestinal path-
in many regions of the world. In the United States, common-source outbreaks of diarrhea caused by this organism have been linked to the consumption of undercooked or improperly handled seafood or of other foods contaminated by seawater. Since the mid-1990s, the incidence of *V. parahaemolyticus* infections has increased in several countries, including the United States. Serotypes O3:K6, O4:K68, and O1:K-untypable, which are genetically related to one another, account for this increase. The enteropathogenicity of *V. parahaemolyticus* is closely linked to its ability to cause hemolysis on Wagatsuma agar (i.e., the *Kanagawa phenomenon*). The genome sequence of *V. parahaemolyticus* contains a pathogenicity island—a cluster of likely virulence-associated genes. Although the mechanism by which the organism causes diarrhea remains unclear, it should be considered a possible etiologic agent in all cases of diarrhea that can be linked epidemiologically to seafood consumption or to the sea itself.

Infections with *V. parahaemolyticus* can result in two distinct gastrointestinal presentations. The more common of the two presentations (including nearly all cases in North America) is characterized by watery diarrhea, usually occurring in conjunction with abdominal cramps, nausea, and vomiting and accompanied in ~25% of cases by fever and chills. After an incubation period of 4 h to 4 days, symptoms develop and persist for a median of 3 days. Dysentery, the less common presentation, is characterized by severe abdominal cramps, nausea, vomiting, and bloody or mucoid stools. This syndrome is reported from India and Bangladesh.

Most cases of *V. parahaemolyticus*-associated gastrointestinal illness, regardless of the presentation, are self-limited and require neither antimicrobial treatment nor hospitalization. Deaths are extremely rare. Severe infections are associated with underlying diseases, including diabetes, preexisting liver disease, iron-overload states, or immunosuppression. The occasional severe case should be treated with fluid replacement and antibiotics, as described above for cholera.

**Non-O1 *V. cholerae*** The heterogeneous non-O1 *V. cholerae* organisms cannot be distinguished from *V. cholerae* O1 by routine biochemical tests but do not agglutinate in O1 antisera. Non-O1 strains have caused several well-studied food-borne outbreaks of gastroenteritis and have also been responsible for sporadic cases of otitis media, wound infection, and bacteremia. Like other vibrios, non-O1 *V. cholerae* organisms are widely distributed in marine environments. In most instances, recognized cases in the United States have been associated with the consumption of raw oysters or with recent travel, typically to Mexico. The broad clinical spectrum of diarrheal illness caused by these organisms is probably due to the group’s heterogeneous virulence attributes. *V. cholerae* O139 Bengal, although technically a non-O1 vibrio, is not grouped with these pathogens because it can cause epidemic cholera.

In the United States, about half of all non-O1 *V. cholerae* isolates are from stool samples. The typical incubation period for gastroenteritis due to these organisms is <2 days, and the illness lasts for ~2 to 7 days. Patients’ stools may be copious and watery or may be partly formed, less voluminous, and bloody or mucoid. Diarrhea can result in severe dehydration. Many cases include abdominal cramps, nausea, vomiting, and fever. Like those with cholera, patients who are seriously dehydrated should receive oral or intravenous fluids; the value of antibiotics is not clear.

Extraintestinal infections due to non-O1 *V. cholerae* commonly follow occupational or recreational exposure to seawater. Around 10% of non-O1 *V. cholerae* isolates come from cases of wound infection, 10% from cases of otitis media, and 20% from cases of bacteremia (which is particularly likely to develop in patients with liver disease). Extraintestinal infections should be treated with antibiotics. Information to guide agent selection and dosing is limited, but most strains are sensitive in vitro to tetracycline, ciprofloxacin, and third-generation cephalosporins. **Species Associated Primarily with Soft Tissue Infection or Bacteremia** *(See also Chap. 110)*

*V. vulnificus* is the most common cause of severe *Vibrio* infections in the United States. Like most vibrios, this organism proliferates in the warm summer months and requires a saline environment for growth. In this country, infections in humans typically occur in coastal states between May and October and most commonly affect men >40 years of age. *V. vulnificus* has been linked unequivocally to two distinct syndromes: primary sepsis, which usually occurs in patients with underlying liver disease, and primary wound infection, which generally affects people without underlying disease. Some authors have suggested that *V. vulnificus* also causes gastroenteritis independent of other clinical manifestations. *V. vulnificus* is endowed with a number of virulence attributes, including a capsule that confers resistance to phagocytosis and to the bactericidal activity of human serum as well as a cytolsin. Measured as the 50% lethal dose in mice, the organism’s virulence is considerably increased under conditions of iron overload; this observation is consistent with the propensity of *V. vulnificus* to infect patients who have hemochromatosis.

Primary sepsis most often develops in patients who have cirrhosis or hemochromatosis. However, *V. vulnificus* bacteremia can also affect individuals who have hematopoietic disorders or chronic renal insufficiency, those who are using immunosuppressive medications or alcohol, or (in rare instances) those who have no known underlying disease. After a median incubation period of 16 h, the patient develops malaise, chills, fever (mean temperature, 39.8°C), and prostration. One-third of patients develop hypotension, which is often apparent at admission. Cutaneous manifestations develop in most cases (usually within 36 h of onset) and characteristically involve the extremities (the lower more often than the upper). In a common sequence, erythematous patches are followed by ecchymoses, vesicles, and bullae. In fact, sepsis and bullous skin lesions suggest the diagnosis in appropriate settings. Necrosis and sloughing may also be evident. Laboratory studies reveal leukopenia more often than leukocytosis, thrombocytopenia, or elevated levels of fibrin split products. *V. vulnificus* can be cultured from blood or cutaneous lesions. The mortality rate approaches 50%, with most deaths due to uncontrolled sepsis. Accordingly, prompt treatment is critical and should include empirical antibiotic administration, aggressive debridement, and general supportive care. *V. vulnificus* is sensitive in vitro to a number of antibiotics, including tetracycline, fluoroquinolones, and third-generation cephalosporins. Data from animal models suggest that either a fluoroquinolone or the combination of minocycline and cefotaxime should be used in the treatment of *V. vulnificus* septicemia.

*V. vulnificus* can infect either a fresh or an old wound that comes into contact with seawater; the patient may or may not have underlying disease. After a short incubation period (4 h to 4 days; mean, 12 h), the disease begins with swelling, erythema, and (in many cases) intense pain around the wound. These signs and symptoms are followed by cellulitis, which spreads rapidly and is sometimes accompanied by
vesicular, bullous, or necrotic lesions. Metastatic events are uncommon. Most patients have a fever (median temperature, 38.9°C) and leukocytosis. *V. vulnificus* can be cultured from skin lesions and occasionally from the blood. Prompt antibiotic therapy and debridement are usually curative.

**V. alginolyticus** First identified as a pathogen of humans in 1973, *V. alginolyticus* occasionally causes eye, ear, and wound infections. This species is the most salt-tolerant of the vibrios and can grow in salt concentrations of >10%. Most clinical isolates come from superinfected wounds that presumably become contaminated at the beach. Although severity varies, *V. alginolyticus* infection tends not to be serious and generally responds well to antibiotic therapy and drainage. A few cases of otitis externa, otitis media, and conjunctivitis due to this pathogen have been described. Tetracycline treatment usually results in cure. *V. alginolyticus* is a rare cause of bacteremia in immunocompromised hosts.

### Etiology

**Brucellosis**

**Michael J. Corbel, Nicholas J. Beeching**

### Definition

Brucellosis is a bacterial zoonosis transmitted directly or indirectly to humans from infected animals, predominantly domesticated ruminants and swine. The disease is known colloquially as *undulant fever* because of its remittent character. Its distribution is worldwide apart from the few countries where it has been eradicated from the animal reservoir (see “Epidemiology,” below). Although brucellosis commonly presents as an acute febrile illness, its clinical manifestations can be quite varied, and definitive signs to indicate the diagnosis can be lacking. Thus the clinical diagnosis must usually be supported by the results of bacteriologic and/or serologic tests.

### Etiologic Agent

Human brucellosis is caused by strains of *Brucella*, a bacterial genus considered on genetic grounds to comprise a single species, *Brucella melitensis*, with a number of biologic variants that exhibit particular host preferences. For the sake of convenience, the traditional classification into nomen species is still in general use; this scheme, which closely follows the epidemiologic patterns of the infection, recognizes *B. melitensis*, which is the commonest cause of symptomatic disease in humans and for which the main sources are sheep, goats, and camels; *B. abortus*, which is usually acquired from cattle or buffalo; *B. suis*, which is generally acquired from swine except for one variant enzootic in reindeer and caribou and another enzootic in rodents; and *B. canis*, which is most often acquired from dogs. *B. ovis*, which causes reproductive disease in sheep, and *B. neotomae*, which is specific for desert rodents, have not been clearly implicated in human disease. Other brucellae have been isolated from marine mammals and probably correspond to at least three distinctive nomen species. At least one case of laboratory-acquired human disease due to these marine types has been described, and apparent cases of natural infection have been reported.

All brucellae are small, gram-negative, unencapsulated, nonsporulating rods or coccobacilli. They grow aerobically on peptone-based media incubated at 37°C; the growth of some types is enhanced by supplementary CO₂. In vivo, brucellae behave as facultative intracellular parasites. The organisms are sensitive to sunlight, ionizing radiation, and moderate heat; they are killed by boiling and pasteurization but are resistant to freezing and drying. Their resistance to drying renders brucellae stable in aerosol form and facilitates airborne transmission. Brucellae can survive for up to 2 months in soft cheeses made from goat or sheep milk; for at least 6 weeks in dry soil contaminated with infected urine, vaginal discharge, or placental or fetal tissues; and for at least 6 months in damp soil or liquid manure kept under cool, dark conditions. The bacteria are easily killed by a wide range of common disinfectants used under optimal conditions but are likely to be much more resistant at low temperatures or in the presence of heavy organic contamination.

### Epidemiology

Brucellosis is a zoonosis whose occurrence is closely related to its prevalence in domesticated animals. The true global prevalence of human brucellosis is unknown because of the imprecision of diagnosis and the inadequacy of reporting and surveillance systems in many countries. Even in developed countries, the true incidence may be 10 to 20 times higher than the reported figures. Bovine brucellosis has been the subject of control programs in many parts of the world and has been eradicated from the cattle populations of Australia, New Zealand, Bulgaria, Canada, Cyprus, Great Britain (including the Channel Islands), Japan, Luxembourg, Romania, the Scandinavian countries, Switzerland, and the Czech and Slovak Republics. Its incidence in cattle has been reduced to a low level in the United States and most Western European countries, with a varied picture in other parts of the world. There is evidence of some resurgence of brucellosis in cattle in Eastern Europe following economic changes in recent years. Efforts to eradicate *B. melitensis* infection from sheep and goat populations have been much less successful. These efforts have relied heavily on vaccination programs, which have tended to fluctuate with changing economic and political conditions. In some countries, such as Israel, *B. melitensis* has caused serious outbreaks in cattle. Brucellosis still represents a major public health problem in Mediterranean countries; in western, central, and southern Asia; and in parts of Africa and South and Central America.

Human brucellosis is usually associated with occupational or domestic exposure to infected animals or their products. Farmers, shepherds, goatherds, veterinarians, and workers in slaughterhouses and meat-processing plants in endemic areas are occupationally exposed to infection. Family members (including children) of individuals involved in animal husbandry may also be at risk, although it is often difficult to differentiate food-borne infection from environmental contamination under these circumstances. Laboratory workers involved in handling cultures or infected samples are also at risk. Travelers and urban dwellers usually acquire the infection through consumption of contaminated foods. In countries that have eradicated the disease, new cases are most often acquired abroad. Dairy products, especially soft cheeses, unpasteurized milk, and ice cream, are the most frequently implicated sources; raw meat and bone marrow may be sources of infection under exceptional circumstances. Infection resulting from contact with cosmetic products containing infected fetal materials has been recorded. Person-to-person transmission is extremely rare, as is transfer of infection by blood or tissue donation. Although brucellosis is a chronic intracellular infection, there is no evidence for increased prevalence or severity among individuals with HIV infection or other forms of immune deficiency or immune suppression.
Brucellosis may be acquired by ingestion or inhalation or through mucosal or percutaneous exposure. *B. melitensis* and *B. suis* are known to have been developed as biological weapons by several countries and could be exploited as weapons of bioterrorism (Chap. 205). This possibility should be borne in mind in the event of sudden unexplained outbreaks.

**IMMUNITY AND PATHOGENESIS** The mechanisms of protective immunity against human brucellosis are presumed to be similar to those documented in laboratory animals. Exposure to infection generates both humoral and cell-mediated immune responses. Although antibodies promote clearance of extracellular brucellae by bactericidal action and through the facilitation of phagocytosis by polymorphonuclear phagocytes, the antibody response cannot eradicate the infection. Organisms taken up by macrophages and other cell types can establish persistent intracellular infections. Early in the course of infection, cytokines such as interleukin (IL) 12 promote production of interferon γ, which drives Th1-type responses and stimulates macrophage activation. Activated macrophages can kill intracellular brucellae (probably mainly through the production of reactive oxygen intermediates) and can clear the infection. Tumor necrosis factor α (TNF-α) is produced early in the immune response and stimulates cytotoxic lymphocytes, which can achieve partial clearance; however, the ability of virulent *Brucella* cells to suppress the TNF-α response may explain its limited role in protection. Inflammatory cytokines, including IL-6 and IL-10, downregulate the protective response. As in other types of intracellular infection, it is assumed that initial replication of brucellae takes place within cells of the lymph nodes draining the point of entry. Subsequent hematogenous spread may result in chronic localizing infection at almost any site, although the reticuloendothelial system, musculoskeletal tissues, and the genitourinary system are most frequently involved. Both acute and chronic inflammatory responses develop in brucellosis, and the local tissue response may include granuloma formation, with or without necrosis and caseation. Abscesses may also develop, especially in chronic localized infection.

The determinants of pathogenicity of *Brucella* have not been fully characterized, and the mechanisms underlying the manifestations of brucellosis are incompletely understood. The survival strategy of the organism is centered on processes that enable it to persist within monocytic cells. The smooth *Brucella* lipopolysaccharide, which has an unusual O-chain composition, possesses endotoxin activity and plays a key role in pyrogenicity and in resistance to phagocytosis and serum killing in the nonimmune host. Specific exotoxins have not been isolated, but a type IV secretion system responsible for secreting proteins that regulate intracellular survival and trafficking has been identified. This system is activated by low pH, and brucellae produce acid-stable proteins that facilitate survival in phagosomes and depress activation of the oxidative burst. Macrophage apoptosis and phagosome-lysosome fusion are also suppressed. Virulent brucellae are resistant to defensins and produce a Cu-Zn superoxide dismutase that enhances resistance to reactive oxygen intermediates.

**CLINICAL FEATURES** Brucellosis almost invariably causes fever, which may be associated with profuse sweats, especially at night. In endemic areas, brucellosis may be difficult to distinguish from the many other causes of fever. However, two features were recognized in the nineteenth century to distinguish brucellosis from other tropical fevers, such as typhoid and malaria: (1) Left untreated, the fever of brucellosis shows an undulating pattern that persists for weeks before the commencement of an afebrile period that may be followed by relapse, and (2) the fever of brucellosis is associated with musculoskeletal symptoms and signs in about one-half of all patients.

The clinical syndromes caused by the different *Brucella* species are similar, although *B. melitensis* tends to be associated with a more acute and aggressive presentation and *B. suis* with focal abscess induction. *B. abortus* infections may be more insidious in onset and more likely to become chronic.

The incubation period varies from 1 week to several months, and the onset of fever and other symptoms may be abrupt or insidious. In addition to fever and sweats, patients become increasingly apathetic and fatigued; lose appetite and weight; and have nonspecific myalgia, headache, and chills. Overall, the presentations of brucellosis often fit into one of three patterns: febrile illness that resembles typhoid but is less severe; fever and acute monarthritis, typically of hip or knee, in a young child; or long-lasting fever, misery, and low-back pain or hip pain in an older man. In an endemic area (e.g., much of the Middle East), a patient with fever and difficulty walking into the clinic would be regarded as having brucellosis until it was proved otherwise.

Diagnostic clues in the patient’s history include travel to an endemic area, employment in a diagnostic microbiology laboratory, consumption of unpasteurized milk products (including soft cheeses), contact with animals, and—in an endemic setting—a history of similar illness in the family (documented in almost 50% of cases).

Focal features are present in the majority of patients. The most common is musculoskeletal pain and physical findings in the peripheral and axial skeleton (~40% of cases). Osteomyelitis more commonly involves the lumbar and lower thoracic vertebrae than the cervical and high thoracic spine. Individual joints that are most commonly affected by septic arthritis are the knee, hip, sacroiliac, shoulder, and sternoclavicular joints, and the pattern may be one of either monarthrits or polyarthrits. Osteomyelits may also accompany septic arthritis.

In addition to the usual causes of vertebral osteomyelitis or septic arthritis, the most important differential diagnosis is tuberculosis. This point has an impact on the therapeutic approach as well as on the prognosis, given that several antimicrobial agents used to treat brucellosis are also used to treat tuberculosis. Septic arthritis in brucellosis progresses slowly, starting with small pericapsular erosions. In the vertebrae, anterior erosions of the superior end plate are typically the first features to become evident, with eventual involvement and sclerosis of the whole vertebra. Anterior osteophytes eventually develop, but vertebral destruction or impingement on the spinal cord is rare and usually suggests tuberculosis (Table 141-1).

Other systems may be involved in a manner that resembles typhoid. About one-quarter of patients have a dry cough, usually with few changes visible on the chest x-ray, although pneumonia, empyema, intrathoracic adenopathy, or lung abscess can occur. One-quarter of patients have hepato-splenomegaly, and 10 to 20% have significant lymphadenopathy; the differential diagnosis includes glandular fever like illness such as that caused by Epstein-Barr virus, *Toxoplasma*, and cytomegalovirus; HIV infection; or tuberculosis. Up to 10% of men have acute epididymoorchitis, which must be distinguished from that due to mumps or surgical problems such as torsion. Prostatitis, inflammation of the seminal vesicles, salpingitis, and pyleonephritis all occur. There is an increased incidence of fetal loss among infected pregnant women, although teratogenicity has not been described and

Diagnostic clues in the patient’s history include travel to an endemic area, employment in a diagnostic microbiology laboratory, consumption of unpasteurized milk products (including soft cheeses), contact with animals, and—in an endemic setting—a history of similar illness in the family (documented in almost 50% of cases).

Focal features are present in the majority of patients. The most common is musculoskeletal pain and physical findings in the peripheral and axial skeleton (~40% of cases). Osteomyelitis more commonly involves the lumbar and lower thoracic vertebrae than the cervical and high thoracic spine. Individual joints that are most commonly affected by septic arthritis are the knee, hip, sacroiliac, shoulder, and sternoclavicular joints, and the pattern may be one of either monarthrits or polyarthrits. Osteomyelits may also accompany septic arthritis.

In addition to the usual causes of vertebral osteomyelitis or septic arthritis, the most important differential diagnosis is tuberculosis. This point has an impact on the therapeutic approach as well as on the prognosis, given that several antimicrobial agents used to treat brucellosis are also used to treat tuberculosis. Septic arthritis in brucellosis progresses slowly, starting with small pericapsular erosions. In the vertebrae, anterior erosions of the superior end plate are typically the first features to become evident, with eventual involvement and sclerosis of the whole vertebra. Anterior osteophytes eventually develop, but vertebral destruction or impingement on the spinal cord is rare and usually suggests tuberculosis (Table 141-1).

Other systems may be involved in a manner that resembles typhoid. About one-quarter of patients have a dry cough, usually with few changes visible on the chest x-ray, although pneumonia, empyema, intrathoracic adenopathy, or lung abscess can occur. One-quarter of patients have hepato-splenomegaly, and 10 to 20% have significant lymphadenopathy; the differential diagnosis includes glandular fever like illness such as that caused by Epstein-Barr virus, *Toxoplasma*, and cytomegalovirus; HIV infection; or tuberculosis. Up to 10% of men have acute epididymoorchitis, which must be distinguished from that due to mumps or surgical problems such as torsion. Prostatitis, inflammation of the seminal vesicles, salpingitis, and pyleonephritis all occur. There is an increased incidence of fetal loss among infected pregnant women, although teratogenicity has not been described and
the tendency to cause abortions is much less pronounced in humans than in farm animals.

Neurologic involvement is common, with depression and lethargy whose severity may not be fully appreciated by either the patient or the physician until after treatment. A small proportion of patients develop lymphocytic meningoencephalitis that mimics neurotuberculosis or non-infectious conditions and that may be complicated by intracerebral abscess, a variety of cranial nerve deficits, and ruptured myotic aneurysms.

Endocarditis occurs in ~1% of cases, most often affecting the aortic valve (natural or prosthetic). Any site in the body may be involved in metastatic abscess formation or inflammation; the female breast and the thyroid gland are affected particularly often. Nonspecific maculopapular rashes and other skin manifestations are uncommon and are rarely noticed by the patient even if they are present.

**DIAGNOSIS** Because the clinical picture of brucellosis is not distinctive, the diagnosis must be based on a history of potential exposure, a presentation consistent with the disease, and supporting laboratory findings. Routine biochemical assays are usually within normal limits, although serum levels of hepatic enzymes and bilirubin may be elevated. Peripheral leukocyte counts are usually normal or low, with relative lymphocytosis. Mild anemia may be documented. Thrombocytopenia and disseminated intravascular coagulation with raised levels of fibrinogen degradation products can develop. The erythrocyte sedimentation rate and C-reactive protein levels are often normal but may be raised.

In body fluids such as cerebrospinal fluid (CSF) or joint fluid, lymphocytosis and low glucose levels are the norm. Elevated CSF levels of adenosine deaminase cannot be used to distinguish tuberculous meningitis, as they may also be found in brucellosis. Biopsied samples of tissues such as lymph node or liver may show noncaseating granulomas (Fig. 141-1) without acid/alkohol-fast bacilli. The radiologic features of bony disease develop late in brucellosis and are much more subtle than those of tuberculosis or septic arthritis of other etiologies, with less bone and joint destruction. Isotope scanning is more sensitive than plain x-ray and continues to give positive results long after successful treatment.

Isolation of brucellae from blood, CSF, bone marrow, or joint fluid or from a tissue aspirate or biopsy sample is definitive, and attempts at isolation are usually successful in 50 to 70% of cases. Duplicate cultures (in air and 10% CO₂, respectively) should be incubated for up to 6 weeks. Concentration and lysis ofuffy coat cells before culture may increase the isolation rate. Cultures in modern nonradiometric or similar signaling systems (e.g., BACTEC) usually become positive within 7 to 10 days but should be maintained for at least 3 weeks before the results are declared negative.

**TREATMENT**

The broad aims of antimicrobial therapy for brucellosis are to treat current infection and relieve its symptoms and to prevent relapse. Focal disease presentations may require surgical intervention (e.g., cardiac valve replacement, abscess drainage, joint replacement) in addition to more prolonged and tailored antibiotic therapy. In addition, tuberculosis must always be excluded, or—to prevent the emergence of resistance—the regimen must be tailored to specifically exclude monotherapy with agents active against tuberculosis (e.g., rifampin) or to include a full antituberculous regimen.

Early experience with streptomycin monotherapy for brucellosis showed that relapse was common; thus dual therapy with streptomycin and tetracyclines became the norm. This is still the most effective combination, but alternatives may be used, with the options depending on local or national policy about the use of rifampin for the treatment of nontuberculous infection. Antimicrobial efficacy can usually be predicted by in vitro testing. The efficacy of fluoroquinolone monotherapy has been disappointing, with a high relapse rate, despite the good in vitro activity and white-cell penetration of most agents of this class.

Nucleic acid amplification techniques are not yet widely available for the diagnosis of human brucellosis, and no single standardized procedure has been adopted. The peripheral blood–based polymerase chain reaction (PCR) has enormous potential to detect bacteremia, to predict relapse, and to exclude “chronic brucellosis” (see “Prognosis and Follow-Up,” below); PCR is probably more sensitive and is certainly quicker than blood culture, and it does not carry the attendant biohazard risk posed by culture. Primers for the spacer region between the genes encoding the 16S and 23S ribosomal RNAs (rrs–rfl), outer-membrane protein Omp2, insertion sequence IS711, or protein BCSP31 are sensitive and specific. Blood or other tissues are the most suitable samples for PCR testing.

Serologic examination often provides the only positive laboratory findings in brucellosis. In acute infection, IgM antibodies appear early and are followed by IgG and IgA antibodies. All these antibodies are active in agglutination tests, whether performed by tube, plate, or microagglutination methods. The majority of patients have detectable agglutinins at this stage. As the disease progresses, IgM levels decline, and the avidity and subclass distribution of IgG and IgA change. The result is reduced or undetectable agglutinin titers. However, the antibodies are detectable by alternative tests, including the complement fixation test, Coombs’ antiglobulin test, and enzyme-linked immunosorbent assay. There is no clear cutoff value for a diagnostic titer. Rather, serologic results must be interpreted in the context of exposure history and clinical presentation. Endemic areas or in settings of potential occupational exposure, agglutinin titers of ≥1:320 to 1:640 are considered diagnostic; in nonendemic areas, a titer of ≥1:160 is considered significant. Repetition of tests after 2 to 4 weeks may demonstrate a rising titer.

In most centers, the standard agglutination test (SAT) is still the mainstay of serologic diagnosis, although some investigators rely on the rose bengal test, which has not been fully validated for human diagnostic use. Dipstick assays for anti-Brucella IgM are useful for the diagnosis of acute infection but are less sensitive for infection with symptoms of several months’ duration. In an endemic setting, ≥90% of patients with acute bacteremia have SAT titers of at least 1:320.

Antibody to the Brucella lipopolysaccharide O chain—the dominant antigen—is detected by all the conventional tests that employ smooth B. abortus cells as antigen. Since B. abortus cross-reacts with B. melitensis and B. suis, there is no advantage in replicating the tests with these antigens. Cross-reactions also occur with the O chains of some other gram-negative bacteria, including Escherichia coli O157, Francisella tularensis, Salmonella enterica group N, Stenotrophomonas maltophilia, and Vibrio cholerae. Cross-reactions do not occur with the cell-surface antigens of rough Brucella strains such as B. canis or B. ovis; serologic tests for these nomen species must employ an antigen prepared from either one. Most protein antigens are shared by all Brucella strains, and some are also common to Ochrobactrum species.
DEFINITION
Tularemia is a zoonosis caused by *Francisella tularensis*. Humans of any age, sex, or race are universally susceptible to this systemic infection. Tularemia is primarily a disease of wild animals and persists in contaminated environments, ectoparasites, and animal carriers. Human infection is incidental and usually results from interaction with biting or blood-sucking insects, wild or domestic animals, or the environment. Tularemia is common in Arkansas, Oklahoma, and Missouri, where more than 50% of the cases in the United States occur. An increasing number of cases of tularemia have been reported from the Scandinavian countries, eastern Europe, and Siberia. The illness is characterized by various clinical syndromes, the most common of which consists of an ulcerative lesion at the site of inoculation, with regional lymphadenopathy and lymphadenitis. Systemic manifestations, including pneumonia, typhoidal tularemia, and fever without localizing findings, pose a greater diagnostic challenge.

ETIOLOGY AND EPIDEMIOLOGY
With rare exceptions, tularemia is the only disease produced by *F. tularensis*—a small (0.2 μm by 0.2 to 0.7 μm), course of the same therapy that was originally used. The general well-being and body weight of the patient are more useful guides than serology to lack of relapse. IgG antibody levels detected by SAT and variants of this test can remain in the diagnostic range for >2 years after successful treatment. Complement fixation titers usually fall to normal within 1 year of cure. Immunity is not solid; patients can be reinfected after repeated exposures. Fewer than 1% of patients die of tularemia. When the outcome of this infection is fatal, death is usually a consequence of cardiac involvement; more rarely, it results from severe neurologic disease. Despite the low mortality rate, recovery from tularemia is slow, and the illness in humans can cause prolonged inactivity, with consequent domestic difficulties and economic losses.

The existence of a prolonged chronic tularemia state after successful treatment remains controversial. Evaluation of patients in whom this state is considered (often those with work-related exposure to *Brucella*) includes careful exclusion of malingering, nonspecific chronic fatigue syndromes and other causes of excessive sweating, such as alcohol abuse and obesity. In the future, the availability of more sensitive assays to detect *Brucella* antigen or DNA may help to identify patients with ongoing infection.

PREVENTION
Vaccines based on live attenuated *Brucella* strains, such as *B. abortus* strain 19BA or 104M, have been used in some countries to protect high-risk populations but have displayed only short-term efficacy and a high incidence of local and systemic side effects (local inflammation, pain, lymphadenopathy, fever, malaise, nausea). Subunit vaccines have been developed but are of uncertain value and cannot be recommended at present. Interest in biodefense has stimulated research in this area (Chap. 205). The mainstay of veterinary prevention is a national commitment to testing and slaughter of infected herds and flocks (with compensation for owners), control of animal movement, and active immunization of animals. These measures are usually sufficient to control human disease as well. In their absence, pasteurization of all milk products before consumption is sufficient to prevent animal-to-human transmission. All cases of *Brucella* infection in animals and humans should be reported to the appropriate public health authorities.

FURTHER READING

PROGNOSIS AND FOLLOW-UP
Relapse occurs in up to 30% of poorly compliant patients. Thus patients ideally should be followed clinically for up to 2 years to detect relapse, which responds to a prolonged
gram-negative, pleomorphic, nonmotile, non-spore-forming bacillus. Bipolar staining results in a coccoid appearance. The organism is a thinly encapsulated, nonpiliated strict aerobe that invades host cells. In nature, *F. tularensis* is a hardy organism that persists for weeks or months in mud, water, and decaying animal carcasses. Dozens of biting and blood-sucking insects, especially ticks and tabanid flies, serve as vectors. Ticks and wild rabbits are the source for most of the human cases in the endemic areas of the southeastern and Rocky Mountain states. In Utah, Nevada, and California, tabanid flies are the most common vectors. Animal reservoirs include wild rabbits, squirrels, birds, sheep, beavers, muskrats, and domestic dogs and cats. Humans become infected by various modes, including bites by infected arthropods; handling of infected animal tissues or fluids; direct contact with or ingestion of contaminated water, food, or soil; and inhalation of infected aerosols.

The two main biovars of *F. tularensis*—*tularensis* (type A) and *paleorctic* (type B)—are both found in the United States. Type A produces more serious disease in humans; without treatment, the associated fatality rate is ~5%. Type B produces a milder, often subclinical infection that is usually contracted from water or marine mammals. Although all strains appear serologically identical, individual strains may possess varying degrees of virulence. *F. tularensis* does not produce an exotoxin, but an endotoxin similar to that of other gram-negative bacilli has been identified. The progression of illness depends on the organism’s virulence, the inoculum size, the portal of entry, and the host’s immune status.

Ticks pass the organism to their offspring via a transovarian route. The organism is found in tick feces but not in large quantities in tick salivary glands. In the United States, the disease can be carried by *Dermacentor andersoni* (Rocky Mountain wood tick), *D. variabilis* (American dog tick), *D. occidentalis* (Pacific coast dog tick), and *Amblyomma americanum* (Lone Star tick). *F. tularensis* is transmitted frequently during blood meals taken by embedded ticks following hours of attachment. It is the taking of a blood meal through a febrally contaminated field that transmits the organism. Tularemia is more common among men than among women. Person-to-person transmission is rare or nonexistent. Transmission of the organism by ticks and tabanid flies takes place mainly in the spring and summer. However, continued transmission in the winter months by trapped or hunted animals has been documented. The organism is extremely infectious. Biosafety level 2 is recommended for clinical laboratory work with material whose contamination is suspected, and biosafety level 3 is required for culture of the organism in large quantities. Issues related to the intentional spread of tularemia through ingestion or inhalation are discussed in Chap. 205.

**PATHOGENESIS AND PATHOLOGY** The most common portal of entry for human infection is through skin or mucous membranes, either directly—through the bite of ticks, other arthropods, or other animals—or via inapparent abrasions. Inhalation or ingestion of *F. tularensis* can also result in infection. Although more than 10⁷ organisms are usually required to produce infection via the oral route (opharyngeal or gastrointestinal tularemia), fewer than 50 organisms will result in infection when injected into the skin (ulceroglandular/glandular tularemia) or inhaled (pneumonia). After inoculation into the skin, the organism multiplies locally; within 2 to 5 days (range, 1 to 10 days), it produces an erythematous, tender, or pruritic papule. The papule rapidly enlarges and forms an ulcer with a black base (chancriform lesion). The bacteria spread to regional lymph nodes, producing lymphadenopathy (buboes), and, with bacteremia, may spread to distant organs.

Tularemia is characterized by mononuclear cell infiltration with pyogranulomatous pathology. The histopathologic findings can be quite similar to those in tuberculosis, although tubercles and granulomas are not always induced. As a facultatively intracellular bacterium, *F. tularensis* can parasitize both phagocytic and nonphagocytic host cells and survive intracellularly for prolonged periods. In the acute phase of infection, the primary organs affected (skin, lymph nodes, liver, and spleen) include areas of focal necrosis, initially surrounded by polymorphonuclear leukocytes (PMNs). Subsequently, granulomas form, with epithelioid cells, lymphocytes, and multinucleated giant cells surrounded by areas of necrosis. These areas may resemble caseation necrosis but later coalesce to form abscesses.

Conjunctival inoculation can result in infection of the eye, with regional lymph node enlargement (preauricular lymphadenopathy, Parinaud’s complex). Aerosolization and inhalation or hematogenous spread of organisms can result in pneumonia. In the lung, an inflammatory reaction develops, including foci of alveolar necrosis and cell infiltration (initially polymorphonuclear and later mononuclear) with granulomas. Chest roentgenograms usually reveal bilateral patchy infiltrates rather than large areas of consolidation. Pleural effusions are common and may contain blood. Lymphadenopathy occurs in regions draining infected organs. Therefore, in pulmonary infection, medias- tinal adenopathy may be evident, whereas patients with opharyngeal tularemia develop cervical lymphadenopathy. In gastrointestinal or typhoidal tularemia, mesenteric lymphadenopathy may follow the infection of large numbers of organisms. The term *typhoidal tularemia* may be used to describe severe bacteremic disease, irrespective of the mode of transmission or portal of entry. Meningitis has been reported as a primary or secondary manifestation of bacteremia. Patients may also present with fever and no localizing signs.

**IMMUNOLOGY** Infection with *F. tularensis* stimulates the host to produce antibodies. However, this antibody response probably plays only a minor role in the containment of infection. In contrast, cell-mediated immunity, which develops over 2 to 4 weeks, plays a major role in containment and eradication. Macrophages, once activated, can kill *F. tularensis*. Recovery from infection generally renders the patient resistant to reinfection; this point is not completely understood.

Immunospecific protection against tularemia can be afforded either by natural infection or by vaccination with live attenuated strains of *F. tularensis*. Killed vaccines, on the other hand, induce no protection against virulent *F. tularensis*. After natural infection or vaccination, serum antibodies to surface-exposed carbohydrate antigens predominate, whereas T cell determinants are located on membrane proteins beneath the bacterial capsule. T cell responses are thought to be due to priming by the organism. The anamnestic T cell response to *F. tularensis* seems to involve a multitude of microbial proteins, each with a distinct set of T cell determinants. A predominant role for CD4+ T cells is supported by the results of experiments in mice, which indicated that resistance to infection was restricted at the level of the major histocompatibility complex (MHC) class II determinants. Humans primed to *F. tularensis* (like those primed to *Mycobacterium tuberculosis*) show a Th1-like response. T cell proliferation is associated with the production of interleukin (IL) 2 and interferon γ but with little or no production of IL-4. Recent evidence indicates that the percentage of γδ T cells expressing tumor necrosis factor α is decreased during the first 7 to 40 days after infection. This decrease may reflect the modulation of an inflammatory response. Investigations of neutrophils in tularemia suggest that PMNs are needed for defense against primary infection. PMNs may restrict the growth of *F. tularensis* before the organism becomes intracellular.

**CLINICAL MANIFESTATIONS** Tularemia often starts with a sudden onset of fever, chills, headache, and generalized myalgias and arthralgias (Table 142-1). This onset takes place when the organism penetrates the skin, is ingested, or is inhaled. An incubation period of 2 to 10 days is followed by the formation of an ulcer at the site of penetration, with local inflammation. The ulcer may persist for several months as organisms are transported via the lymphatics to the regional lymph nodes. These nodes enlarge and may become necrotic and suppurative. If the organism enters the bloodstream, widespread dissemination as well as signs and symptoms of endotoxemia may result.

In the United States, most patients with tularemia (75 to 85%) acquire the infection by inoculation of the skin. In adults, the most
common localized form is inguinal/femoral lymphadenopathy; in children, it is cervical lymphadenopathy. About 20% of patients develop a generalized maculopapular rash, which occasionally becomes pustular. Erythema nodosum occurs infrequently. The clinical manifestations of tularemia have been divided into various syndromes, which are listed in Table 142-2.

**Ulceroglandular/Glandular Tularemia** These two forms of tularemia account for ~75 to 85% of cases. The predominant form in children involves cervical or posterior auricular lymphadenopathy and is usually related to tick bites on the head and neck. In adults, the most common form is inguinal/femoral lymphadenopathy resulting from insect and tick exposures on the lower limbs. In cases related to wild game, the usual portal of entry for *F. tularensis* is either an injury sustained while skinning or cleaning an animal carcass or a bite (usually on the hand). Epitrochlear lymphadenopathy/lymphadenitis is common in patients with bite-related injuries.

In ulceroglandular tularemia, the ulcer is erythematous, indurated, and nonhealing, with a punched-out appearance that lasts from 1 to 3 weeks. The papule may begin as an erythematous lesion that is tender or pruritic; it evolves over several days into an ulcer with sharply demarcated edges and a yellow exudate. The ulcer gradually develops a black base, and simultaneously the regional lymph nodes become tender and severely enlarged (Fig. 142-1). The affected lymph nodes may become fluctuant and drain spontaneously, but usually the condition resolves with effective treatment. Late suppuration of lymph nodes has been described in up to 25% of patients with ulceroglandular/glandular tularemia. Examination of material taken from these late fluctuant nodes after successful antimicrobial treatment has revealed sterile necrotic tissue. In 5 to 10% of patients, the skin lesion may be inapparent, with lymphadenopathy plus systemic signs and symptoms the only physical findings (*glandular tularemia*). Conversely, a tick or deerfly bite on the trunk may result in an ulcer without evident lymphadenopathy.

**Oculoglandular Tularemia** In ~1% of patients, the portal of entry for *F. tularensis* is the conjunctiva. Usually, the organism reaches the conjunctiva through contact with contaminated fingers. The inflamed conjunctiva is painful, with numerous yellowish nodules and pinpoint ulcers. Purulent conjunctivitis with regional lymphadenopathy is evident. Because of debilitating pain, the patient may seek medical attention before regional lymphadenopathy develops. Painful preauricular lymphadenopathy is unique to tularemia and distinguishes it from cat-scratch disease, tuberculosis, sporotrichosis, and syphilis. Corneal perforation may occur.

**Oropharyngeal and Gastrointestinal Tularemia** Rarely, tularemia follows the ingestion of contaminated undercooked meat, the oral inoculation of *F. tularensis* from the hands in association with the skinning and cleaning of animal carcasses, or the consumption of contaminated food or water. Oral inoculation may result in acute, exudative, or membranous pharyngitis associated with cervical lymphadenopathy or in ulcerative intestinal lesions associated with mesenteric lymphadenopathy, diarrhea, abdominal pain, nausea, vomiting, and gastrointestinal bleeding. Infected tonsils become enlarged and develop a yellowish-white pseudomembrane, which can be confused with that of diphtheria. The clinical severity of gastrointestinal tularemia varies from mild, unexplained, persistent diarrhea with no other symptoms to a fulminant, fatal disease. In fatal cases, the extensive intestinal ulceration found at autopsy suggests an enormous inoculum.

**Pulmonary Tularemia** Tularemia pneumoniapresents as variable parenchymal infiltrates that are unresponsive to treatment with β-lactam antibiotics. Tularemia must be considered in the differential diagnosis of atypical pneumonia in a patient with a history of travel to an endemic area. The disease can result from either inhalation of an infectious aerosol or can spread to the lungs and pleura after bloodstream dissemination. Inhalation-related pneumonia has been described in laboratory workers after exposure to contaminated materials and is associated with a relatively high mortality rate. Exposure to *F. tularensis* in aerosols from live domestic animals or dead wildlife (including birds) has been reported to cause pneumonia. Hematogenous dissemination to the lungs occurs in 10 to 15% of cases of ulceroglandular tularemia and in about half of cases of typhoidal tularemia. Previously, tularemia pneumonia was thought to be a disease of older patients, but as many as 10 to 15% of children with clinical manifestations of tularemia have parenchymal infiltrates detected by chest roentgenography. Patients with pneumonia usually have a nonproductive cough and may have dyspnea or pleuritic chest pain. Roentgenograms of the chest usually reveal bilateral patchy infiltrates (described as ovoid or lobar densities), lobar parenchymal infiltrates, and cavitary lesions. Pleural effusions may have a predominance of mononuclear cells.
leukocytes or PMNs and sometimes red blood cells. Empyema may be caused by influenza virus A and B, parainfluenza virus, respiratory syncytial virus, adenovirus, enteroviruses, hantavirus.

Adenovirus, enteroviruses, parainfluenza virus, influenza virus A and B, respiratory syncytial virus.

The typhoidal presentation is now considered rare. Typhoidal Tularemia

F. tularensis may develop prostration and shock. If presumptive antibiotic therapy is used, a wide variety of antibiotics, including all β-lactam antibiotics and the newer cephalosporins, are ineffective for the treatment of this infection. Several studies indicated that third-generation cephalosporins were active against F. tularensis in vitro, but clinical case reports suggested a nearly universal failure rate of ceftriaxone in pediatric patients with tularemia. Although in vitro data indicate that imipenem may be active, therapy with imipenem, sulfanilamides, and macrolides is presently recommended because of the lack of relevant clinical data. Fluoroquinolones have shown promise in terms of their relatively low toxicity and their potential for oral administration. With intracellular activity, fluoroquinolones have been used for successful treatment of tularemia and are candidates for primary or alternative therapy, pending clinical trials. The use of these agents should also be considered.

**LABORATORY DIAGNOSIS**  Direct microscopic examination of polychromatically stained tissue smears or clinical specimens reveals F. tularensis organisms, singly and in groups, both intra- and extracellularly. Gram’s staining of clinical or biopsy material is of little value, as the small, weakly staining organisms cannot be readily distinguished from the background. An indirect fluorescent antibody test with commercially available antisera can be useful, although false-positive results due to Legionella spp. have been reported.

The diagnosis of tularemia is most frequently confirmed by serologic testing. In the standard tube agglutination test, a single titer of ≥1:160 is interpreted as a presumptive positive result. A fourfold increase in titer between paired serum samples collected 2 to 3 weeks apart is considered diagnostic. False-negative serologic responses are obtained early in infection; up to 30% of patients infected for 3 weeks have sera that test negative. Late in infection, titers into the thousands are common, and titers of 1:20 to 1:80 may persist for years. A microagglutination test that may be as much as 100-fold more sensitive than the standard tube agglutination test has been described and is currently being used in many clinical microbiology laboratories. Enzyme-linked immunosorbent assays have proved useful for the detection of both antibodies and antigens. Analysis of urine for F. tularensis antigen has yielded promising results in clinical trials, but facilities for this type of analysis are not widely available. A skin test for delayed hypersensitivity to F. tularensis turns positive during the first week of illness and remains positive for years. The skin-test antigen, which is not commercially available, can boost titers of agglutinating antibody.

Culture and isolation of F. tularensis are difficult. In one study the organism was isolated in only 10% of more than 1000 human cases, 84% of which were confirmed by serology. The medium of choice is cysteine-glucose-blood agar. F. tularensis can be isolated directly from infected ulcer scrapings, lymph-node biopsy specimens, gastric washings, sputum, and blood cultures. Colonies are blue-gray, round, smooth, and slightly mucoid. On media containing blood, a small zone of α hemolysis usually surrounds the colony. Slide agglutination tests or direct fluorescent antibody tests with commercially available antisera can be applied directly to culture suspensions for identification.

The polymerase chain reaction (PCR) has been used to detect F. tularensis DNA in multiple clinical specimens. During one outbreak, a multiplex PCR was used to target 16S rRNA and to diagnose ulceroglandular tularemia with DNA extracted from wound swabs; the PCR result was positive in 29 (73%) of 40 serologically confirmed cases. However, this test has not been shown to be more sensitive than direct culture and at present remains a research tool.

**TREATMENT**  F. tularensis cannot be subjected to standardized antimicrobial susceptibility testing because the organism will not grow on the media used. A wide variety of antibiotics, including all β-lactam antibiotics and the newer cephalosporins, are ineffective for the treatment of this infection. Several studies indicated that third-generation cephalosporins were active against F. tularensis in vitro, but clinical case reports suggested a nearly universal failure rate of ceftriaxone in pediatric patients with tularemia. Although in vitro data indicate that imipenem may be active, therapy with imipenem, sulfanilamides, and macrolides is presently recommended because of the lack of relevant clinical data. Fluoroquinolones have shown promise in terms of their relatively low toxicity and their potential for oral administration. With intracellular activity, fluoroquinolones have been used for successful treatment of tularemia and are candidates for primary or alternative therapy, pending clinical trials. The use of these agents should also be considered.
Etiologic Agent

**Important Potential Agent of Biological Terrorism**

If tularemia goes untreated, symptoms usually last 1 to 4 weeks. Delayed defervescence may be delayed. Relapses are uncommon with streptomycin or gentamicin therapy. Late lymph-node suppuration, however, occurs in 40% of children, regardless of the treatment received. These nodes have typically been found to contain sterile necrotic tissue without evidence of active infection. Patients with fluctuant nodes should receive several days of antibiotic therapy before drainage to minimize the risk to hospital personnel. Unlike streptomycin and gentamicin, tobramycin is ineffective in the treatment of tularemia, a 5- to 7-day course has been successful.

Gentamicin, at a dose of 1.7 mg/kg given intravenously or intramuscularly every 8 h, is also effective and may be more readily available. The published experience in adults consists of two reports describing, respectively, nine and eight patients who were treated effectively with gentamicin. The eight patients in one of the reports all had fever before treatment, and all eight became afebrile within 24 to 72 h. In a pediatric study, other symptoms, such as tender lymphadenitis and pharyngitis, also responded within 24 to 72 h of the start of gentamicin therapy.

Virtually all strains of *F. tularensis* are susceptible to streptomycin and gentamicin. In successfully treated patients, defervescence usually occurs within 2 days, but skin lesions and lymph nodes may take 1 to 2 weeks to heal. When therapy is not initiated within the first several days of illness, defervescence may be delayed. Relapses are uncommon with streptomycin or gentamicin therapy. Late lymph-node suppuration, however, occurs in 40% of children, regardless of the treatment received. These nodes have typically been found to contain sterile necrotic tissue without evidence of active infection. Patients with fluctuant nodes should receive several days of antibiotic therapy before drainage to minimize the risk to hospital personnel. Unlike streptomycin and gentamicin, tobramycin is ineffective in the treatment of tularemia and should not be used.

**Prognosis**

If tularemia goes untreated, symptoms usually last 1 to 4 weeks but may continue for months. The mortality rate from severe untreated infection (including all cases of untreated tularemia pneumonia and typhoidal tularemia) can be as high as 30%. However, the overall mortality rate for untreated tularemia is <3%. Mortality is <1% with appropriate treatment. Poor outcomes are often associated with long delays in diagnosis and treatment. Lifelong immunity usually follows tularemia.

**Prevention**

The prevention of tularemia is based on avoidance of exposure to biting and blood-sucking insects, especially ticks and deerflies. An intradermal vaccine made from live attenuated *F. tularensis* is available from the Centers for Disease Control and Prevention. This vaccine is effective in reducing the frequency and severity of infection. Vaccination of high-risk individuals working with large quantities of cultured organisms is recommended. Others who come into contact with the organisms, such as veterinarians, hunters, or game wardens, should consider vaccination, particularly if they live in endemic areas. The avoidance of skinning wild animals, especially rabbits, and the wearing of gloves while handling animal carcasses decrease the risk of transmission. Use of insect repellents and preparations that prevent tick attachment as well as prompt removal of ticks can be helpful. Prophylaxis of tularemia has not proved effective in patients with embedded ticks or insect bites. However, in patients who are known to have been exposed to large quantities of organisms (e.g., in the laboratory) and who have incubating infection with *F. tularensis*, early treatment can prevent the development of significant clinical disease.

**Further Reading**

143 Plague and Other Yersinia Infections

**Plague**

**Definition**

Plague is an acute, febrile, zoonotic disease caused by infection with *Yersinia pestis*. Although human cases are infrequent and are curable with antibiotics, plague is one of the most virulent and potentially lethal bacterial diseases known. The plague bacterium occurs in widely scattered foci in Asia, Africa, and the Americas, where its usual hosts are various wild rodents and human-associated rats. Infection is transmitted to humans typically by flea bite and less commonly by direct contact with infected animal tissues or by airborne droplet. The principal clinical forms of plague are bubonic, septicemic, and pneumatic. Although most cases are now sporadic, occurring singly or in small clusters, the potential for outbreaks and epidemic spread remains. Because of its virulence and transmissibility, *Y. pestis* is considered an important potential agent of biological terrorism that requires special countermeasures to protect the public’s health (Chap. 205).

**Etiologic Agent**

*Y. pestis* is a gram-negative coccobacillus in the family Enterobacteriaceae. Genomic analysis suggests that it has recently evolved from *Y. pseudotuberculosis*. *Y. pestis* is microaerophilic, non-motile, non-spore-forming, oxidase and urease negative, and biochemically unreactive. The organism is nonfastidious and infective for laboratory rodents. It grows well, if slowly, on routinely used microbiologic media (e.g., sheep blood agar, brain-heart infusion broth, and MacConkey agar). *Y. pestis* can multiply within a wide range of temperatures (−2°C to 45°C) and pH values (5.0 to 9.6), but optimal growth occurs at 28°C and at pH 7.4. When stained with a polychromatous stain (e.g., Wayson or Giemsa), *Y. pestis* isolated from clinical specimens exhibits a characteristic bipolar appearance, resembling closed safety pins. The bacterium is nonencapsulated but when grown at ≥30°C produces a plasmid-expressed envelope glycoprotein, fraction I (F1) antigen—a virulence factor that serves as the principal immunodiagnostic marker of infection.

**Historic Background**

Plague’s deadly epidemic potential is notorious and well documented. The Justinian pandemic (542 to 767 A.D.) spread from central Africa to the Mediterranean littoral and thence to Asia Minor, causing an estimated 40 million deaths. The second pan-
demic began in central Asia, was carried to Sicily by ship from Constantinople in 1347, and within a few years spread through Europe and the British Isles; successive epidemics of lesser magnitude occurred over the next four centuries. At its height, the second plague pandemic killed as many as a quarter of the affected population and became known as the Black Death. In the third (modern) pandemic, plague appeared in Yunnan, China, in the latter half of the nineteenth century; established itself in Hong Kong in 1894; and spread by ship to Bombay in 1896 and subsequently to major port cities throughout the world, including San Francisco and several other West Coast and Gulf Coast ports in the United States. The plague bacillus was first cultured by Alexandre Yersin in Hong Kong in 1894. In 1898, Paul-Louis Simond, a French scientist sent to investigate epidemic bubonic plague in Bombay, identified the bacillus in the tissues of dead rats and proposed transmission by rat fleas. Waldemar Haffkine, also in Bombay at that time, developed a crude vaccine.

By 1910, plague had circled the globe and was established in rodent populations on all inhabited continents other than Australia. After 1920, however, the spread of plague was largely halted by international regulations that mandated control of rats in harbors and inspection and rat-proofing of ships. Before subsiding, the third pandemic had resulted in an estimated 26 million plague cases and >12 million deaths, the vast majority in India. By 1950, plague outbreaks around the world had become isolated, sporadic, and manageable with modern techniques of surveillance, flea and rat control, and antimicrobial treatment of patients. Plague has nearly disappeared from cities and now occurs mostly in rural and semirural areas, where it is maintained in various rodents and their fleas. In the United States, the last outbreak of urban plague occurred in Los Angeles in 1924 and 1925, and human cases since then have, with very few exceptions, resulted from exposures in rural areas of western states.

Plague remains one of three quarantinable diseases subject to international health regulations (the other two being cholera and yellow fever). The alarm that plague is still able to evoke was highlighted by the public panic and exaggerated official responses to reported outbreaks of bubonic and pneumonic plague in India in 1994. The plague bacillus is considered to have a high potential for use in biological terrorism; the agent is available around the world, has been “weaponized” for airborne delivery, and would be expected to cause a high primary fatality rate as well as secondary spread among an affected population (Chap. 205).

**Epidemiology** 

*Y. pestis* is maintained in well-established “silent” enzootic cycles involving relatively resistant wild rodents and their fleas in remote, lightly populated areas of Asia, Africa, and the Americas and in limited rural foci in extreme southeastern Europe near the Caspian Sea. Humans and mammals other than rodents are incidental hosts. Outbreaks (epizootics) of plague in susceptible rodent populations may result in widespread die-offs of these animals, an avian search by their fleas for new hosts, and an increased risk of spread of infection to humans. In the United States, the principal epizootic hosts are various ground squirrels, prairie dogs, and chipmunks; a variety of burrowing rodents act as epizootic hosts in rural areas elsewhere in the world. *Y. pestis* occasionally spills over from wild rodents to rat species that inhabit cultivated fields and adjacent homes, villages, and towns. The organism can then be transported from towns to cities by these highly adaptable rats and their fleas.

Plague in populated areas is most likely to develop when sanitation is poor and rats are numerous—especially the common black or roof rat (*Rattus rattus*), its close relatives, and the larger brown sewer or Norway rat (*R. norvegicus*). The cosmopolitan oriental rat flea *Xenopsylla cheopis* and (in southern Africa and Brazil) the related species *X. brasilienensis* are efficient vectors of the plague bacillus from rat to rat and from rats to humans. *Y. pestis* multiplies to enormous numbers, in the foregut (proventriculus) of these fleas, resulting in a bolus of organisms and clotted blood that blocks the passage of subsequent blood meals. This situation occurs only at temperatures of $\leq 28^\circ C$ and depends on a single protease expressed by the plasminogen activator (plg) gene of a 9.5-kb plasmid of *Y. pestis*. Regurgitation by a “blocked” flea while it feeds facilitates transmission of the plague bacillus to the new host. Except for large outbreaks of pneumonic plague in Manchuria in the early part of the twentieth century, person-to-person respiratory transmission of plague has since occurred only sporadically and has been limited to clusters of close, direct contacts of pneumonic plague patients, such as household members and caregivers.

International health regulations require that national authorities immediately report plague cases to the World Health Organization. From 1987 through 2001, 36,876 human plague cases (mean, 2458 cases per year) and 2847 deaths (mortality, 8%) were reported by 24 countries. In the same 15-year period, the United States reported 125 cases and 12 deaths (mortality, 10%). Cases reported by the United States are confirmed by the plague laboratory of the Centers for Disease Control and Prevention (CDC). Animal plague occurs in 17 contiguous western states, extending from the Great Plains states and eastern Texas to the Pacific Coast; around 80% of human cases in this country now occur in New Mexico, Arizona, and Colorado and around 10% in California. The arid Native American reservations of New Mexico and Arizona are active plague foci, and Native Americans account for a disproportionately high percentage of plague cases in the United States. Although plague is a rural disease in this country, >50% of cases are thought to be caused by peridomestic exposures, especially in the southwestern states, where homes are often situated in natural surroundings that provide a favorable habitat for plague-susceptible animals (such as rock squirrels and wood rats) and their fleas. In the Sierra Nevadas of California and Nevada, epizootic plague in chipmunks and ground squirrels poses a risk to visitors in public parks. Hikers, campers, and hunters in natural areas throughout the western states are at a small but finite risk of exposure to plague, especially in the summer months.

Plague can be transmitted during the skinning and handling of carcasses of wild animals such as rabbits and hares, prairie dogs, wildcats, and coyotes. Such direct inoculation of mammal-adapted organisms expressing the F1 antigen is associated with primary septicemia and high mortality. Pharyngeal plague can result from the ingestion of undercooked contaminated meat, from inhaling respiratory droplets, and perhaps from the manual transfer of infected fluids to the mouth during the handling of infected animal tissues.

Carnivores, including dogs and cats, can become infected with *Y. pestis* by eating infected rodents and possibly by being bitten by infective fleas. Although clinical plague commonly develops in infected cats, it rarely does so in infected dogs. Both dogs and cats may transport infected fleas from rodent-infested areas to the home environment.

From 1947 through 2001, 421 plague cases were reported in the United States. Of the 409 evaluable cases, 349 cases (85%) presented as primary lymphadenitic (bubonic) plague, almost all of them thought to be associated with flea bites; 55 cases (13%) presented as primary septicemic plague, many of them following direct animal exposures; and 8 cases (2%) presented as primary pneumonic plague, 6 resulting from the inhalation of respiratory droplets released by infected cats and 2 from unknown sources. The last case of human-to-human plague transmission in the United States occurred in Los Angeles in 1924.

**Pathogenesis and Pathology** 

*Y. pestis* is highly invasive and pathogenic. The mechanisms by which the organism causes disease are incompletely understood, but both chromosome- and plasmid-encoded gene products as well as altered cell-mediated immune responses are involved. Three plasmids encode for a variety of known or presumed virulence factors; these include the F1 envelope antigen and various *Yersinia* outer-membrane proteins (*Yops*), which confer bacterial resistance to phagocytosis; the V antigen, which is essential for virulence and immunocompromises the host by suppressing the synthesis of various proinflammatory cytokines (e.g., interferon $\gamma$ and tumor necrosis factor $\alpha$); pesticin, which interferes with iron uptake; a protease that...
activates plasminogen and degrades serum complement and is thought to enhance dissemination of *Y. pestis* following inoculation of the skin; a coagulase; and a fibrinolysin. A chromosomally encoded lipopoly-
saccharide endotoxin is important in sepsis, triggering the systemic inflammation response syndrome and its complications.

*Y. pestis* organisms inoculated through the skin or mucous membranes are typically carried to regional lymph nodes via lymphatic channels, although direct bloodstream inoculation and dissemination may take place. Mononuclear phagocytes, which can phagocytize *Y. pestis* organisms without destroying them, may play a role in dissemination of the infection to distant sites. Plague can involve almost any organ, and untreated plague generally results in widespread and massive tissue destruction. In the early stages, infected lymph nodes (buboes, Fig. 143-1) are characterized by edema and congestion without inflammatory infiltrates or apparent vascular injury. Fully developed buboes contain huge numbers of infectious plague organisms and show distorted or obliterated lymph node architecture with loss of vascular integrity, hemorrhage, necrosis, infiltration of polymorphonuclear neutrophils (PMNs), and extensive serosanguineous effusion. The effusion typically involves perinodal tissues. If several adjacent lymph nodes are involved, a boggy edematous mass can result.

Primary septicemic plague consists of sepsis in the absence of a bubo; secondary septicemic plague is a complication of bubonic or pneumatic plague that occurs when local host defenses are breached. In fatal septicemic plague, multifocal hepatic and splenic necrosis is common. Diffuse interstitial myocarditis with cardiac dilatation is sometimes found. If disseminated intravascular coagulation (DIC) ensues, vascular necrosis may lead to widespread cutaneous, mucosal, and serosal ecchymoses and petechiae. Acral ischemia and resulting gangrene sometimes develop.

Primary plague pneumonia generally begins as a lobular process and then extends by confluence, becoming lobar and then multilobar (Fig. 143-2). Plague organisms are typically most numerous in the alveoli. Secondary plague pneumonia begins more diffusely, with organisms at first most numerous in the interstitium. In advanced cases of both primary and secondary plague pneumonia, affected lung tissue is characterized by edema, hemorrhagic necrosis, and infiltration by neutrophilic leukocytes.

**MANIFESTATIONS** Plague is characterized by a rapid onset of fever and other systemic manifestations of gram-negative bacterial infection. If it is not quickly and correctly treated, plague can follow a toxic course, resulting in shock, multiple-organ failure, and death. In humans, the three principal forms of plague are bubonic, septicemic, and pneumatic. Bubonic plague, the most common form, is almost always caused by the bite of an infected flea but occasionally results from direct contact with infectious materials. Septicemic and pneumonic plague can be either primary or secondary to metastatic spread. Unusual forms include plague meningitis, endophthalmitis, and lymphadenitis at multiple sites. Primary plague pharyngitis has been documented by culture of organisms from throat swabs and can result from respiratory exposure or ingestion of undercooked flesh of infected animals.

**Bubonic Plague** Bubonic plague has a usual incubation period of 2 to 6 days. Patients experience chills; fever, with temperatures that rise within hours to ≥38°C; myalgias; arthralgias; headache; and a feeling of weakness. Soon—usually within 24 h—the patient notices tenderness and pain in one or more regional lymph nodes proximal to the site of inoculation of the plague bacillus (Fig. 143-1). Because fleas most often bite the legs, femoral and inguinal nodes are most commonly involved; axillary and cervical nodes are next most commonly affected. Within hours, the enlarging bubo becomes progressively painful and tender, sometimes exquisitely so. The patient usually guards against palpation and limits movement, pressure, and stretch around the bubo. The surrounding tissue often becomes edematous, sometimes markedly so, and the overlying skin may be erythematous, warm, and tense. Inspection of the skin surrounding or distal to the bubo sometimes reveals the site of a flea bite marked by a papule, pustule, or ulcer. The ulcer may be covered by an eschar (Fig. 143-1).

A list of lymphadenitic conditions that could be confused with bubonic plague includes *Staphylococcus aureus* and group A β-hemolytic streptococcal infections, cat-scratch disease, tularemia, and—in filariasis endemic areas—acute filarial lymphadenitis. The bubo of plague

**FIGURE 143-1** Plague patient in the southwestern United States with a left axillary bubo and an unusual plague ulcer and eschar at the site of the infective flea bite.

**FIGURE 143-2** Sequential chest radiographs of a patient with fatal primary plague pneumonia. *Left:* Upright posteroanterior film taken at admission to hospital emergency department on third day of illness, showing segmental consolidation of right upper lobe. *Center:* Portable anteroposterior film taken 6 h after admission, showing extension of pneumonia to right middle and right lower lobes. *Right:* Portable anteroposterior film taken 13 h after admission (when patient had clinical adult respiratory distress syndrome), showing diffuse infiltration throughout right lung and patchy infiltration of left lower lung. A cavity later developed at the site of initial right-upper-lobe consolidation.
is distinguishable from lymphadenitis of most other causes, however, by its rapid onset, its extreme tenderness, the accompanying signs of toxemia, and the absence of cellulitis or obvious ascending lymphangitis. The pain and swelling of bubonic plague can be confused with a strangulated hernia or trauma.

Treated in the uncomplicated state with an appropriate antibiotic, bubonic plague usually responds quickly, with resolution of fever and alleviation of other systemic manifestations over 2 to 5 days. Buboes often remain enlarged and tender for a week or more after the initiation of treatment and can become fluctuant. Without effective antimicrobial treatment, patients with typical bubonic plague manifest an increasingly toxic state of fever, tachycardia, lethargy leading to prostration, agitation and confusion, and (occasionally) convulsions and delirium. Secondary plague sepsis may result in an alarmingly rapid and refractory cascade of DIC, bleeding, shock, and organ failure. Mild forms of bubonic plague, called *pestis minor*, have been described in South America and other plague endemic areas; in these cases, the patients are ambulatory, are only mildly febrile, and have subacute buboes.

**Septicemic Plague**  Septicemic plague is a progressive, overwhelming gram-negative infection. Primary sepsicemia develops in the absence of a bubo, and the diagnosis is often not suspected until preliminary blood culture results are reported to be positive by the laboratory. *Y. pestis*, however, can also be cultured from the blood of most bubonic plague patients, and bacteremia should be distinguished from sepsicemia, in which the patient is desperately ill and requires aggressive care. Septic patients often present with gastrointestinal symptoms of nausea, vomiting, diarrhea, and abdominal pain, which may further confound the correct diagnosis. If not treated early with appropriate antibiotics, septicemic plague can be fulminant and fatal. In the United States in 1947 through 2001, 55 cases of primary septicemic plague with 13 deaths were reported, for a case-fatality rate of 24%. Petechiae, ecchymoses, bleeding from puncture wounds and orifices, and gangrene of acral parts are manifestations of DIC; refractory hypotension, renal shutdown, obtundation, and other signs of shock are prerterminal events. Adult respiratory distress syndrome (ARDS), which can occur at any stage of septicemic plague, is sometimes confused with other conditions, such as hantavirus pulmonary syndrome. The differential diagnosis of septicemic plague includes sepsis of other gram-negative bacterial etiology, meningococcemia, and acute severe viral infections such as hantavirus illness.

**Pneumonic Plague**  Of all forms of the disease, pneumatic plague develops most rapidly and is most frequently fatal. The incubation period for primary pneumonic plague is usually 3 to 5 days (range, 1 to 7 days). The onset is most often sudden, with chills, fever, headache, myalgias, weakness, and dizziness. Pulmonary signs, including tachypnea and dyspnea, cough, sputum production, and chest pain, typically arise on the second day of illness and may be accompanied by hemoptyis, increasing respiratory distress, cardiopulmonary insufficiency, and circulatory collapse. In primary plague pneumonia, the sputum is often watery or mucoid, frothy, and blood-tined, but it may become frankly bloody. Pulmonary signs in primary pneumonic plague may indicate involvement of a single lobe in the early stage, with rapidly developing segmental consolidation before bronchopneumonic spread to other lobes of the same and opposite lungs (Fig. 143-2). Liquefaction necrosis and cavitation may occur early in areas of consolidation and may or may not leave significant residual scarring.

Secondary plague pneumonia, which occurs in 10 to 15% of bubonic plague cases in the United States, typically manifests first as a diffuse interstitial pneumonitis in which sputum production is scant; since the sputum is more likely to be inspissated and tenacious in character than the sputum found in primary pneumonitis, it may be less infectious. In the United States in 1947 through 2001, 46 cases of secondary pneumonic plague and 8 cases of primary pneumonic plague were described, with no known transmission to contacts and an overall case-fatality rate of 41%. Observers in the early twentieth century remarked on the relative lack of auscultatory findings, the usual presence of toxemia, and the frequency of sudden death among patients with pneumonic plague as compared to patients with other bacterial pneumonias.

The differential diagnosis of pneumonic plague includes acute community-acquired pneumonia of another bacterial or a viral etiology, tularemia, coccidioidomycosis, *Pneumocystis* pneumonia, and Q fever.

**Plague Meningitis**  Meningitis is an unusual manifestation of plague. In the United States, there were 17 meningitis cases among the 409 evaluable plague cases reported in 1947 through 2001. All cases of meningitis were complications of bubonic plague, and all but three patients survived. Although meningitis may be a part of the initial presentation of plague, its onset is often delayed and is a manifestation of insufficient treatment. Recent cases in the United States have occurred in association with treatment of bubonic plague with tetracyclines, which are bacteriostatic against *Y. pestis*. Chronic relapsing meningeal plague over periods of weeks or even months was described in the preantibiotic era. The affected patients typically present with fever, headache, meninigismus, and neutrophilic pleocytosis.

**Plague Pharyngitis**  Plague pharyngitis presents as fever, sore throat, cervical lymphadenitis, and headache and is often indistinguishable clinically from pharyngitis and tonsillitis of other infectious etiologies, especially streptococcal pharyngitis. Plague pharyngitis can be difficult to distinguish from cervical bubonic plague arising from an infective flea bite on the head and neck region. Caregivers working in endemic areas must be alert to plague in the differential diagnosis of pharyngitis to avoid delayed and/or inappropriate treatment.

**LABORATORY FINDINGS AND DIAGNOSIS**  Since plague is a rare disease in the United States, a high index of clinical suspicion as well as the elicitation of a thorough clinical and epidemiologic history and a careful physical examination are required for timely diagnosis and prompt institution of specific therapy. When the diagnosis of plague is delayed or missed altogether, a high case-fatality rate results; infected travelers who seek medical care after they have left endemic areas (periapatic plague cases) are at especially high risk. Plague must be considered in the differential diagnosis of acute regional lymphadenitis, sepsis, or acute severe pneumonia in an otherwise healthy person who has a history of recent travel to or residence in the rural western United States. When the diagnosis of plague is being considered, close communication between clinicians and the diagnostic laboratory and between the diagnostic laboratory and a qualified reference laboratory is essential. Tests for plague are highly reliable when conducted by laboratory personnel experienced with *Y. pestis*, but such expertise is usually limited to selected reference laboratories, including state health department laboratories in some plague-endemic states and the CDC plague laboratory (Fort Collins, Colorado; tel. 970-221-6400).

When plague is suspected, specimens should be collected promptly for laboratory studies, chest roentgenograms should be obtained, and specific antimicrobial therapy should be initiated pending confirmation. Appropriate diagnostic specimens for smear and culture include citrated or heparinized whole blood from all patients with suspected plague; lymph node aspirates from those with suspected buboes; sputum samples, pharyngeal swabs, and tracheal or pulmonary alveolar aspirates from those with suspected pneumonic plague; and cerebrospinal fluid (CSF) from those with suspected plague meningitis. Since early buboes are often exquisitely tender and are seldom fluctuant or necrotic, these lesions usually require aspiration under local anesthesia following the injection of 1 to 2 mL of normal saline (sterile but nonbacteriostatic) into the bubo with a 20- to 22-gauge needle. Typically, aspiration produces a scant amount of serosanguineous fluid. A variety of appropriate culture media (including brain-heart infusion broth, sheep blood agar, and MacConkey agar) should be inoculated with a portion of each specimen. Moreover, for each specimen, at least one smear should be examined immediately with Wayson or Giemsa stain and at least one with Gram’s stain; a smear should also be submitted to a reference laboratory for direct fluorescent antibody testing, anti-
gen-capture enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR) analysis, or testing by another rapid detection method (e.g., immunochromatographic hand-held assay). An acute-phase serum specimen should be tested for antibody to *Y. pestis*; whenever possible, a convalescent-phase serum specimen collected 3 to 4 weeks later should also be tested. When a patient dies and plague is suspected, appropriate autopsy tissues for culture, direct fluorescent antibody testing, and immunohistochemical staining include buboes, all solid organs (especially liver, spleen, and lung), and bone marrow. If culture of such specimens is to be attempted, they should be sent to the laboratory either fresh or frozen on dry ice, not in preservatives or fixatives. If necessary, Cary-Blair or a similar medium can be used to transport *Y. pestis*-infected tissues.

Laboratory confirmation of plague depends on the isolation of *Y. pestis* from cultures of body fluids or tissues. Cultures of three blood samples taken over a 45-min period before treatment will usually result in isolation of the bacterium. *Y. pestis* strains are readily distinguished from those of the closely related species *Y. pseudotuberculosis* by differences in biochemical profile, temperature-dependent susceptibility to lysis by a *Y. pestis*-specific bacteriophage, and motility. Automated bacteriologic test systems can be used to assist in the identification of isolates as *Y. pestis*, but *Y. pestis* can be misidentified (e.g., as *Y. pseudotuberculosis*) or overlooked if these systems are improperly programmed.

In the absence of *Y. pestis* isolation, plague cases can be confirmed either by the demonstration of seroconversion (a fourfold or greater titer rise) to *Y. pestis* F1 antigen in passive hemagglutination tests of acute- and convalescent-phase serum specimens or by detection of an antibody titer of >128 in a single serum sample from a patient with a plague-compatible illness who has not received plague vaccine. The specificity of a positive passive-hemagglutination test requires confirmation with the F1 antigen hemagglutination-inhibition test. A few plague patients seroconvert to F1 antigen as early as 5 days after the onset of illness; most seroconvert between 1 and 2 weeks after onset; and a few (<5%) fail to seroconvert at all. Early, specific antibiotic treatment may delay seroconversion by several weeks. After seroconversion, positive serologic titers diminish gradually over months to years. ELISAs for IgM and IgG antibodies to *Y. pestis* are replacing hemagglutination tests in some laboratories. Other new test methods include those mentioned above; antigen-capture ELISAs, PCR, and immunochromatographic hand-held assays for rapid identification of *Y. pestis* in aspirates, sputum, and other infected body fluids or tissues. The hand-held assays can be used at the bedside in the remote rural settings where most plague cases occur and could prove important in responding to bioterrorism (Chap. 205).

Patients with plague typically have white blood cell (WBC) counts of 10,000 to 25,000/μL, with a predominance of PMNs and a left shift. Leukemoid reactions with WBC counts as high as 100,000/μL can occur. Modest thrombocytopenia is usually documented, and fibrinogen split products are often detected even in patients without frank DIC. Serum levels of aminotransferases and bilirubin may be elevated. In plague pneumonia, stained respiratory secretions usually contain PMNs and characteristic bipolar-staining bacilli. In *Y. pestis* septicemia, visualization of the characteristic bacilli in a routine blood smear or auffy-coat smear is an uncommon but grave prognostic sign (Fig. 143-3). In patients with plague meningitis, PMN pleocytosis is typical, and the bacilli are usually visible in stained CSF smears.

### Treatment

Left untreated, plague is fatal in >50% of cases of bubonic disease and in nearly all cases of septicemic and pneumatic disease. The overall mortality rate for plague cases in the United States since 1950 has been ~14%; deaths are almost always due to delays in seeking treatment, misdiagnosis, delays in the institution of treatment, or incorrect treatment. Rapid diagnosis and appropriate antimicrobial therapy are essential.

* Dosage should be reduced to 3 mg/kg daily as soon as clinically indicated.

* For meningitis, up to 100 (mg/kg)/d initially.
disorders require intensive monitoring and close physiologic support, as outlined elsewhere (Chaps. 102 and 251). Buboes may require surgical drainage. Abscessed nodes can cause recurrent fever in patients who have apparently recovered; the cause may be occult if intrathoracic or intraabdominal nodes are involved. Although \( Y. \) \( p. \) is considered to be genetically stable, a multidrug-resistant strain was recently isolated from a plague patient in Madagascar. This strain exhibited resistance (mediated by a transferable plasmid) to principal first-line antibiotics used for treatment and prophylaxis of plague.

**PREVENTION AND CONTROL** Persons at greatest risk for plague in the United States are individuals who live, work, and participate in outdoor recreational activities in areas of those western states in which plague is enzootic. Surveillance, education, and environmental management are the cornerstones of prevention and control. A network of biologists and public health specialists coordinates these activities through local and state health departments and the CDC. Personal protective measures include the avoidance of areas with known epizootic plague (in which warning signs may be posted) and of sick or dead animals; the use of repellents, insecticides, and protective clothing when at risk of exposure to rodents’ fleas; and the wearing of gloves when handling animal carcasses. Short-term antibiotic prophylaxis (Table 143-2) is recommended for persons known to have had close contact with a patient with suspected or confirmed pneumonic plague and occasionally for persons who are unable to avoid an area where a plague outbreak is in progress or who may be caring for patients with plague. Patients in whom respiratory plague is suspected should be managed under isolation, with use of respiratory-droplet precautions until pneumonia has been ruled out or until 48 h of effective antimicrobial therapy has been administered, after which standard infection-control precautions are adequate. Masks are considered to be protective against respiratory transmission of plague and would be expected to be an important tool to prevent secondary plague spread in the event of bioterrorism (Chap. 205).

Rodent food (garbage, pet food) and habitats (brush piles, junk heaps, woodpiles) should be eliminated in domestic, peridomestic, and working environments; buildings and food stores should be rodent-proofed. The control of fleas with insecticides is a key public health measure in situations where epizootic plague activity places humans at high risk; this effort includes dusting and spraying of rodent burrows, rodent runs, and other sites where rodents and their fleas are found. In plague-endemic areas of the western United States, persons should keep their dogs and cats free of fleas and restrained. The decision to control plague by killing rodents should be left to public health authorities, and such a program should be carried out only in conjunction with effective flea control. Killing of rodents has no lasting benefit without environmental sanitation.

\( m \) Recommended as an alternative to doxycycline in bioterrorism-response plans.

The previously used killed, whole-cell plague vaccine is no longer available in the United States. New and improved vaccines are being evaluated that use recombinant F1 and V antigens to induce protective antibodies. In the United States, the indications for use of these newer vaccines would probably be similar to those for the previously available killed vaccine, which was mostly limited to protecting laboratory personnel who routinely worked with \( Y. \) \( p. \) and some persons whose vocations brought them into regular contact with wild rodents and their fleas in areas with enzootic or epizootic plague. In addition, a vaccine might be useful in protecting selected persons at risk from biowarfare or bioterrorism.

**OTHER YERSINIA INFECTIONS**

**DEFINITION** Yersiniosis is an uncommon bacterial zoonosis caused primarily by infection with either of two enteropathogenic *Yersinia* species: \( Y. \) enterocolitica or \( Y. \) pseudotuberculosis. Reservoir hosts of these bacteria include swine and other wild and domestic animals, and transmission to humans is predominantly via the oral route. Both sporadic cases and common-source outbreaks occur. The most frequent acute clinical manifestations are (1) enteritis or enterocolitis with self-limited diarrhea (especially with \( Y. \) enterocolitica) and (2) mesenteric adenitis and terminal ileitis (especially with \( Y. \) pseudotuberculosis), which can be confused with acute appendicitis. Septicemia and metastatic focal infections are less common. Yersiniosis can be complicated by nonsuppurative, extraintestinal, inflammatory sequelae — e.g., reactive arthritis (Chap. 305) and erythema nodosum (Chap. 17). Other nonplague *Yersinia* species, including \( Y. \) intermedia, \( Y. \) frederiksenii, and \( Y. \) kristensenii, have been associated with enteritis or enterocolitis in humans (particularly immunocompromised adults), but little is known about their pathogenicity, public health importance, or clinical management.

**ETIOLOGIC AGENTS** \( Y. \) enterocolitica and \( Y. \) pseudotuberculosis are pleomorphic gram-negative bacilli in the family Enterobacteriaceae. They can multiply within a wide temperature range (−1°C to 45°C). Pathogenic \( Y. \) enterocolitica isolates are most commonly identified by biotyping based on biochemical profiles and serotyping according to somatic O and H antigens. Six biotypes and >60 serotypes of \( Y. \) enterocolitica are recognized. A separate serotyping system for \( Y. \) pseudotuberculosis (also based on somatic antigens) has distinguished six major serotypes (I through VI) and their subtypes.

**EPIDEMOLOGY** *Yersinia enterocolitica* \( Y. \) enterocolitica is distributed worldwide and has been isolated from soil, fresh water, contaminated foodstuffs (e.g., meat, milk, and vegetables), and a wide variety of wild and domestic animals. Many serotypes isolated from environmental sources, however, evidently are not human pathogens. Most human infections have been caused by \( Y. \) enterocolitica serotypes O:3, O:5,7,9, O:8, and O:9, which are primarily associated with wild and domestic mammals. The recognized incidence of these infections and their sequelae is highest in Scandinavia and some other northern European countries, but reliable population-based estimates of incidence are unavailable.

All age groups are susceptible to \( Y. \) enterocolitica infections, but the majority of cases of enterocolitis are in children aged 1 to 4. Moreover, these infections show a modest predilection for males. Mesenteric adenitis and terminal ileitis are most common among older children and young adults. Risk factors for \( Y. \) enterocolitica septicemia and metastatic focal infections include chronic liver disease, malignancy, diabetes mellitus, immunosuppressive therapy, alcoholism, malnutrition, advanced age, iron overload (see below), and hemolytic anemias (including the thalassemias). The nonsuppurative sequelae of yersiniosis are most common among adults. HLA-B27 is expressed in 70 to 80% of patients who develop reactive arthritis associated with yersiniosis. HLA-B27 is not a risk factor for *Yersinia*-induced erythema nodosum; females with this condition outnumber males by 2 to 1.

Among \( Y. \) enterocolitica strains isolated from patients in recent decades, serotypes O:3 and O:9 have predominated in Europe, while
serotype O:3 has predominated in Canada, Japan, and the United States. The apparent incidence of *Yersinia*-induced nonsuppurative sequelae reportedly is 10 to 30% in Scandinavia and much lower in most other countries, including the United States.

Common-source outbreaks of *Y. enterocolitica* enteritis have been traced to such vehicles as raw milk, contaminated pasteurized milk, and foods prepared with contaminated fresh water. Because *Y. enterocolitica* commonly colonizes the gastrointestinal tracts of swine, sporadic human cases and outbreaks of yersiniosis have also been associated with the preparation or ingestion of raw pork products (e.g., pâté). In some cases of yersiniosis, epidemiological evidence suggests transmission via contact with dogs and cats or their feces. Several nosocomial outbreaks of *Y. enterocolitica* infection have been described. Fecal-oral transmission from person to person is likely, but frank suppuration is sometimes evident. Fecal-oral transmission among family members may also explain occasional secondary cases in households. In a prospective study of 50 children with *Y. enterocolitica* enteritis, fecal excretion of the organism persisted for an average of 27 days (range, 4 to 79 days) after the cessation of symptoms. A chronic carrier state, however, has not been demonstrated. *Y. enterocolitica* is a rare but often lethal cause of transfusion-associated septicemia. The explanation is that blood donors occasionally have transient, occult *Y. enterocolitica* bacteremia and that this organism can slowly multiply to high concentrations in blood refrigerated for at least 10 days.

**Yersinia pseudotuberculosis** The ecology of *Y. pseudotuberculosis* seems to parallel that of *Y. enterocolitica* closely. *Y. pseudotuberculosis* is also widespread in wild and domestic animals and is isolated from many environmental sources. Human infections with *Y. pseudotuberculosis*, however, appear to be rare. Swine appear to be an important reservoir for pathogenic strains of *Y. pseudotuberculosis*.

**PATHOGENESIS AND PATHOLOGY** With rare exceptions (e.g., transmission via contaminated blood products or direct cutaneous inoculation), the enteropathogenic yersiniae are thought to enter the host via the oral route. The incubation period averages 5 days (range, 1 to 11 days). Studies of animals have shown that the organisms initially invade the ileal epithelium, then are translocated via M cells into the lamina propria, and finally enter Peyer’s patches, where they are able to replicate. They subsequently drain into the mesenteric lymph nodes, which undergo hyperplasia and from which the bacteria can be disseminated. The mesenteric lymph nodes can become intensely swollen and matted and are occasionally detected on physical examination as a tender right-lower-quadrant mass. Intestinal inflammation (most commonly of the distal ileum and less commonly of the ascending colon) develops and may be accompanied by mucosal ulcerations and by the shedding of PMNs and red blood cells into the intestinal lumen. In relatively severe cases, thrombosis of mesenteric blood vessels, intestinal hemorrhage, and necrosis can occur. In patients with enteropathogenic yersinial infections who undergo exploratory laparotomy, the appendix is sometimes involved. The syndrome of mesenteric adenitis and terminal ileitis, the most common presentation of *Y. pseudotuberculosis* infection, appears to be an important reservoir for pathogenic strains of *Y. pseudotuberculosis*.

**MANIFESTATIONS** The clinical manifestations of *Y. enterocolitica* infection are enteritis, enterocolitis, mesenteric adenitis, and terminal ileitis. Less common manifestations include extraintestinal pathogeny, septicemia, metastatic focal infections, reactive polyarthritis, and erythema nodosum. When age groups are combined, the most common presentation of *Y. enterocolitica* infection is acute diarrhea from enteritis or enterocolitis. Low-grade fever and cramping abdominal pain occur in most cases, nausea and vomiting in 15 to 40%, hematochezia in up to 30%, and a generalized maculopapular skin rash in a few cases. Diarrhea persists for an average of 2 weeks (range, 1 day to many months), during which the frequency of bowel movements diminishes. Uncommonly, enteritis or enterocolitis can be complicated by severe abdominal pain and high fever. Rare (and sometimes fatal) complications include diffuse inflammation, ulceration, hemorrhage, and necrosis of the small bowel and colon; intestinal perforation; peritonitis; ascending cholangitis; mesenteric vein thrombosis; diverticulitis; toxic megacolon; and ileocecal intussusception.

The syndrome of mesenteric adenitis and terminal ileitis without diarrhea is easily confused with appendicitis. Low-grade fever and right-lower-quadrant pain, tenderness, guarding, and rebound tenderness are common. During six recognized common-source outbreaks in the United States, 10% of 444 patients with symptomatic undiagnosed *Y. enterocolitica* infections underwent laparotomy for suspected appendicitis; surgical incisions became infected with *Y. enterocolitica* in a few of these cases.

Acute pharyngitis and pharyngotonsillitis, with or without cervical adenitis or intestinal illness, are less common but potentially lethal manifestations of *Y. enterocolitica* infection, particularly in adults. *Y. enterocolitica* septicemia generally presents as a severe illness with fever and leukocytosis, often with abdominal pain and jaundice and without localized signs of infection. Metastatic focal *Y. enterocolitica* infections can occur with or without clinically apparent bacteremia and can affect almost any organ system. Examples include abscess formation (e.g., in liver, spleen, kidney, lung, skeletal muscle, lymph node, or cutaneous tissue), osteomyelitis, meningitis, peritonitis, uri-
nary tract infection, pneumonia, empyema, endocarditis, pericarditis, mycotic aneurysm, septic arthritis, suppurrative conjunctivitis, pan-opthalmitis, Parinaud’s oculoglandular syndrome, and cutaneous pustules or bullae.

In Scandinavia, the incidence of reactive arthritis following *Y. enterocolitica* infection among adults is estimated to be at least 10%. About 80% of these patients have preceding symptoms such as fever, diarrhea, or abdominal pain. Typically, these symptoms precede the arthritis by 1 week and are of short duration. The most commonly affected joints are the knees and ankles, but other joints can be involved. Typically, multiple (two to eight) joints become involved sequentially and asymmetrically over a period of a few days to 2 weeks, after which no additional joints are affected. Monarticular arthritis occurs less commonly. In two-thirds of cases, the acute arthritis remits spontaneously within 1 to 3 months. Chronic joint disease is documented in a minority of cases. A few HLA-B27-positive patients with *Y. enterocolitica*-induced arthritis have subsequent ankylosing spondylitis, but this development is best explained by the fact that HLA-B27 is a major risk factor for each of these diseases. Mild, self-limited myocarditis accompanies ~10% of cases of *Yersinia*-induced arthritis and can occur independently. Typical manifestations include cardiac murmurs and transient electrocardiographic abnormalities, such as prolongation of the PR interval and nonspecific ST-segment and T-wave changes. The syndrome of *Yersinia*-induced arthritis and carditis can be confused with acute rheumatic fever. In Scandinavia, erythema nodosum occurs in 15 to 20% of patients with yersiniosis, usually within a few days to 3 weeks after the onset of intestinal illness. Lesions typically are located on the lower extremities and resolve within 1 month. Less commonly reported nonsuppurative sequelae of *Y. enterocolitica* infections include reactive uveitis, iritis, conjunctivitis, urethritis, and glomerulonephritis. The complete triad of Reiter’s syndrome (arthritis, conjunctivitis, and urethritis) is seen in 5 to 10% of patients with *Yersinia*-induced arthritis.

*Yersinia pseudotuberculosis* The most common clinical presentation of *Y. pseudotuberculosis* infection is fever and abdominal pain caused by mesenteric adenitis; diarrheal illness is less common than in *Y. enterocolitica* infection. Systemic manifestations, including septicemia, focal infections, reactive arthritis, and erythema nodosum, are generally similar to those associated with *Y. enterocolitica* infection. In addition, *Y. pseudotuberculosis* has been associated with a scarlet fever–like syndrome, acute interstitial nephritis, and hemolytic-uremic syndrome.

**LABORATORY FINDINGS AND DIAGNOSIS** Results of routine laboratory tests in most patients with yersiniosis are nonspecific. Leukocyte counts are usually normal or slightly elevated, often with a modest left shift. Standard microbiologic methods are sufficient to isolate *Y. enterocolitica* and *Y. pseudotuberculosis* from otherwise-sterile sites, such as blood, CSF, lymph node tissue, and peritoneal fluid, and from abscesses. Isolation of these organisms from feces is impeded by their slow growth and the overgrowth of normal fecal flora on culture media routinely used to select for enteric bacteria. The yield from feces and other grossly contaminated specimens can be increased by the use of *Yersinia*-selective (e.g., cefsulodin-Irgasan-novobiochin (CIN)) agar and by cold enrichment. Because bacteriologic procedures designed to isolate yersiniae from feces are not considered cost-effective, many laboratories undertake them by special request only.

The results of serologic tests can be used to support a diagnosis of yersiniosis. Agglutination tests or ELISAs are used most commonly; immunoblotting has also been used. The existence of multiple serotypes makes routine serologic tests laborious; thus these tests are generally conducted only in research laboratories or large commercial laboratories. Since these tests are experimental and are neither standardized nor well validated, and since some strains of *Yersinia* cross-react with other bacteria (e.g., *Brucella*, *Salmonella*, and *Vibrio*) and with serum from some patients with thyroiditis, results should be interpreted with caution. In typical uncomplicated cases of yersiniosis, agglutinin titers begin to rise within the first week of illness, peak in the second week, and then gradually diminish and return to normal within 3 to 6 months, although agglutinating antibody may remain detectable for several years in some cases. Because an initial serum specimen is often collected a week or more after the onset of illness, when agglutinin titers are already high, it is usually impossible to document a fourfold or greater rise in titer between paired specimens (although a fourfold or greater fall in titer may be found). Immuno-histochemical techniques and PCR tests to detect yersinial antigens and DNA, respectively, in clinical specimens are experimental at this time.

In patients with *Yersinia*-induced reactive arthritis, synovial fluid is sterile and the leukocyte count ranges from a few hundred to 60,000/µL, with a majority of PMNs. The erythrocyte sedimentation rate is often >100 mm/h. Rheumatoid factor and antinuclear antibodies are usually absent. The diagnosis of *Yersinia*-induced reactive arthritis or other nonsuppurative inflammatory sequelae can be difficult, especially when triggering infections are asymptomatic or clinically mild or occur several weeks before the diagnosis is attempted. Because the isolation of a pathogenic *Yersinia* strain from feces is the most specific diagnostic test in such cases, it should be attempted. Since culture is of limited sensitivity in this clinical setting, a high index of suspicion and positive results of serologic tests for *Y. enterocolitica* or *Y. pseudotuberculosis* are usually required for diagnosis.

**PREVENTION AND CONTROL** The importance of safe food-handling and food-preparation practices in the prevention of yersiniosis cannot be overemphasized. Caution is particularly warranted in the case of pork and other animal products. The consumption of raw or undercooked meats, especially pork, should be avoided. Increased efforts to prevent the spread of enteric pathogens in household, pet-care, day-care, and hospital settings and in the food industry would be likely to decrease the incidence of yersiniosis. Current regulations of the U.S. Food and Drug Administration require visual inspection of packed red cell units before transfusion, with the discarding of units in which bacterial contamination is suspected on the basis of darkening (reflecting decreased...
Azithromycin therapy for cat-scratch disease is based on clinical-trial data; all other convalescent phase of Oroya fever or during chronic infection with anemia, and—unless antibiotic treatment is given—high mortality.

PATHOLOGY

Oroya fever and verruga peruana are caused by B. bacilliformis. In 1885 Daniel Carrion, a Peruvian medical student, inoculated himself with material from a patient with verruga peruana and subsequently died of Oroya fever, thus proving that a single agent causes both diseases.

EPIDEMIOLOGY

Infection with B. bacilliformis follows the bite of the sandfly vector Phlebotomus, an insect found in the river valleys of the Andes Mountains at altitudes of 600 to 2500 m. Oroya fever develops in nonimmune individuals who are not residents of the endemic region, whereas verruga peruana occurs in persons who apparently have been exposed in the past, including those who have recently had Oroya fever. The infection has not been acquired in the United States.

PATHOLOGY

During initial infection in the nonimmune host, B. bacilliformis cells adhere to erythrocytes and produce indentations in the cell membrane; the bacteria subsequently enter the erythrocytes and cause persistent deformation of the cytoskeleton. The parasitized erythrocytes are ultimately phagocytosed and destroyed. Although the life span of infected erythrocytes is markedly shortened, not all of this erythrocytes are phagocytosed.

Oxytocin saturation and hemolysis. Since the risk is minimal, more specific measures to further decrease the likelihood of transfusion of Y. enterocolitica–contaminated blood products (e.g., limiting the period for which red cells can be stored before transfusion) have not been widely implemented.

Yersiniosis is not routinely reportable to public health authorities in most jurisdictions. However, clinicians who suspect a common-source outbreak (e.g., because they have documented a familial case cluster) or some other public health threat (e.g., because they have found Y. enterocolitica bacteremia in a recent blood donor) should consult promptly with local public health officials.

BARTONELLA INFECTIONS, INCLUDING CAT-SCRATCH DISEASE

Lucy Stuart Tompkins

Bartonella species, including B. bacilliformis, B. henselae, and B. quintana, are tiny gram-negative bacilli that can adhere to and invade mammalian cells, including endothelial cells and erythrocytes. Previously classified as Rochalimaea species within the rickettsia group, Bartonella species have now been removed from the order Rickettsiales on the grounds that they are not obligate intracellular parasites. These agents cause a wide spectrum of clinical illnesses, including trench fever, cat-scratch disease (CSD), bacillary angiomatosis, peliosis hepatitis, endocarditis, Oroya fever, and verruga peruana. The pathologic manifestations of Bartonella disease vary with the immune status of the host. Key features of major Bartonella infections are summarized in Table 144-1.

OROYA FEVER AND VERRUGA PERUANA

DEFINITION AND ETIOLOGY

Oroya fever and verruga peruana are caused by B. bacilliformis. Oroya fever is characterized by fever, profound anemia, and—unless antibiotic treatment is given—high mortality. The lesions referred to as verruga peruana may develop during the convalescent phase of Oroya fever or during chronic infection with B. bacilliformis. In 1885 Daniel Carrion, a Peruvian medical student, inoculated himself with material from a patient with verruga peruana and subsequently died of Oroya fever, thus proving that a single agent causes both diseases.

a Azithromycin therapy for cat-scratch disease is based on clinical-trial data; all other recommendations are based on case reports or case series.

b If culture results confirm Bartonella infection, ceftriaxone may be discontinued and therapy with azithromycin or doxycycline given for a prolonged period.
change can be attributed to the mechanical fragility induced by the internalization of bacteria. Decreased bone marrow erythropoiesis also contributes to anemia.

**CLINICAL MANIFESTATIONS** The onset of symptoms in Oroya fever may be either insidious or abrupt, after an incubation period of ~3 weeks. The subacute presentation may include low-grade fever, malaise, headache, and anorexia. Sudden-onset disease commences with high fever, chills, diaphoresis, headaches, and changes in mental status. These manifestations are followed by the sudden development of profound anemia, which is due to a marked decrease in erythrocyte numbers and is associated with macrocytic changes, poikilocytosis, Howell-Jolly bodies, nucleated erythrocytes, and immature myeloid cells. The leukocyte differential usually shifts to the left, although the total leukocyte count may be normal. The erythrocyte count may fall to extremely low levels. In eosin/thiazine-stained peripheral-blood smears, numerous microorganisms can be seen adhering to most erythrocytes.

During the acute phase, muscle and joint pain and headache may be severe; central nervous system changes include insomnia, delirium, and a decreased level of consciousness. Thrombocytopenic purpura may develop. If the patient survives, a convalescent phase ensues, characterized by the sudden disappearance of bacteria from blood smears, declining fever, and an increase in the erythrocyte count. Although much of the mortality associated with Oroya fever is due to profound anemia and toxicity, secondary bacterial infections (including salmonellosis and other enteric infections, malaria, and tuberculosis) are often an important contributing factor.

After convalescence from acute Oroya fever, nodular dermal eruptions known as verrugas, verruga peruana, or Peruvian warts may develop. These red or purple cutaneous lesions may be either tiny and sessile or large, pedunculated, and nodular. They bear a marked resemblance to the lesions of bacillary angiomatosis and to Kaposi’s sarcoma.

**DIAGNOSIS** During acute infection, bacteria can be cultured from the blood on agar containing rabbit blood, with incubation at 28°C. The hallmark of verruga peruana is the formation of new blood vessels (angiogenesis) at the sites of bacterial replication.

**TREATMENT**

Oroya fever responds to a variety of antimicrobial agents, including chloramphenicol, tetracyclines, penicillin, and streptomycin. In South America, chloramphenicol is used most often because of its simultaneous efficacy against most *Salmonella* infections (which may develop intermittently). Ampicillin (1 g every 6 h) has also been used, as has cephalexin (500 mg every 6 h). Verruga peruana may respond similarly; rifampin (300 mg twice a day) and ciprofloxacin (500 mg/d) have also been used. Failure to respond to therapy and relapse are common and require the reinstitution of prolonged therapy.

**CAT-SCRATCH DISEASE**

**DEFINITION AND ETIOLOGY** Typical CSD is manifest by painful regional lymphadenopathy persisting for several weeks or months after a cat scratch. Occasionally, infection may disseminate and produce more generalized lymphadenopathy and systemic manifestations, which may be confused with the manifestations of lymphoma. *B. henselae* is the causative agent of CSD. There is no evidence that other Bartonella species cause CSD. The role of *Afania felis* (originally proposed as the agent of CSD) is unclear inasmuch as only a few cases are associated with its isolation. Several reports suggest that *B. claridgeiae* may cause feline lymphadenopathy.

**Epidemiology** Acquisition of *B. henselae* has been significantly associated with exposure to young cats infested with fleas (*Ctenocephalides felis*). The finding that a high proportion of cats with fleas have persistent asymptomatic *B. henselae* bacteremia suggests that the domestic cat is the animal reservoir of this microorganism. The flea can serve as a transmitting vector in the cross-infection of cats, but its role in human infection is not clear. Regions of the United States where fleas are endemic have higher rates of CSD. Approximately 60% of cases occur in children.

**Microbiology** *B. henselae* may be isolated from blood and rarely from lymph nodes or other tissues. Co-cultivation with endothelial cell monolayers has been employed to detect growth. Colonies develop after prolonged incubation (1 to 4 weeks) with 5 to 10% CO2 at 37°C on blood-containing media (rabbit blood is preferred); the colonies pit the agar. Bacterial cells are gram-negative.

**CLINICAL MANIFESTATIONS** A localized papule, progressing to a pustule that often crusts over, develops 3 to 5 days after a cat scratch. Tender regional lymphadenopathy develops within 1 to 2 weeks after inoculation; by this time, the papule may have healed spontaneously. Scratches are most often sustained on the hands or face, producing epistaxis, axillary, pectoral, or cervical lymph node involvement. The involved nodes occasionally become suppurative; bacterial superinfection with staphylococci or other cutaneous pathogens may develop. Although most patients do not have fever, systemic symptoms are frequent and include malaise, anorexia, and weight loss. Without treatment, lymphadenopathy persists for weeks or even months and may be confused with lymphatic malignancy. Other manifestations in apparently immunocompetent patients include encephalitis, seizures and coma (especially in children), meningitis, transverse myelitis, granulomatous hepatitis and splenitis, osteomyelitis, and disseminated infection. Conjunctival inoculation may cause Parinaud’s ocular-glandular syndrome, with conjunctivitis and periauricular lymphadenopathy. *B. henselae* is considered the most common cause of acute neuritis. This condition may present as an acute change in vision associated with a stellate macular lesion; other pathologic changes of the retina may also occur.

**Pathology** The histopathologic hallmark of CSD is granulomatous inflammation with stellate necrosis but no evidence of angiogenesis. Infection by *B. henselae* can produce two entirely different pathologic reactions, depending on the immune status of the host: granulomatous inflammation or angiogenesis.

**Diagnosis** CSD should be suspected if the patient has a history of exposure to cats and develops lymphadenopathy and a skin lesion. The diagnosis can be confirmed by pathologic examination of the involved nodes. Tiny bacilli in clusters can sometimes be seen in biopsy samples stained with Warthin-Starry silver. The CSD skin test, in which lymph node material obtained from patients with CSD serves as an antigen, is no longer used. Specific serologic tests have been developed and produce positive results in 70 to 90% of patients with intact immunity. These tests are commercially available. The identification of *B. henselae* 16S ribosomal RNA genes in biopsy material by polymerase chain reaction (PCR) amplification with specific oligonucleotide primers can also be diagnostically useful; however, these methods are not commercially available. Cultures of lymph nodes, cerebrospinal fluid, or other tissues are rarely positive.
that appear to be useful are those that also are most effective for the treatment of bacillary angiomatosis; they include doxycycline (100 mg/d), rifampin (300 mg daily or twice daily), and azithromycin (250 mg/d). Unlike bacillary angiomatosis, CSD may also respond to treatment with ciprofloxacin (500 mg/d). The necessary duration of therapy is variable. Antbiotic treatment of neuroretinitis is followed by partial or complete resolution.

**TRENCH FEVER**

**DEFINITION AND ETIOLOGY** Trench fever was first described as a debilitating febrile illness associated with prolonged *B. quintana* bacteremia in soldiers fighting in Europe during World War I. Cases have since occurred throughout the world. In recent years, trench fever has re-emerged in the United States and France among urban homeless patients.

**EPIDEMIOLOGY** Although trench fever was once thought to have disappeared from the United States, recent cases have been diagnosed in homeless persons with alcohol abuse. Similar epidemiologic features have been noted in Marseilles, France. An outbreak of infection occurred in Seattle, Washington, in 1993, and few cases have been documented subsequently. In World War I, *B. quintana* was transmitted from person to person by the human body louse, and recent cases in Seattle and Marseilles have also been associated with lice.

**CLINICAL MANIFESTATIONS** Trench fever is characterized by the sudden onset of headache, aseptic meningitis, persistent or relapsing fever (which can be high-grade and is commonly paroxysmal), malaise, weight loss, and other nonspecific symptoms. Some patients may have an indolent course with minimal clinical manifestations. The incubation period is 3 to 38 days. Severe musculoskeletal pain is more common among immunocompetent than among immunocompromised patients. Bacteremia can persist for days or weeks, and relapses have followed short courses of antibiotic therapy. Localized findings are uncommon.

**DIAGNOSIS** The infection is diagnosed by the finding of sustained bacteremia. *B. quintana* grows slowly, and colonies may develop on rabbit blood agar after 1 to 4 weeks of incubation under conditions of increased CO₂. The infection may also be detected serologically, although these tests are not standardized.

**TREATMENT**

A prolonged course (4 to 6 weeks) of antimicrobial therapy may be required. Agents that can cross the mammalian cell membrane are most effective, including doxycycline (100 mg by mouth twice daily), erythromycin (2 g/d), or azithromycin (500 mg/d). Data on the efficacy of these agents come from a limited number of case reports.

**BACILLARY ANGIOMATOSIS**

**DEFINITION AND ETIOLOGY** Bacillary angiomatosis was initially described as a condition occurring primarily in patients with AIDS and characterized by vascular cutaneous lesions resembling verruca peruana and Kaposi’s sarcoma. The disease can disseminate to involve virtually any organ system, including the liver (peliosis hepatis). Immunocompromised individuals, especially those infected with HIV, are at particularly high risk for bacillary angiomatosis, although in rare instances the patient is not obviously immunosuppressed. Both *B. henselae* and *B. quintana* produce bacillary angiomatosis in persons with immunodeficiency.

**EPIDEMIOLOGY** A case-control study revealed that *B. henselae* and *B. quintana* differ significantly in terms of epidemiologic risk factors. All cases of *B. henselae* infection were associated with exposure to cats and their fleas and occurred sporadically, whereas the cases of *B. quintana* bacillary angiomatosis occurred in clusters and were associated with low socioeconomic status, homelessness, and exposure to body lice. Direct transmission of *B. henselae* from cats to their owners, presumably through cutaneous trauma, was supported by the matching DNA fingerprint patterns of isolates from the two sources.

**PATHOGENESIS AND PATHOLOGY** Bacillary angiomatosis is characterized by a lobular proliferation of new blood vessels (angiogenesis) and a neutrophilic inflammatory response to myriad bacilli located within collagen-rich microscopic and macroscopic nodules. The organisms can be visualized with Warthin-Starry silver stain. The endothelial cells lining the vascular spaces have a typical epithelioid appearance, and the lesions may resemble Kaposi’s sarcoma histopathologically, although the characteristic spindle cell of the latter disease is usually absent. The bacterial and eukaryotic host factors that elicit the pathologic response are unknown.

**CLINICAL MANIFESTATIONS** The skin lesions of bacillary angiomatosis (also called *epithelioid angiomatosis*) are vascular nodules, papules, or tumors that range from tiny lesions resembling cherry angiomas or pyogenic granulomas to large, pedunculated, exophytic masses (Fig. 144-1). Characteristically, the lesions are red or purple, resembling Kaposi’s sarcoma; they may be surrounded by an epithelial collarette, may be located anywhere on the skin, and may involve mucous membranes. The overlying epidermis may be focally ulcerated, and the underlying bone may be invaded and destroyed.

Dissemination of *B. henselae* infection occurs primarily in patients with cellular immune defects. Clinical manifestations accompanying dissemination are often nonspecific and include persistent fever, abdominal pain, weight loss, and malaise. Although the liver, spleen, bone marrow, and lymph nodes are primarily affected, HIV-infected patients may also develop central nervous system abnormalities (including psychiatric disorders and brain lesions), which are responsive to antibiotic therapy. Skin lesions usually are not evident in disseminated infection. Involvement of the liver or spleen may produce bacillary peliosis hepatis. Patients with the latter condition may report localized pain on palpation of the abdomen. Nodular lesions of variable size can be demonstrated by computed tomography or magnetic resonance imaging, with or without contrast agents. As these lesions are associated with neovascularization, percutaneous biopsy may lead to hemorrhage.

In a case-control study of bacillary angiomatosis (see “Epidemiology” above), only *B. henselae* was associated with hepatosplenic disease (peliosis hepatis) and displayed a predilection for lymph nodes. *B. quintana*, in contrast, was associated with osseous and subcutaneous infection.

**DIAGNOSIS** The diagnosis of bacillary angiomatosis is based primarily on the typical histopathologic findings of angiomatosis in association with clumps of tiny bacilli revealed by Warthin-Starry silver stain. Infection can also be established by blood cultures performed with a lysis-centrifugation system or by identification of specific DNA sequences. Bacilli picked from new colonies growing on blood agar but not subcultured may not stain, even with acridine orange; they stain weakly with presumeable DNA fingerprint patterns of isolates from the two sources.

**FIGURE 144-1** Characteristic skin lesion of bacillary angiomatosis in an HIV-positive young woman. This large, pedunculated tumor exhibits the typical angiomatous appearance. The patient was treated with oral erythromycin, with nearly complete resolution of the lesion; however, on discontinuation of antibiotic therapy after a 4-week course, the lesion recurred.
Donovanosis is a chronic, progressively destructive bacterial infection of the genital region that is generally regarded as sexually transmitted. The disease has been known by many other names, the most common of which are granuloma inguinale and granuloma venereum.

**ETIOLOGY** Donovanosis is caused by *Calymmatobacterium granulomatis*, an intracellular, gram-negative, pleomorphic, encapsulated (when mature) bacterium measuring 1.5 by 0.7 μm. *C. granulomatis* shares many morphologic and serologic characteristics and >99% homology at the nucleotide level with *Klebsiella* species that are pathogenic to humans. Polymerase chain reaction (PCR) amplification of the *phoE* gene shows it to be closely related to that in *Klebsiella pneumoniae*, *K. rhinoscleromatis*, and *K. ozaenae*. Electron microscopy shows typical gram-negative morphology and a large capsule but no flagella. Filiform or vesicular protrusions occur on a corrugated cell wall.

**EPIDEMIOLOGY** Donovanosis is endemic among Aborigines in central Australia as well as in Papua New Guinea, southeastern India, southern Africa, and the Caribbean and adjacent areas of South America. In the first half of the twentieth century, the disease was endemic in parts of the United States (with an estimated 5000 to 10,000 cases in 1947); small epidemics still occur in this country and in other developed countries. The decline in the United States to fewer than 20 reported cases annually in the past decade has probably resulted from lower transmission rates due to earlier presentation for increasingly effective antibiotic therapy. Over 70% of cases involve persons 20 to 40 years of age. The infection is predominantly sexually transmitted, but extragenital skin lesions can follow transmission from concurrent genital lesions via the fingers or through other nonsexual contact, and autoinoculation may produce new lesions from contact with adjacent skin (“kissing” lesions). Infants born to infected mothers have acquired infection at birth.

The classification of donovanosis as a sexually transmitted disease (STD) has been disputed because of cases in young children and occasionally in sexually inactive individuals, transmission by direct body contact and via inanimate intermediaries, and the low and variable prevalence of donovanosis among sexual partners (0.4 to 52%). The dominance of sexual transmission is suggested by the combined factors of lesions predominantly affecting the genitalia, the highest prevalence among persons in age and socioeconomic groups that are most
often affected by STDs, and the predictable occurrence of disease in visitors to areas of endemicity following sexual exposure.

CLINICAL MANIFESTATIONS The incubation period is usually 1 to 4 weeks but may extend to 1 year. Skin lesions have been detected in infants 6 weeks to 6 months after birth. The disease begins as one or more subcutaneous nodules that erode through the skin to produce clean, granulomatous, sharply defined, usually painless lesions (Fig. 145-1). These lesions, which bleed readily on contact, slowly enlarge. The genitalia are involved in 90% of cases, the inguinal region in 10%, and the anal region in 5 to 10%. Genital swelling, particularly of the labia, is a common feature and occasionally progresses to pseudoelephantiasis. Phimosis and paraphimosis are common local complications, and progressive erosion of affected tissues may completely destroy the penis or other organs. Less common clinical variants include a hypertrophic form (cauliflower-or wartlike lesions), a necrotic form (destructive lesions with foul-smelling exudate, often resembling amebiasis), and a sclerotic or cicatricial form, which has a dry base with extensive scar tissue.

Extragenital lesions occur in at least 6% of cases. Oral donovanosis, the most common extragenital manifestation, presents as pain or bleeding in the mouth, lesions on the lips, or extensive swelling of the gums and palate. Donovanas may affect most bones, and sometimes many bones are affected at the same time; the tibia is involved in over 50% of such cases. Bony lesions are associated with constitutional symptoms (weight loss, fever, night sweats, and malaise) and are usually found in women. More than 50% of women with donovanosis have primary lesions on the cervix. Prompt pelvic examinations and early diagnosis are likely to substantially decrease the morbidity and mortality (likely outcomes in misdiagnosed spinal lesions) associated with extragenital donovanosis in women.

DIAGNOSIS ■ Laboratory Diagnosis The preferred diagnostic method involves demonstration of typical intracellular Donovan bodies within large mononuclear cells visualized in smears prepared from lesions or biopsy specimens. With typical beefy lesions, a small piece of tissue is removed with forceps and scalpel, and a crush impression of the deep surface is made on a glass slide. The smear is air-dried, heat-fixed, and stained with Giemsa, Leishman’s, or Wright’s stain. For dry, flat, or necrotic lesions, a punch-biopsy specimen should be obtained from the advancing edge. This specimen can be used to prepare a smear or embedded for histologic examination (with a silver stain). Histologic examination shows epithelial proliferation, often simulating neoplasia, with a heavy inflammatory infiltrate of plasma cells, some neutrophils, and few if any lymphocytes. The large mononuclear cells are 25 to 90 μm in diameter, with a vesicular or pyknotic nucleus. Up to 20 intracytoplasmic vacuoles contain pleomorphic Donovan bodies (destructive lesions with foul-smelling exudate, often resembling amebiasis), and a sclerotic or cicatricial form, which has a dry base with extensive scar tissue.

Extragenital lesions occur in at least 6% of cases. Oral donovanosis, the most common extragenital manifestation, presents as pain or bleeding in the mouth, lesions on the lips, or extensive swelling of the gums and palate. Donovanas may affect most bones, and sometimes many bones are affected at the same time; the tibia is involved in over 50% of such cases. Bony lesions are associated with constitutional symptoms (weight loss, fever, night sweats, and malaise) and are usually found in women. More than 50% of women with donovanosis have primary lesions on the cervix. Prompt pelvic examinations and early diagnosis are likely to substantially decrease the morbidity and mortality (likely outcomes in misdiagnosed spinal lesions) associated with extragenital donovanosis in women.
Nocardiosis refers to disease associated with members of the genus *Nocardia*. Of several distinctive syndromes associated with these bacteria, pneumonia and disseminated disease are most common. Others include cellulitis, lymphocutaneous syndrome, actinomycetoma, and keratitis.

**MICROBIOLOGY** Nocardiae are saprophytic aerobic actinomycetes that are common worldwide in soil, where they contribute to decay of organic matter. Nocardial taxonomy is complex and incompletely understood. Seven species have been clearly associated with human disease: *N. asteroides*, *N. brasiliensis*, *N. otitidis-caviarum* (formerly *N. caviae*), *N. farcinica*, *N. nova*, *N. transvalensis*, and *N. pseudobrasiliensis*. In addition, two newly described species have been associated with disease in humans: *N. abscessus* from soft-tissue abscesses and *N. africana* from respiratory secretions of patients in the Sudan with pneumonia.

*N. asteroides* is the species most commonly associated with invasive disease. *N. farcinica* disease is less common, but this species is more virulent and prone to dissemination. *N. pseudobrasiliensis* is most often associated with invasive disease, and *N. brasiliensis* is usually associated with disease limited to the skin. *N. transvalensis* is generally associated with pulmonary or systemic disease in immunosuppressed persons or with *actinomycetoma*, an indolent, slowly progressive disease of skin and underlying tissues with nodular swellings and draining sinuses.

**EPIDEMIOLOGY** Approximately 1000 cases of nocardial infection are diagnosed annually in the United States, 85% of them pulmonary and/or systemic. The disease is more common among adults than among children and among males than among females. Nearly all cases are sporadic, but outbreaks have been associated with contamination of the hospital environment, solutions, or drug injection equipment. Person-to-person spread is not well documented. There is no known seasonality.

The risk of pulmonary or disseminated disease is greater than usual among persons with deficient cell-mediated immunity, especially that associated with lymphoma, transplantation, glucocorticoid therapy, or AIDS. In AIDS, nocardiosis usually affects persons with CD4 lymphocytes < 250/μL. Nocardiosis has also been associated with pulmonary alveolar proteinosis, tuberculosis, and other mycobacterial diseases, chronic granulomatous disease, and interleukin 12 deficiency.

*N. brasiliensis*, *N. asteroides*, *N. otitidis-caviarum*, and *N. transvalensis* are associated with actinomycetoma. Cases occur mainly in tropical and subtropical regions, especially those of Mexico, Central and South America, Africa, and India. The most important risk factor is frequent contact with soil or vegetable matter.

**PATHOLOGY AND PATHOGENESIS** Pneumonia and disseminated disease are both thought to follow inhalation of fragmented bacterial mycelia. The characteristic histologic feature of nocardiosis is an abscess with extensive neutrophil infiltration and prominent necrosis. Granulomatous tissue usually surrounds the lesions, but extracellular fibrosis or encapsulation is uncommon. Actinomycetoma is characterized by supplicative inflammation with sinus tract formation. Granules—microcolonies composed of dense masses of bacterial filaments extending radially from a central core—are occasionally observed in histologic preparations. They are frequently found in discharges from lesions of actinomycetoma but almost never from lesions in other forms of nocardiosis. Infrequently, nocardiae and other indolent pathogens, including fungi or mycobacteria, are isolated from the same patient.

Nocardiae have evolved a number of properties that enable them to survive within phagocytes, including neutralization of oxidants, prevention of phagosome-lysosome fusion, and prevention of phagosome acidification. Neutrophils phagocytose the organisms and limit their growth but do not kill them efficiently. Cell-mediated immunity is important for definitive control and elimination of nocardiae.

**CLINICAL MANIFESTATIONS**

**Respiratory Tract Disease** Pneumonia is by far the most common respiratory tract nocardial disease. Nocardial pneumonia is typically subacute; symptoms have usually been present for days or weeks at presentation. The onset is more acute in some immunosuppressed patients. Cough is prominent and produces small amounts of thick, purulent sputum that is not malodorous. Fever, anorexia, weight loss, and malaise are common; dyspnea, pleuritic pain, and hemoptysis are less common. Remissions and exacerbations over several weeks are frequent.

Roentgenographic patterns vary, but some are highly suggestive of nocardial pneumonia. Infiltrates vary in size and are typically of at least moderate density. Single or multiple nodules are common, sometimes suggesting tumor metastases (Fig. 146-1). Infiltrates and nodules tend to cavitate. Empyema is present in one-third of cases.

Nocardiosis may spread directly from the lungs to adjacent tissues. Pericarditis, mediastinitis, and the superior vena cava syndrome have all been reported. Nocardial laryngitis, tracheitis, and bronchitis are much less common than pneumonia. In the major airways, disease often presents as a nodular or granulomatous mass. A few cases of sinusitis have been reported.

Nocardiae are sometimes isolated from respiratory secretions of patients without apparent nocardial disease. Most of these patients have chronic pulmonary disease with abnormal airways or parenchyma and do not necessarily require treatment for nocardiosis (see “Diagnosis,” below).

**Extrapulmonary Disease** In half of all cases of pulmonary nocardiosis, disease appears outside the lungs. In one-fifth of cases of disseminated disease, lung disease is not apparent. The most common site of dissemination is the brain. Other common sites include the skin and sup-
Nocardiosis

Lesions are usually firm and nonfluctuant. Disease may progress to involve underlying muscle, tendon, bones, or joints. Dissemination is rare. *N. asteroides* is common in colder climates, while *N. brasiliensis* predominates in warmer climates.

Lymphocutaneous disease usually begins with a pyodermatous lesion at the site of inoculation, with central ulceration and purulent or honey-colored drainage. Subcutaneous nodules often appear along lymphatics that drain the primary lesion. The lymphangitic form closely resembles lymphocutaneous sporotrichosis (Chap. 190). Most cases of the lymphocutaneous syndrome are associated with *N. brasiliensis*.

Actinomycetoma usually begins with a nodular swelling, sometimes at a site of local trauma. Lesions typically develop on the feet or hands but may involve the posterior part of the neck, the upper back, the head, and other sites. The nodule eventually breaks down and a fistula appears, which is then accompanied by others. The fistulas tend to come and go, with new ones forming as old ones disappear. The discharge is serous or purulent, may be bloody, and often contains 0.1- to 2-mm white granules consisting of masses of mycelia. The lesions spread slowly along fascial planes to involve adjacent areas of skin, subcutaneous tissue, and bone. Over months or years, there may be extensive deformation of the affected part. Lesions involving soft tissues are often mildly painful; those affecting bones or joints are more so. Systemic symptoms are absent or minimal. Infection rarely disseminates from actinomycetoma, and lesions on the hands and feet usually cause only local disability. Lesions on the head, neck, and trunk can invade locally to involve deep organs and result in severe disability or death.

Keratitis *Nocardia* species, usually *N. asteroides*, are uncommon causes of subacute keratitis. The infection usually follows eye trauma. Nocardial infection of lacrimal glands has been reported. Endophthalmitis and other diseases involving deeper eye structures are usually manifestations of dissemination.

Diagnosis

The first step in diagnosis is examination of sputum or pus for crooked, branching, beaded, gram-positive filaments 1 μm wide and up to 50 μm long. Most nocardiae are acid-fast in direct smears if a weak acid is used for decolorization (e.g., in the modified Kinyoun, Ziehl-Neelsen, and Fite-Faraco methods). The organisms often take up silver stains. Nocardiae grow relatively slowly; colonies may take

![FIGURE 146-1](image1.png) Nocardial pneumonia. Top: Three large nodules with apparent cavitation are apparent on the anterior-posterior chest roentgenograph. Bottom: A computed tomographic scan of the same patient confirms the presence of bilateral nodules and cavitation in the nodule in the left midlung field.

![FIGURE 146-2](image2.png) Nocardial abscesses in the right cerebellum. The appearance suggests one large abscess and multiple daughter abscesses.
nocardial DNA. None is ready for clinical use at this time. Several presumptive diagnostic tests for nocardial infection have been studied, including tests for antibodies, nocardial metabolites, and nocardial DNA. None is ready for clinical use at this time.

As 5 mg/kg and 25 mg/kg, respectively. In persons with sulfonamide allergies, desensitization usually allows continuation of therapy with these effective and inexpensive drugs.

Mycobacterium is the best-established alternative oral drug and should be given in doses of 100 to 200 mg twice a day. Other tetra-
clycines are usually ineffective. N. nova infections can be treated with erythromycin (500 to 750 mg four times a day) and/or ampicillin (1 g four times a day), but other Nocardia species are often resistant to both drugs. Amoxicillin (500 mg) combined with clavulanic acid (125 mg), given three times a day, has been effective in a few cases but should be avoided in cases due to N. nova, in which clavulanate indu-
duce β-lactamase production. Ofloxacin (400 mg twice a day) and clari-
thromycin (500 mg twice a day) have each been successful in a few cases. Linezolid is active in vitro against most Nocardia isolates, but there is little clinical experience with this drug as nocardiosis therapy.

Amikacin, the best-established parenteral drug, is given in doses of 5 to 7.5 mg/kg every 12 h. Serum levels should be monitored during prolonged therapy in patients with diminished renal function and in the elderly. Newer β-lactam antibiotics, including cefotaxime, cef-
tizoxime, ceftriaxone, and imipenem, are usually effective. These agents may be less effective in some cases caused by N. farcinica.

In vitro, strains of N. farcinica differ from most in that they are usually resistant to cephalosporins and in one-fifth of cases are resis-
tant to imipenem. N. pseudobrasiliensis strains often exhibit resistance to minocycline or amoxicillin/clavulanic acid and susceptibility to cip-
rroloxacin or clarithromycin. N. transvalensis displays increased resis-
tance to many antimicrobial agents, including amikacin, tobramy-
cin, cefotaxime, ceftriaxone, and amoxicillin/clavulanic acid. N. nova isolates appear to be susceptible to ampicillin and erythromycin in vitro but also produce β-lactamase constitutively or in the presence of a β-lactam.

Use of SMX and TMP in high-risk populations to prevent Pneu-
monocystis carinii disease or urinary tract infections appears to reduce the risk of nocardiosis as well. However, the incidence of nocardiosis is infrequent enough that prophylaxis of this disease is not recommended.

In patients with nocardiosis who need immunosuppressive therapy for an underlying disease or prevention of transplant rejection, such therapy should be continued. In many cases, two or more antimicrobial agents have been used to treat nocardiosis, often in combinations in-
cluding drugs that are usually effective by themselves, like a sulfona-
mine or minocycline. Whether such combination therapy is better than monotherapy is not known, and it certainly increases the risk of toxicity.

Surgical management of nocardial disease is similar to that of other bacterial diseases. Brain abscesses should be aspirated, drained, or excised if the diagnosis is unclear, if an abscess is large and accessible,
Actinomycosis is an indolent, slowly progressive infection caused by anaerobic or microaerophilic bacteria, primarily of the genus *Actinomyces*, that colonize the mouth, colon, and vagina. Mucosal disruption may lead to infection at virtually any site in the body. In vivo growth of actinomycetes usually results in the formation of characteristic clumps called "grains" or "sulfur granules." The clinical presentations of actinomycosis are myriad. Common in the preantibiotic era, actinomycosis has diminished in incidence, as has its timely recognition.

Actinomycosis has been called "the most misdiagnosed disease," and it has been said that "no disease is so often missed by experienced clinicians." Thus this entity remains a diagnostic challenge. Three clinical presentations that should prompt consideration of this unique infection are (1) the combination of chronicity, progression across tissue boundaries, and mass-like features (mimicking malignancy, with which it is often confused); (2) the development of a sinus tract, which may spontaneously resolve and recur; and (3) a refractory or relapsing infection after a short course of therapy, since cure of established actinomycosis requires prolonged treatment. An awareness of the full course of the disease will expedite its diagnosis and treatment and will minimize the unnecessary surgical interventions, morbidity, and mortality that are reported all too often.

**ETIOLOGIC AGENTS** Actinomycosis is most commonly caused by *A. israelii*, *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, *A. meyeri*, *A. gerencseriae*, and *Propionibacterium propionicum* are established but less common causes of the disease. Most if not all actinomycotic infections are polymicrobial. *Actinobacillus actinomycetemcomitans*, *Eikenella corrodens*, *Enterobacteriaceae*, and species of *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus*, and *Streptococcus* are commonly isolated with actinomycetes in various combinations, depending on the site of infection. The contribution of these other species to the pathogenesis of actinomycosis is uncertain.

Comparative 16S rRNA gene sequencing has led to the identification of *A. europaenus*, *A. neuii*, *A. radingsae*, *A. graevenitzii*, *A. turicensis*, and *A. funkei* in clinical specimens. Increasing data suggest that these species may also cause actinomycosis.

**EPIDEMIOLOGY** Actinomycosis occurs throughout life, with a peak incidence in the middle decades. Males have a threefold higher incidence of infection than females, possibly because of poorer dental hygiene and/or more frequent trauma. Likely contributing factors to the decrease in the incidence of actinomycosis since the preantibiotic era include improved dental hygiene and the initiation of antimicrobial treatment early on—before the full development of the disease. Individuals who do not seek or have access to health care are undoubtedly at higher risk.

**PATHOGENESIS AND PATHOLOGY** The etiologic agents of actinomycosis are members of the normal oral flora and are often cultured from the bronchi, the gastrointestinal tract, and the female genital tract. The critical step in the development of actinomycosis is disruption of the mucosal barrier. Local infection may consequently ensue. Once established, actinomycosis spreads contiguously in a slow progressive manner, ignoring tissue planes. Although acute inflammation may initially develop at the site of infection, the hallmark of actinomycosis is the characteristic chronic, indolent phase. This stage is manifested by lesions that usually appear as single or multiple indurations. Central necrosis consisting of neutrophils and sulfur granules develops and is virtually diagnostic of this disease. The fibrotic walls of the mass are typically described as "wooden." The responsible bacterial and/or host factors have not yet been identified. Over time, sinus tracts to the skin, adjacent organs, or bone may develop. In rare instances, distant hematogenous seeding may occur. As mentioned above, these unique features of actinomycosis mimic malignancy, with which it is often confused.

**CLINICAL MANIFESTATIONS**

**Oral-Cervicofacial Disease** Actinomycosis occurs most frequently at an oral, cervical, or facial site, usually as a soft tissue swelling, abscess, or mass lesion that is often mistaken for a neoplasm. The angle of the jaw is generally involved, but a diagnosis of actinomycosis should be considered with any mass lesion or relapsing infection in the head and neck (Chap. 27). Otitis, sinusitis, and canaliculitis can also develop. Pain, fever, and leukocytosis are variably reported. Contiguous extension to the cranial, cervical spine, or thorax is a potential sequela.

**Thoracic Disease** Thoracic actinomycosis usually follows an indolent progressive course, with involvement of the pulmonary parenchyma and/or the pleural space. Chest pain, fever, and weight loss are common. A cough, when present, is variably productive. The usual radiographic appearance is either a mass lesion or pneumonia. On computed tomography (CT), central areas of low attenuation and ringlike rim
Hepatic infection usually presents as single or multiple abscesses or masses. Isolated disease presumably develops via hematogenous seeding from cryptic foci. Presently available imaging and percutaneous techniques have resulted in improved diagnosis and treatment. All levels of the urogenital tract can be infected. Renal disease usually presents as pyelonephritis and/or renal and perinephric abscess. Bladder involvement, usually due to extension of pelvic disease, may result in ureteral obstruction or fistulas to bowel, skin, or uterus. *Actinomyces* can be detected in urine with use of appropriate stains and cultures.

**Pelvic Disease** Actinomycotic involvement of the pelvis occurs most commonly in association with an IUCD. Pelvic symptoms when an IUCD is in place or has recently been removed should prompt consideration of actinomycosis. Although the risk has not yet been quantified, it appears to be small. The disease rarely develops when the IUCD has been in place for <1 year, but the risk increases with time. Actinomycosis can also present months after the removal of the device. Symptoms are typically indolent; fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge are the most common. The earliest stage of disease—often endometritis—commonly progresses to pelvic masses or a tuboovarian abscess (Fig. 147-2). Unfortunately, because the diagnosis is often delayed, a “frozen pelvis” mimicking malignancy or endometriosis can develop by the time of recognition.

An unresolved issue is whether screening of cervical or endometrial specimens for *Actinomyces*-like organisms (ALOs) can predict or prevent IUCD-associated disease. Although the risk appears to be small, the consequences of infection are significant. Therefore, until more quantitative data become available, it would appear prudent to remove the IUCD in the presence of symptoms that cannot be accounted for, regardless of whether ALOs or immunofluorescence-positive organisms are detected, and—if advanced disease is excluded—to initiate a 14-day course of empirical treatment for possible early pelvic actinomycosis. The detection of ALOs or immunofluorescence-positive organisms in the absence of symptoms warrants education of the patient and close follow-up but not removal of the IUCD unless an equally suitable means of contraception can be agreed upon.

**Central Nervous System Disease** Actinomycosis of the central nervous system is rare. Single or multiple brain abscesses are most common. An abscess usually appears on CT as a ring-enhancing lesion with a thick wall that may be irregular or nodular. Meningitis, epidural or subdural space infection, and cavernous sinus syndrome have also been described.
Musculoskeletal and Soft Tissue Infection  
Actinomycotic infection of the bone is usually due to adjacent soft-tissue infection but may be associated with trauma (e.g., fracture of the mandible) or hematogenous spread. Because of slow disease progression, new bone formation and bone destruction are seen concomitantly. Infection of an extremity is uncommon and is usually a result of trauma. Skin, subcutaneous tissue, muscle, and bone (with periostitis or acute or chronic osteomyelitis) are involved alone or in various combinations. Cutaneous sinus tracts frequently develop.

Disseminated Disease  
Hematogenous dissemination of disease from any location rarely results in multiple-organ involvement. The lungs and liver are most commonly affected, with the presentation of multiple nodules mimicking disseminated malignancy. The clinical presentation may be surprisingly indolent given the extent of disease.

DIAGNOSIS  
The diagnosis of actinomycosis is rarely considered. All too often, the first mention of actinomycosis is by the pathologist after extensive surgery has been performed. Since medical therapy alone is often sufficient for cure, the challenge for the clinician is to consider the possibility of actinomycosis in time to diagnose it in the least invasive fashion and to avoid unnecessary surgery. The clinical and radiographic presentations that suggest actinomycosis have been discussed above. Aspirations and biopsies (with or without CT or ultrasound guidance) are being used successfully to obtain clinical material for diagnosis, although surgery may be required. The diagnosis is most commonly made by microscopic identification of sulfur granules (an in vivo matrix of bacteria, calcium phosphate, and host material) in pus or tissues. Occasionally these granules can be grossly identified from draining sinus tracts or pus. Although sulfur granules are a defining characteristic of actinomycosis, granules are also found in mycetoma (Chaps. 146 and 190) and botryomycosis (a chronic suppurative bacterial infection of soft tissue or, in rare cases, visceral tissue). The histopathologic and microbiologic studies. Microbiologic identification of actinomycetes is often precluded by the administration of prior antimicrobial therapy or the failure to perform appropriate microbiologic cultures. For optimal yield, the avoidance of even a single dose of antibiotics is mandatory. Primary isolation usually requires 5 to 7 days but may take as long as 2 to 4 weeks. Immunofluorescence testing for A. israelii, A. naeslundii, and P. propionicum (available through the Centers for Disease Control and Prevention in Atlanta) is a useful diagnostic alternative. Although 16S rRNA gene amplification and sequencing would be predicted to have increased diagnostic sensitivity, this method apparently has not been used so far. Because these organisms are components of the normal oral and genital-tract flora, their identification in the absence of sulfur granules in sputum, bronchial washings, and cervicovaginal secretions is of little significance.

TREATMENT  
Decisions about treatment are based on the collective clinical experience of the past 50 years. Actinomycosis must be treated with high doses of antimicrobials for a prolonged period. The need for this intensive treatment is presumably due to difficulty encountered by antimicrobial agents in penetrating the thick-walled masses that commonly occur in this infection and/or the sulfur granules themselves. Although therapy needs to be individualized, the intravenous administration of 18 to 24 million units of penicillin daily for 2 to 6 weeks, followed by oral therapy with penicillin or amoxicillin for 6 to 12 months, is a reasonable guideline for serious infections. Less extensive disease, particularly that involving the oral-cervicofacial region, may require less intensive therapy. If therapy is extended beyond the point of resolution of measurable disease, the risk of relapse—a clinical hallmark of this infection—will be minimized; CT and magnetic resonance imaging (MRI) are generally the most sensitive and objective techniques by which to accomplish this goal. A similar approach is reasonable for immunocompromised patients, although refractory disease has been described in HIV-infected individuals. Suitable alternative antimicrobial agents and those deemed unreliable are listed in Table 147-1. Although the role played by “companion” microbes in actinomycosis is unclear, many isolates are pathogens in their own right, and a regimen covering these organisms during the initial treatment course is reasonable.

Combined medical-surgical therapy is still advocated by some authorities. However, an increasing body of literature now supports an initial attempt at cure with medical therapy alone, even in extensive disease. CT and MRI should be used to monitor the response to therapy. In most cases, either surgery can be avoided or a less extensive procedure can be used. This approach is particularly valuable in sparing critical organs, such as the bladder or the reproductive organs in women of child-bearing age. For a well-defined abscess, percutaneous drainage in combination with medical therapy is a reasonable approach. When a critical location is involved (e.g., the epidural space, the central nervous system) or when suitable medical therapy fails, surgical intervention may be appropriate.

FURTHER READING  
DEFINITIONS  Anaerobic bacteria are organisms that require reduced oxygen tension for growth, failing to grow on the surface of solid media in 10% CO₂ in air. (In contrast, microaerophilic bacteria can grow in an atmosphere of 10% CO₂ in air or under anaerobic or aerobic conditions, although they grow best in the presence of only a small amount of atmospheric oxygen, and facultative bacteria can grow in the presence or absence of air.) This chapter describes infections caused by nonsporulating anaerobic bacteria. In general, anaerobes associated with human infections are relatively aerotolerant. They can survive for as long as 72 h in the presence of oxygen, although generally they will not multiply in this environment. A far smaller number of pathogenic anaerobic bacteria (which are also part of the normal flora) die after brief contact with oxygen, even in low concentrations.

The nonsporulating anaerobic bacteria exist as components of the normal flora on the mucosal surfaces of humans and animals. The major reservoirs of these bacteria are the mouth, lower gastrointestinal tract, skin, and female genital tract. Among the constituents of the oral flora, anaerobes are the predominant commensal organisms, ranging in concentration from 10⁹/mL in saliva to 10¹²/mL in gingival scrapings. In the oral cavity, the ratio of anaerobic to aerobic bacteria ranges from 1:1 on the surface of a tooth to 1000:1 in the gingival crevice. Anaerobic bacteria are not found in appreciable numbers in the normal upper intestine until the distal ileum. In the colon, the proportion of anaerobes increases significantly, as does the overall bacterial count. For example, in the colon there are 10¹¹ to 10¹³ organisms per gram of stool, with an anaerobe-to-aerobe ratio of ~1000:1. In the female genital tract, there are ~10⁹ organisms per milliliter of secretions, with an anaerobe-to-aerobe ratio of ~10:1.

It is becoming clear that anaerobes play a key role in maintaining the balance between the host and its colonizing organisms. Hundreds of species of anaerobic bacteria have been identified as part of the normal flora of humans. Identification of as many as 500 different anaerobic species in fecal specimens reflects the diversity of the anaerobic flora. Despite the complex array of bacteria in the normal flora, relatively few species are isolated commonly from human infection. Anaerobic infections occur when the harmonious relationship between the host and the bacteria is disrupted. Any site in the body is susceptible to infection with these indigenous organisms when a mucosal barrier or the skin is compromised by surgery, trauma, tumor, or ischemia or necrosis, all of which can reduce local tissue redox potentials. Because the sites that are colonized by anaerobes contain many species of bacteria, disruption of anatomical barriers allows the penetration of many organisms, resulting in mixed infections involving multiple species of anaerobes combined with facultative or microaerophilic organisms. Such mixed infections are seen in the head and neck (chronic sinusitis, chronic otitis media, Ludwig’s angina, and peridontal abscesses). Brain abscesses and subdural empyema are the most common anaerobic infections of the central nervous system. Anaerobes are responsible for pleuropulmonary diseases such as aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema. These organisms also play an important role in various intraabdominal infections, such as peritonitis and intraabdominal and liver abscesses (Chap. 112). They are isolated frequently in female genital tract infections, such as salpingitis, pelvic peritonitis, tuboоварian abscess, vulvovaginal abscess, septic abortion, and endometritis (Chap. 115). Anaerobic bacteria are also found often in infections of the skin, soft tissues, and bones and in bacteremia.

ETIOLOGY  The taxonomic classification of anaerobes is a rapidly evolving field, with frequent changes in nomenclature based on newly discovered relationships among bacterial species. The major anaerobic gram-positive cocci that produce disease are Peptostreptococcus spp. The major species of this genus that are involved in infections are Peptostreptococcus micros, P. magnus, P. asaccharolyticus, P. anaerobius, and P. prevotii. Clostridia (Chap. 126) are gram-positive rods that are isolated from wounds, abscesses, sites of abdominal infection, and blood. The principal anaerobic gram-negative bacilli found in human infections are the Bacteroides fragilis group as well as Fusobacterium, Prevotella, and Porphyromonas spp. Other members of the Bacteroidaceae family include Bifidobacteria, which is part of the normal bowel flora; they include several distinct species, including B. fragilis, B. thetaiotaomicron, B. distasonis, B. vulgatus, B. uniformis, and B. ovatus. Of this group, B. fragilis is the most important clinical isolate. However, B. fragilis is isolated from the normal fecal flora in lower numbers than some of the other Bacteroides spp.

A second major group of phenotypically similar organisms is part of the indigenous oral flora. Thus these organisms are found at infected sites that can be seeded with oral microflora. Many of these species are pigment-producing bacteria previously classified as Bacteroides melaninogenicus. The nomenclature of this group has changed so that two distinct genera, Prevotella and Porphyromonas, are now recognized; these genera comprise several pathogenic species, including Porphyromonas gingivalis, Porphyromonas asaccharolytica, and Prevotella oralis. Porphyromonas and Prevotella spp. cause localized infections that can spread contiguously.

In female genital tract infections, organisms normally colonizing the vagina, such as Prevotella bivia and Prevotella disiens, are the most frequent isolates, although B. fragilis is not uncommon. The Fusobacterium species Fusobacterium necrophorum, F. nucleatum, and F. varium, which reside primarily in the oral cavity and the gastrointestinal tract, are also isolated from clinical infections, including necrotizing pneumonia and abscesses.

Infections caused by anaerobic bacteria most frequently are due to more than one organism. These polymicrobial infections may be caused by one or several anaerobic species or by a combination of anaerobic organisms and microaerophilic or facultative bacteria acting synergistically.

APPRAISAL TO THE PATIENT  The physician must consider several points when approaching the patient with presumptive infection due to anaerobic bacteria.

1. Most of the organisms colonizing mucosal sites are harmless commensals; very few cause disease.
2. For anaerobes to cause tissue infection, they must spread beyond the normal mucosal barriers.
3. Conditions favoring the propagation of these bacteria, particularly a lowered oxidation-reduction potential, are necessary. These conditions exist at sites of trauma, tissue destruction, compromised vascular supply, and complications of preexisting infection, which produce necrosis.
4. There is a complex array of infecting flora. For example, as many as 12 different types of organisms can be isolated from a supplicative site.
5. Anaerobic organisms tend to be found in abscess cavities or in necrotic tissue. The failure of an abscess to yield organisms on routine culture is a clue that the abscess is likely to contain...
anaerobic bacteria. Often smears of this “sterile pus” are found to be teeming with bacteria when Gram’s stain is applied. Malodorous pus suggests anaerobic infection. Although some facultative organisms, such as Staphylococcus aureus, are also capable of causing abscesses, abscesses in organs or deeper body tissues should call to mind anaerobic infection.

6. Gas is found in many anaerobic infections of deep tissues.

7. Some species (the best example being the B. fragilis group) require specific therapy. However, many synergistic infections can be cured with antibiotics directed at some but not all of the organisms involved. Antibiotic therapy, combined with debridement and drainage, disrupts the interdependent relationship among the bacteria, and some species that are resistant to one antibiotic do not survive with the associated aerobic organisms.

8. Manifestations of disseminated intravascular coagulation are unusual in patients with purely anaerobic infection.

**EPIDEMIOLOGY** Difficulties in the performance of appropriate cultures, contamination of cultures by aerobic bacteria or components of the normal flora, and the lack of readily available, reliable culture techniques have made it impossible to obtain accurate incidence or prevalence data. However, anaerobic infections are encountered frequently in hospitals with active surgical, trauma, and obstetric and gynecologic services. In some centers, anaerobic bacteria, particularly B. fragilis, account for ~4% of positive blood cultures.

**PATHOGENESIS** Anaerobic bacterial infections usually occur when an anatomical barrier has been disrupted and contaminants of the local flora enter a site that was previously sterile. Because of the specific growth requirements of anaerobic organisms and their presence as commensals on mucosal surfaces, conditions must arise that allow these organisms to penetrate mucosal barriers and enter tissue with a reduced oxygen-reduction potential. Therefore, tissue ischemia, trauma, surgery, perforated viscus, shock, and aspiration provide environments conducive to the proliferation of anaerobes. In the case of a perforated viscus, hundreds of species of anaerobic bacteria are spilled into the peritoneal cavity, but many of these organisms are unable to survive because the highly vascularized tissue provides a sufficiently high redox potential. The entry of oxygen into the environment results in the selection of the more aerotolerant anaerobic organisms.

The ability of an organism to adhere to host tissues is important to the establishment of infection. Some oral species adhere to crevicular epithelium in the oral cavity.Prevotella melaninogenica actually attaches to other microorganisms; P. gingivalis is a common isolate in periodontal disease. These organisms have fimbiae that facilitate attachment. Some unencapsulated Bacteroides strains appear to be piliated, a characteristic that may account for their ability to adhere.

The most extensively studied virulence factor of the nonsporulating anaerobes is the polysaccharide capsule of B. fragilis. This polysaccharide possesses distinct biologic properties, such as the ability (owing to a unique zwiterionic motif of charged sugars) to promote abscess formation. Intraabdominal abscess induction is related to the capacity of the polysaccharide to stimulate the release of cytokines and chemokines—in particular interleukin (IL) 8, IL-17, and tumor necrosis factor (TNF) α—from resident peritoneal cells. The release of cytokines and chemokines results in the chemotaxis of polymorphonuclear neutrophils (PMNs) into the peritoneum, where they adhere to mesothelial cells induced by TNF-α to upregulate their expression of intercellular adhesion molecule 1 (ICAM-1). PMNs adherent to ICAM-1-expressing cells probably represent the nidus for an abscess. Prophylactic or therapeutic administration of the polysaccharide or a zwiterionic mimic to experimental animals confers protection against abscess induction following challenge with intestinal microorganisms capable of inducing abscesses. This protection is mediated by T cells controlling cytokine release; IL-10 appears to be the cytokine primarily responsible for downregulating the tissue response of abscess formation. Although abscesses constitute a host response that localizes and contains infecting bacteria, abscess formation in patients with sepsis often results in severe and chronic illness that requires surgical drainage in combination with antimicrobial therapy.

Anaerobic bacteria produce a number of exoproteins that are capable of enhancing the organisms’ virulence. The collagenase produced by P. gingivalis may enhance tissue destruction. An enterotoxin has been identified in B. fragilis strains associated with diarrheal disease in animals and young children. This 20-kDa zinc-dependent metalloprotease reversibly alters the morphology of the tight junctional complexes of intestinal epithelial cells. Both B. fragilis and P. melaninogenica possess lipopolysaccharides (endotoxins) that are less biologically potent than endotoxins associated with aerobic gram-negative bacteria. This relative biologic inactivity may account for the lower frequency of disseminated intravascular coagulation and purpura in Bacteroides bacteremia than in facultative and aerobic gram-negative bacillary bacteremia.

**CLINICAL MANIFESTATIONS** Anaerobic Infections of the Mouth, Head, and Neck (See also Chap. 27) Infections of the mouth can arise from either the supragingival or the subgingival dental plaque. Supragingival plaque formation begins with the adherence of gram-negative aerobic bacteria to the tooth surface. This form of plaque is influenced by salivary and dietary components, oral hygiene, and local host factors. Once the supragingival plaque is established, the acquisition of pathogenic bacteria and an increase in the amount of plaque are responsible for the ultimate development of gingivitis. Early bacteriologic changes in the supragingival plaque initiate an inflammatory response in the gingiva, including edema, swelling, and increased gingival fluid, and cause the development of caries and endodontic (pulp) infections. In addition, these changes contribute to the subsequent pathogenic alteration in the subgingival plaque that arises from poor or inadequate oral hygiene.

Subgingival plaque is associated with periodontal disease and disseminated infection arising from the oral cavity. Bacteria that colonize the subgingival area are primarily anaerobic. The black-pigmented gram-negative anaerobic bacilli (principally P. gingivalis, P. asaccharolytica, and P. melaninogenica) are the most important. Infections in this area are frequently mixed and involve both anaerobic and aerobic bacteria. After establishment of local infection either in root canals or in the periodontal area, infection may extend into the mandible, causing osteomyelitis of the maxillary sinuses, or to local tissues in the submandibular or submental spaces, depending on which teeth are involved. Periodontitis may also result in spreading infection that can involve adjacent bone or soft tissues.

**NECROTIZING ULCERATIVE GINGIVITIS** Gingivitis may become a necrotizing infection (trench mouth, Vincent’s stomatitis). The onset of disease is usually sudden and is associated with tender bleeding gums, foul breath, and a bad taste. The gingival mucosa, especially the papillae between the teeth, becomes ulcerated and may be covered by a gray exudate, which is removable with gentle pressure. Patients may become systemically ill, developing fever, cervical lymphadenopathy, and leukocytosis. Occasionally, ulcerative gingivitis can spread to the buccal mucosa, the teeth, and the mandible or maxilla, resulting in widespread destruction of bone and soft tissue. This infection is termed acute necrotizing ulcerative gingivitis (canecrum oris, noma). It destroys tissue rapidly, causing the teeth to fail out and large areas of bone—or even the whole mandible—to be sloughed. A strong putrid odor is frequently detected, although the lesions are not painful. The gangrenous lesions eventually heal, leaving large disfiguring defects. This infection most commonly follows a debilitating illness or affects severely malnourished children. It has been known to complicate leukemia or to develop in individuals with a genetic deficiency of catalase.

**ACUTE NECROTIZING INJECTIONS OF THE PHARYNX** These infections usually occur in association with ulcerative gingivitis. Symptoms include an extremely sore throat, foul breath, and a bad taste accompanied by fever and a sensation of choking. Examination of the pharynx demonstrates that the tonsillar pillars are swollen, red, ulcerated, and covered with
Anaerobic pleuropulmonary infections result from the aspiration of oropharyngeal contents, often in the context of an altered state of consciousness or an absent gag reflex. Four clinical syndromes are associated with anaerobic pleuropulmonary infection produced by aspiration: simple aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema.

**ASPIRATION PNEUMONITIS**

Aspiration pneumonitis must be distinguished from two other clinical syndromes associated with aspiration that are not of bacterial etiology. One syndrome results from aspiration of solids, usually food. Obstruction of major airways typically results in atelectasis and moderate nonspecific inflammation. Therapy consists of removal of the foreign body.

The second aspiration syndrome is more easily confused with bacterial aspiration. *Mendelson’s syndrome* results from regurgitation of stomach contents and aspiration of chemical material, usually gastric juices. Pulmonary inflammation—including the destruction of the alveolar lining, with transudation of fluid into the alveolar space—occurs with remarkable rapidity. Typically this syndrome develops within hours, often following anesthesia when the gag reflex is depressed. The patient becomes tachypneic, hypoxic, and febrile. The leukocyte count may rise, and the chest x-ray may evolve suddenly from normal to a complete bilateral “whiteout” within 8 to 24 h. Spontaneous production is minimal. The pulmonary signs and symptoms can resolve quickly with symptom-based therapy or can culminate in respiratory failure, with the subsequent development of bacterial superinfection over a period of days. Antibiotic therapy is not indicated unless bacterial infection supervenes. The signs of bacterial infection include sputum production, persistent fever, leukocytosis, and clinical evidence of sepsis.

In contrast to these syndromes, bacterial aspiration pneumonia develops more slowly. It is seen in patients who are hospitalized and have a depressed gag reflex, impaired swallowing, or a tracheal or nasogastric tube; elderly patients; or those with transiently impaired consciousness in the wake of seizures, cerebrovascular accidents, or alcoholic blackouts. Patients who enter the hospital with this syndrome typically have been ill for several days and generally report low-grade fever, malaise, and sputum production. Usually the history reveals factors predisposing to aspiration, such as alcohol overdose or residence in a nursing home. Sputum characteristically is not malodorous unless the process has been underway for at least a week. A mixed bacterial flora with many PMNs is evident on Gram’s staining of sputum. The most commonly encountered anaerobes in sputum in these infections are pigmented and nonpigmented *Prevotella* spp., *F. nucleatum*, *Peptostreptococcus* spp., and *Bacteroides* spp. Cultures are reliable only if contamination with the normal oral flora is avoided—that is, if specimens are obtained by open lung biopsy. In general, this procedure is not indicated in the evaluation of these patients. Chest x-rays show consolidation in dependent pulmonary segments: in the basilar segments of the lower lobes if the patient has aspirated while upright and in either the posterior segment of the upper lobe (usually on the right side) or the superior segment of the lower lobe if the patient has aspirated while supine. The organisms isolated from the lungs reflect the pharyngeal flora: *P. melaninogenica*, *Fusobacterium* spp., and anaerobic cocci are the most common isolates. The patient who aspirates in the hospital may also have a mixed infection involving enteric gram-negative rods.

**NECROTIZING PNEUMONITIS**

This form of anaerobic pneumonitis is characterized by numerous small abscesses that spread to involve several pulmonary segments. The process can be indolent or fulminating. This syndrome is less common than either aspiration pneumonia or lung abscess and includes features of both types of infection.

**ANAEROBIC LUNG ABSCESSES**

These abscesses result from subacute anaerobic pulmonary infection. The clinical syndrome typically involves a history of constitutional symptoms, including malaise, weight loss, fever, chills, and foul-smelling sputum, perhaps over a period of weeks (Chap. 239). Patients who develop lung abscesses characteristically have dental infection and periodontitis, but lung abscesses in edentu-
loos patients have been reported. Abscess cavities may be single or multiple and generally occur in persistent pulmonary segments (Fig. 148-1). Anaerobic abscesses must be distinguished from those associated with tuberculosis, neoplasia, and other conditions. Oral anaerobes predominate, although B. fragilis is isolated in up to 10% of cases. S. aureus may be found as well.

**EMPYEMA** Empyema is a manifestation of long-standing anaerobic pulmonary infection. The clinical presentation, which includes the presence of foul-smelling sputum, resembles that of other anaerobic pulmonary infections. Patients may report pleuritic chest pain and marked chest-wall tenderness.

Empyema may be masked by overlying pneumonitis and should be considered especially in cases of persistent fever despite antibiotic therapy. Diligent physical examination and the use of ultrasound to localize a loculated empyema are important diagnostic tools. The collection of a foul-smelling exudate by thoracentesis is typical. Cultures of infected pleural fluid yield an average of 3.5 anaerobes and 0.6 facultative or aerobic bacterial species. Drainage is required. Defervescence, a return to a feeling of well-being, and resolution of the process may require several months.

Extension from a subdiaphragmatic infection may also result in anaerobic empyema. Septic pulmonary emboli may originate from intraabdominal or female genital tract infections and can produce anaerobic pneumonia.

**Intraabdominal Infections** Enterotoxigenic B. fragilis has been associated with watery diarrhea in a small number of young children and adults. In case-control studies of children with undiagnosed diarrheal disease, enterotoxigenic B. fragilis was isolated from significantly more children with diarrhea than children in the control group. This organism may play a role in a small proportion of childhood diarrhea cases. Neutropenic enterocolitis (typhlitis) has been associated with anaerobic infection of the fecalum but—in the setting of neutropenia (Chap. 72)—may involve the entire bowel. Patients usually present with fever; abdominal pain, tenderness, and distention; and watery diarrhea. The bowel wall is edematous with hemorrhage and necrosis. The primary pathogen is thought by some authorities to be *Clostridium septicum*, but other clostridia and mixed anaerobic infections have also been implicated. More than 50% of patients developing early clinical signs can benefit from antibiotic therapy and bowel rest. Surgery is sometimes required to remove gangrenous bowel. →See Chap. 112 for a complete discussion of intraabdominal infections.

**Pelvic Infections** The vagina of a healthy woman is one of the major reservoirs of anaerobic and aerobic bacteria. In the normal flora of the female genital tract, anaerobes outnumber aerobes by a ratio of ~10:1 and include anaerobic gram-positive cocci and *Bacteroides* spp. Anaerobes are isolated from most women with genital tract infections that are not caused by a sexually transmitted pathogen. The major anaerobic pathogens are *B. fragilis*, *P. bivia*, *P. distens*, *P. melanogenica*, anaerobic cocci, and *Clostridium* spp. Anaerobes are frequently encountered in tubovarian abscess, septic abortion, pelvic abscess, endometritis, and postoperative wound infection, particularly following hysterectomy. Although these infections are often of mixed etiology, involving both anaerobes and coliforms, pure anaerobic infections without coliform or other facultative bacterial species occur more often in pelvic than in intraabdominal sites and are characterized by drainage of foul-smelling pus or blood from the uterus, generalized uterine or local pelvic tenderness, and continued fever and chills. Suppurative thrombophlebitis of the pelvic veins may complicate the infections and lead to repeated episodes of septic pulmonary emboli.

Anaerobic bacteria have been thought to be contributing factors in the etiology of bacterial vaginosis. This syndrome of unknown etiology is characterized by a profuse malodorous discharge and an increase in the number of bacteria in the vagina, including *Gardnerella vaginalis*, *Prevotella* spp., *Mobiluncus* spp., peptostreptococci, and genital mycoplasmas. Anaerobic bacteria are thought to play a role in the etiology of pelvic inflammatory disease (Chap. 115), and several investigations have shown an association between bacterial vaginosis and the development of pelvic inflammatory disease.

Pelvic infections due to *Actinomyces* spp. have been associated with use of intrauterine devices (Chap. 147).

**Skin and Soft Tissue Infections** Injury to skin, bone, or soft tissue by trauma, ischemia, or surgery creates a suitable environment for anaerobic infections. These infections are most frequently found in sites prone to contamination with feces or with upper airway secretions—for example, wounds associated with intestinal surgery, decubitus ulcers, or human bites. Anaerobic bacteria can be isolated in cases of crepitant cellulitis, synergistic cellulitis, or gangrene and necrotizing fasciitis (Chaps. 110 and 126). Moreover, these organisms have been isolated from cutaneous abscesses, rectal abscesses, and axillary sweat gland infections (hidradenitis suppurativa). Anaerobes are frequently cultured from foot ulcers in diabetic patients.

These soft tissue or skin infections are usually polymicrobial. A mean of 4.8 bacterial species are isolated, with an anaerobe-to-aerobe ratio of ~3:2. The most frequently isolated organisms include *Bacteroides* spp., peptostreptococci, enterococci, clostridia, and *Proteus* spp. The involvement of anaerobes in these types of infections is associated with a higher frequency of fever, foul-smelling lesions, gas in the tissues, and visible foot ulcer.

Anaerobic bacterial synergistic gangrene (Meleney’s gangrene) is characterized by exquisite pain, redness, and swelling followed by induration. Erythema surrounds a central zone of necrosis. A granulating ulcer forms at the original center as necrosis and erythema extend outward. Symptoms are limited to pain; fever is not typical. These infections usually involve a combination of *Peptostreptococcus* spp. and *S. aureus*; the usual site of infection is an abdominal surgical wound or the area surrounding an ulcer on an extremity. Treatment includes surgical removal of necrotic tissue and antimicrobial administration.

*Necrotizing fasciitis*, a rapidly spreading destructive disease of the fascia, is usually attributed to group A streptococci (Chap. 121) but can also be a mixed infection involving anaerobes and aerobes. The most frequently isolated anaerobes in these infections are *Peptostreptococcus* and *Bacteroides* spp. Gas may be found in the tissues. Similarly, myonecrosis can be associated with mixed anaerobic infection. *Fournier’s gangrene* consists of cellulitis involving the scrotum, perineum, and anterior abdominal wall, with mixed anaerobic organisms spreading along deep external fascial planes and causing extensive loss of skin.

**Bone and Joint Infections** Although actinomycosis (Chap. 147) accounts on a worldwide basis for most anaerobic infections in bone, organisms including peptostreptococci or microaerophilic cocci, *Bacteroides* spp., *Fusobacterium* spp., and *Clostridium* spp. can also be found. These infections frequently arise adjacent to soft tissue infections. Hematogenous seeding of bone is uncommon. *Prevotella* and *Porphyromonas* spp. are detected in infections involving the maxilla and
mandible, whereas Clostridium spp. have been reported as anaerobic pathogens in cases of osteomyelitis of the long bones following fracture or trauma. Fusobacteria have been isolated in pure culture from sites of osteomyelitis adjacent to the perinasal sinuses. Peptostreptococci and microaerophilic cocci have been reported as significant pathogens in infections involving the skull, mastoid, and prosthetic implants placed in bone. In patients with osteomyelitis (Chap. 111), the most reliable culture specimen is a bone biopsy sample free of normal uninected skin and subcutaneous tissue. In patients with anaerobic osteomyelitis, a mixed flora is frequently isolated from a bone biopsy specimen.

In cases of anaerobic septic arthritis, the most common isolates are Fusobacterium spp. Most of the patients involved have uncontrolled peritonitis. Anaerobic bacteria are found in blood from clinically ill patients when proper culture techniques are used. B. fragilis is the single most common anaerobic isolate from the bloodstream.

In recent years, the rate of isolation of anaerobic bacteria from blood cultures has been decreasing. Studies from the 1970s and early 1980s found that 10 to 15% of positive blood cultures yielded anaerobes, while more recent surveys have found rates as low as 4%. The cause of this change is unknown but may be related to the administration of antibiotic prophylaxis before intestinal surgery, the earlier recognition of localized infections, and the empirical use of broad-spectrum antibiotics for presumed infection.

Once the organism has been identified, both the portal of bloodstream entry and the underlying problem that probably led to seeding of the bloodstream can often be deduced from an understanding of the organism’s normal site of residence. For example, mixed anaerobic bacteremia including B. fragilis usually implies colonic pathology with mucosal disruption from neoplasia, diverticulitis, or some other inflammatory lesion. The initial manifestations are determined by the portal of entry and reflect the localized condition. When bloodstream invasion occurs, patients can become extremely ill, with rigors and hectic fevers ranging up to 40.6°C (105°F). The clinical picture may be quite similar to that seen in sepsis involving aerobic gram-negative bacilli. Although other complications of anaerobic bacteremia, such as septic thrombophlebitis and septic shock, have been reported, the incidence of these complications in association with anaerobic bacteremia is low. Anaerobic bacteremia is potentially fatal and requires rapid diagnosis and appropriate therapy. Mortality appears to increase with the age of the patient (with reported rates of >66% among patients >60 years old), with the isolation of multiple species from the bloodstream, and with the failure to surgically remove a focus of infection.

**Endocarditis and Pericarditis** (See also Chap. 109) Endocarditis due to anaerobes is uncommon. However, anaerobic streptococci, which are often classified incorrectly, are responsible for this disease more frequently than is generally appreciated. Gram-negative anaerobes are unusual causes of endocarditis. Signs and symptoms of anaerobic endocarditis are similar to those of endocarditis due to facultative organisms. The mortality rate for anaerobic endocarditis has been reported as 21 to 43%.

Anaerobes, particularly B. fragilis and Peptostreptococcus spp., are uncommonly found in infected pericardial fluids. Anaerobic pericarditis is associated with a mortality rate of >50%.

**DIAGNOSIS** There are three critical steps in the diagnosis of anaerobic infection: (1) proper specimen collection; (2) rapid transport of the specimens to the microbiology laboratory, preferably in anaerobic transport media; and (3) proper handling of the specimens by the laboratory. Specimens must be collected by meticulous sampling of infected sites, with avoidance of contamination by the normal flora. When such contamination is likely, the specimen is unacceptable. Examples of specimens unacceptable for anaerobic culture include sputum collected by expectoration or nasal tracheal suction, bronchoscopy specimens, samples collected directly through the vaginal vault, urine collected by voiding, and feces. Specimens that can be cultured for anaerobes include blood, pleural fluid, transtracheal aspirations, pus obtained by direct aspiration from an abscess cavity, fluid obtained by culdocentesis, suprapubic bladder aspirations, cerebrospinal fluid, and lung puncture specimens.

Because even brief exposure to oxygen may kill some anaerobic organisms and result in failure to isolate them in the laboratory, air must be expelled from the syringe used to aspirate the abscess cavity, and the needle must be capped with a sterile rubber stopper. Proper precautions should be used in the handling of contaminated needles. Specimens can be injected into transport bottles containing a reduced medium or taken immediately in syringes to the laboratory for direct culture on anaerobic media. In general, swabs should not be used. If a swab must be used, it should be placed in a reduced semisolid carrying medium before transport to the laboratory. Delays in transport may lead to a failure to isolate anaerobes due to exposure to oxygen or overgrowth of facultative organisms, which may eliminate or obscure any anaerobes that are present. All clinical specimens from suspected anaerobic infections should be Gram-stained and examined for organisms with characteristic morphology. It is not unusual for organisms to be observed on Gram’s staining but not isolated in culture. If purulent materials are found to be sterile or organisms are seen on Gram’s staining but do not grow in the culture, the involvement of anaerobes should be suspected.

Because of the time and difficulty involved in the isolation of anaerobic bacteria, diagnosis of anaerobic infections must frequently be based on presumptive evidence. Certain sites (such as avascular necrotic tissues) with lowered oxidation-reduction potential favor the diagnosis of an anaerobic infection. When infections occur in proximity to mucosal surfaces normally harboring an anaerobic flora, such as the gastrointestinal tract, female genital tract, or oropharynx, anaerobes should be considered as potential etiologic agents. A foul odor is often indicative of anaerobes, which produce certain organic acids as they proliferate in necrotic tissue. Although these odors are nearly pathognomonic for anaerobic infection, the absence of odor does not exclude an anaerobic etiology. Because anaerobes often coexist with other bacteria to cause mixed or synergistic infection, Gram’s staining of exudate frequently reveals numerous pleomorphic cocci and bacilli suggestive of anaerobes. Sometimes these organisms have morphologic characteristics associated with specific species.

The presence of gas in tissues is highly suggestive, but not diagnostic, of anaerobic infection. When cultures of obviously infected sites yield no growth, streptococci only, or a single aerobic species (such as Escherichia coli) and Gram’s staining reveals a mixed flora, the implication is that the anaerobic microorganisms failed to grow because of inadequate transport and/or culture techniques. Failure of a patient to respond to antibiotics that are not active against anaerobes (e.g., aminoglycosides and—in some circumstances—penicillin, cephalosporins, or tetracyclines) suggests anaerobic infection.

**TREATMENT** Successful therapy for anaerobic infections requires the administration of a combination of appropriate antibiotics, surgical resection, debridement of devitalized tissues, and drainage. Perforations must be closed promptly, closed spaces drained, tissue compartments decompressed,
and an adequate blood supply established. Abscess cavities should be drained as soon as fluctuation or localization occurs. Surgery was formerly required to establish drainage; however, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound now allow diagnostic radiologists to drain many abscess sites percutaneously.

**Antibiotic Therapy and Resistance**

Decisions about the treatment of anaerobic infections with antibiotics are usually based on known resistance patterns in certain species, on the likelihood of encountering a given species in the case at hand, and on Gram’s stain findings. Antibiotics active against *Bacteroides* spp., penicillin-resistant *Prevotella* and *Porphyromonas* spp., and *Fusobacterium* spp. can be grouped into four categories on the basis of their predicted activity against anaerobes (Table 148-1). (Nearly all the drugs listed have toxic side effects, which are described in detail in Chap. 118.) In many infections, anaerobes are mixed with coliforms and other facultative organisms. The best therapeutic regimens, therefore, are usually those active against both aerobic and anaerobic bacteria. The choice of empirical antibiotics for the anaerobes in mixed infections can nearly always be made reliably, since patterns of antimicrobial susceptibility are usually predictable (Chap. 118 and Table 148-1).

Antibiotic susceptibility testing of anaerobic bacteria has been difficult and controversial. Owing to the slow growth rate of many anaerobes, the lack of standardized testing methods and of clinically relevant standards for resistance, and the generally good results obtained with empirical therapy, there has been limited interest in testing these organisms for antibiotic susceptibility. However, a recent study found mortality rates of 45 and 16% among antibiotic-treated patients with *Bacteroides* blood isolates deemed resistant and sensitive, respectively, to the agent used. These figures suggest that in vitro susceptibility testing should be performed for *Bacteroides* isolates from hospitalized patients with bactereemia and that the results of this testing should guide treatment.

Clinically important *Bacteroides* spp. are essentially all resistant to penicillin, and penicillin resistance rates among *Porphyromonas*, *Prevotella*, and *Fusobacterium* spp. are increasing rapidly. Failures of therapy are common when documented *Bacteroides* (especially *B. fragilis*) infection is treated with penicillin or first-generation cephalosporins. The number of antimicrobial agents effective against *Bacteroides* has expanded, and there are currently several useful choices (Table 148-1). In general, cure rates of >80% can be attained in patients with *Bacteroides* infection by means of appropriate antimicrobial therapy and drainage.

Resistance to metronidazole has been reported mostly rarely in *Bacteroides* spp. This well-tolerated drug, which reaches significant levels in serum and can also be found at high concentrations in abscess cavities and anerobic infections, it is imperative that other appropriate antibi-otics be used in conjunction. Metronidazole is inactive against aerobic and facultative bacteria, *Actinomyces* spp., and *Propionibacterium* spp. The sensitivity of peptostreptococci to metronidazole is unpredictable, and penicillin remains the drug of choice.

If a patient fails to respond to one of the category 1 or category 2 drugs (Table 148-1), consideration should be given to alternative therapy and to determination of the resistance patterns among *Bacteroides* isolates. Although in vitro resistance of *Bacteroides* spp. to chloramphenicol has not been reported, this drug may not be as effective as other category 1 drugs. Ampicillin/sulbactam, ticarcillin/clavulanic acid, piperacillin/tazobactam, imipenem, and meropenem have been effective in the treatment of *B. fragilis* infection. Some newer quinolones, such as moxifloxacin, appear to be highly active in vitro against certain anaerobes, including *B. fragilis*, but not against all members of the *B. fragilis* group; consideration of their use must await appropriate clinical trials.

**Treatment of Infections at Specific Sites**

In clinical situations, specific regimens must be tailored to the initial site of infection. The duration of therapy also depends on the infection site; the reader is referred to specific chapters on sites of infection for recommendations.

* Usually needs to be given in combination with aerobic bacterial coverage. For infections originating below the diaphragm, aerobic gram-negative coverage is essential. For infections from an oral source, aerobic gram-positive coverage is added. Metronidazole also is not active against *Actinomyces*, *Propionibacterium*, or other gram-positive non-spore-forming bacilli (e.g., *Eubacterium*, *Bifidobacterium*) and is unreliable against peptostreptococci.

* Moxifloxacin appears to have in vitro activity against many anaerobes.

* Chloramphenicol is probably not as effective as other category 1 antimicrobials in treating anaerobic infections.

Although many oral anaerobic infections and most cases of anaerobic pneumonia still respond to penicillin therapy, some infections due to oral organisms fail to respond to this drug, and in these cases the use of a drug that is effective against penicillin-resistant anaerobes is recommended (Table 148-1). Life-threatening infections involving the anaerobic flora of the mouth, such as space infections of the head and neck, should be treated empirically as if penicillin-resistant anaerobes are involved. Less serious infections involving the oral microflora can be treated with penicillin alone; metronidazole can be added (or clindamycin can be substituted) if the patient responds poorly to penicillin therapy. Combinations of antibiotics used to treat mixed infections of oral origin must include drugs active against the gram-positive aerobic flora of the mouth.

Chloramphenicol has been used successfully against anaerobic central nervous system infections at doses of 30 to 60 mg/kg per day, with the exact dose depending on the severity of illness. However, penicillin G and metronidazole also cross the blood-brain barrier and are bactericidal for many anaerobic organisms (Chap. 360).

Anaerobic infections arising below the diaphragm (e.g., colonic and intraabdominal infections) must be treated specifically with agents active against *Bacteroides* spp. (Table 148-1). In intraabdominal sepsis (Chap. 112), the use of antibiotics effective against penicillin-resistant anaerobes has clearly reduced the incidence of postoperative infections and serious infectious complications. Specifically, a drug from cate-

**Section 8 Mycobacterial Diseases**

The physician is greatly challenged to provide optimal therapy for mycobacterial illnesses because of the increase in both drug-susceptible and multidrug-resistant tuberculosis; the increasing number of pathogenic nontuberculous mycobacteria (NTM); drug-related toxicities and drug-drug interactions (especially in patients who have AIDS, with their complex antiretroviral drug regimens); and the plethora of new antibiotics with antimycobacterial potential. This chapter reviews the therapeutic agents used for treatment of tuberculosis, leprosy (Hansen’s disease), and diseases caused by NTM, including *Mycobacterium avium-intracellulare* (MAI), *M. kansasii*, the rapidly growing mycobacteria, and *M. marinum*. The use of antimycobacterial agents in patients with renal or hepatic dysfunction and in pregnant women is summarized in Table 149-1. The effects of antimycobacterial agents on the levels, activity, and toxicity of other commonly used drugs are summarized in Table 149-2.

**TUBERCULOSIS**

Drugs used to treat tuberculosis have been classified into first-line and second-line agents. **First-line essential** antituberculous agents are the most effective and are a necessary component of any short-course therapeutic regimen. The three drugs in this category are rifampin, isoniazid, and pyrazinamide. The **first-line supplemental** agents, which are highly effective and infrequently toxic, include ethambutol and streptomycin. Favorable experience in patients with tuberculosis resistant to first-line essential drugs suggests that rifabutin and the fluorquinolones ciprofloxacin and levofloxacin are important additions to multidrug antituberculosis regimens; thus these agents have now been added to the list of first-line supplemental drugs. **Second-line antituberculous** drugs are clinically much less effective than first-line agents and elicit severe reactions much more frequently. These drugs are rarely used in therapy and then only by caregivers experienced with their use. The older agents include para-aminosalicylic acid (PAS), ethionamide, cycloserine, amikacin, and capreomycin. **Newer antituberculous** drugs, which have not yet been placed in the above categories, include rifapentine and the 8-methoxyfluoroquinolones gatifloxacin and moxifloxacin.

**FIRST-LINE ESSENTIAL ANTITUBERCULOUS DRUGS**

**Rifampin**

Rifampin, a semisynthetic derivative of *Streptomyces mediterranei*, is considered the most important and potent antituberculous agent. It is also active against a wide spectrum of other organisms, including some gram-positive and gram-negative bacteria, *Legionella* spp., *M. kansasi*, and *M. marinum*.

**MECHANISM OF ACTION**

Rifampin has both intracellular and extracellular bactericidal activity. It blocks RNA synthesis by specifically binding and inhibiting DNA-dependent RNA polymerase. Susceptible strains
of *M. tuberculosis* as well as *M. kansasii* and *M. marinum* are inhibited by ≤ 1 μg/mL.

**PHARMACOLOGY** Rifampin is a fat-soluble complex macrocyclic antibiotic that is absorbed readily after either oral or intravenous administration. Serum levels of 10 to 20 μg/mL follow a standard adult oral dose of 600 mg. Rifampin distributes well throughout most body tissues, including inflamed meninges. The fact that rifampin turns body fluids (urine, saliva, sputum, tears) a red-orange color makes it simple and inexpensive to check on patients’ compliance with therapy. Rifampin is excreted primarily through the bile and the enterohepatic circulation, while 30 to 40% of a dose is excreted via the kidneys. The drug is administered either twice weekly or daily at a dose of 600 mg for adults (10 mg/kg) and 10 to 20 mg/kg for children. As mentioned above, rifampin is also available for intravenous administration.

a Based on Food and Drug Administration pregnancy categories of A–D, X.

b Prudent but not absolutely necessary.

c Use in pregnancy is recommended by international organizations outside the United States.

**ADVERSE EFFECTS** (Table 149-3) Rifampin is generally well tolerated; the most common adverse event is gastrointestinal upset. Patients with chronic liver disease, especially those with alcoholism and the elderly, appear to be at unusually high risk for the most serious adverse drug reaction: hepatitis. Other adverse effects of rifampin include rash (0.8%), hemolytic anemia (<1%), thrombocytopenia, and immunosuppression of unknown clinical importance. Rifampin is a potent inducer of the hepatic microsomal enzymes and thereby decreases the half-life of a number of drugs, including digoxin, warfarin, prednisone, cyclosporine, methadone, oral contraceptives, clarithromycin, the HIV protease inhibitors, the HIV nonnucleoside reverse transcriptase inhibitors, and quinidine (Table 149-2). The dose of rifampin generally does not require reduction in patients with renal failure, especially those receiving intermittent rifampin administration (Table 149-1).

**RESISTANCE** Resistance to rifampin results from spontaneous point mutations that alter the β subunit of the RNA polymerase (rpoB) gene. Studies have shown that 96% of rifampin-resistant strains have a missense mutation within a 91-bp central core region of the gene. Rifampin-resistant strains of *M. leprae* have similar mutations that alter a single serine residue (Ser-425) in the same core region of the rpoB gene.

**Isoniazid** After rifampin, isoniazid is considered the best antituberculous drug currently available. Isoniazid should be included in all tuberculosis treatment regimens unless the organism is resistant. Isoniazid is inexpensive, readily synthesized, available worldwide, highly selective for mycobacteria, and well tolerated, with only 5% of patients exhibiting adverse effects.

**MECHANISM OF ACTION** Isoniazid is the hydrazide of isonicotinic acid, a small, water-soluble molecule that easily penetrates the cell. Its mechanism of action involves inhibition of mycolic acid cell-wall synthesis via oxygen-dependent pathways such as the catalase-peroxidase reaction. Isoniazid is bacteriostatic against resting bacilli and bactericidal against rapidly multiplying organisms, both extracellularly and intracellularly. The minimal inhibitory concentrations (MICs) of isoniazid for wild-type (untreated) strains of *M. tuberculosis* are <0.1 μg/mL, while those for *M. kansasii* are usually 0.5 to 2.0 μg/mL. The MICs of this drug for other NTM are often higher.

**PHARMACOLOGY** Both oral and intramuscular preparations of isoniazid are readily absorbed. The standard adult daily oral dose of 300 mg produces peak serum levels of 3 to 5 μg/mL. Isoniazid diffuses well throughout the body and reaches therapeutic concentrations in serum, cerebrospinal fluid (CSF), and infected tissue, including caseous granulomas. Isoniazid is metabolized in the liver via acetylation and hydrolysis; its metabolites are excreted into the urine. The rate of acetylation is genetically controlled. The recommended daily dose for the treatment of tuberculosis in the United States is 5 mg/kg for adults and 10 to 20 mg/kg for children, with a maximal daily dose of 300 mg for both groups. (Tuberculosis organizations outside the United States have recommended 5 mg/kg daily for both groups.) For inter-
Isoniazid can be given in an urgent situation. The adult dose rarely needs to be reduced below 200 mg/d. Although twice or thrice weekly is used. Even in moderate to severe renal failure, mittent therapy (usually directly observed), a maximal dose of 900 mg twice or thrice weekly is used. Even in moderate to severe renal failure, the adult dose rarely needs to be reduced below 200 mg/d. Although not approved by the Food and Drug Administration (FDA), intravenous isoniazid can be given in an urgent situation.

**ADVERSE EFFECTS** (Table 149-3) The two most important adverse effects of isoniazid therapy are hepatotoxicity and peripheral neuropathy. Other adverse reactions are either rare or less significant and include rash (2%), fever (1.2%), anemia, acne, arthritic symptoms, a systemic lupus erythematosus—like syndrome, optic atrophy, seizures, and psychiatric symptoms. Isoniazid-associated hepatitis is idiosyncratic and increases in incidence with age, daily alcohol consumption, concomitant rifampin administration, and HIV infection as well as in women who are pregnant or in the immediate (3 months) postpartum period. Appropriate clinical monitoring of patients receiving isoniazid includes at least monthly questioning about hepatitis-related symptoms and filling of prescriptions for no more than 1 month’s worth of medication. Clinical monitoring is essential for all patients since discontinuation of the drug at the onset of hepatitis symptoms reduces the risk of progression to fatal hepatitis. The Centers for Disease Control and Prevention (CDC) and the American Thoracic Society (ATS) recommend that serum concentrations of aspartate aminotransferase (AST) or alanine aminotransferase (ALT) be determined at baseline in patients with liver disorders or HIV infection, in women who are pregnant or in the immediate postpartum period (3 months), in persons with a history of liver disease (e.g., hepatitis B or C, alcoholic hepatitis, or cirrhosis), in persons who use alcohol regularly, and in other individuals at risk for chronic liver disease who are receiving isoniazid for treatment of latent tuberculosis. Baseline testing is no longer routinely indicated in persons >35 years of age. Routine laboratory monitoring during isoniazid treatment is indicated for patients whose baseline liver function tests yield abnormal results and for persons at risk for hepatic disease, including the groups just mentioned. Measurement of the ALT or AST level is certainly mandatory whenever a patient notices the onset of symptoms suggestive of isoniazid-associated hepatitis (e.g., fever, anorexia, nausea, vomiting, and/or a flulike syndrome including fever and myalgias), and treatment should be discontinued until the relationship between therapy and symptoms is ascertained. Several studies have demonstrated that many patients with isoniazid intolerance can be desensitized. The CDC/ATS recommends that discontinuation of isoniazid be strongly considered whenever any asymptomatic elevation of the AST or ALT level exceeds 150 to 200 IU (three to five times the upper limit of normal) in high-risk patients whose baseline values were normal. In one study, only 11 (0.1%) of 11,141 patients had hepatotoxic reactions to isoniazid during preventive treatment.

Peripheral neuritis associated with isoniazid is uncommon and probably relates to interference with pyridoxine (vitamin B₆) metabolism. The risk of isoniazid-related neurotoxicity is greatest for patients with preexisting disorders that also pose a risk of neuropathy, such as diabetes, alcohol abuse, or malnutrition. In these patients, the prophylactic administration of 25 to 50 mg of pyridoxine daily should be considered.

**RESISTANCE** Isoniazid-resistant mutants of *M. tuberculosis* occur spontaneously at a rate of 1 in 10⁶ to 10⁷ organisms. The molecular sites of isoniazid resistance have been detailed. Most isoniazid-resistant strains have amino acid changes in either the catalase-peroxidase gene (*katG*) or the promoter of a two-gene locus known as *inhA*. Missense mutations or deletion of *katG* is also associated with reduced catalase and peroxidase activity. Rates of primary isoniazid resistance in untreated patients are much higher in many foreign-born populations than in populations born in the United States.

**Pyrazinamide** A derivative of nicotinic acid, pyrazinamide is an important bactericidal drug used in short-course therapy for tuberculosis.

**MECHANISM OF ACTION** Pyrazinamide is similar to isoniazid in its narrow spectrum of antibacterial activity, which essentially includes only *M. tuberculosis*. The drug is bactericidal to slowly metabolizing organisms located within the acidic environment of the phagocyte or c eosus granuloma; it is active only at a pH of <6.0. Pyrazinamide is considered a prodrug and is converted by the tubercle bacillus to the active form pyrazinoic acid. The target for this compound is thought to be a fatty acid synthase gene (*fasI*). Susceptible strains of *M. tuberculosis* are inhibited by 20 μg/mL.

**PHARMACOLOGY** Pyrazinamide is well absorbed after oral administration, with a plasma concentration range of 20 to 60 μg/mL 1 to 2 h after oral ingestion of the currently recommended adult daily dose of 15 to 30 mg/kg (maximum, 2 g/d). The drug is well distributed throughout the body. Levels in CSF are excellent, reaching 50 to 100% of levels.
in serum. The serum half-life of the drug is 9 to 11 h. Pyrazinamide is metabolized by at least two major pathways and one minor pathway in the liver; its several metabolites include pyrazinoic acid, 5-hydroxy-pyrazinamide, and 5-hydroxypyrazinoic acid. Pyrazinamide is not available in a parenteral formulation.

ADVERSE EFFECTS (Table 149-3) At the high dosages used in the past, hepatotoxicity was a prominent complication of pyrazinamide therapy. However, at the currently recommended dosages, the frequency of hepatotoxicity is no higher than that for concomitant isoniazid and rifampin therapy. Although pyrazinamide is recommended by international tuberculosis organizations for routine use in pregnancy, it is not recommended in the United States because of inadequate teratogenicity data (Table 149-1). The combination of rifampin/pyrazinamide once recommended for treatment of latent tuberculosis has recently been shown to have an unacceptably high rate of hepatitis. Hyperuricemia is a common adverse effect of pyrazinamide therapy; the incidence is probably reduced by concurrent rifampin therapy. Clinical gout is seen only rarely. Polyarthralgias are encountered fairly commonly but are not related to the hyperuricemia.

RESISTANCE Resistance to pyrazinamide is associated with loss of pyrazinamidase activity such that pyrazinamide is no longer converted to pyrazinoic acid. More than 90% of isolates with MICs of >100 μg/mL have mutations in the pncA gene, which encodes for pyrazinamide. All strains of M. bovis are naturally resistant to pyrazinamide and have a point substitution within the pncA gene.

FIRST-LINE SUPPLEMENTAL DRUGS Ethambutol A derivative of ethylenediamine, ethambutol is a water-soluble compound that is active only against mycobacteria. Susceptible species include M. tuberculosis, M. marinum, M. kansasi, and MAI. Among first-line drugs, ethambutol is the least potent against M. tuberculosis. It is used most often with rifampin for treatment of tuberculosis in patients who cannot tolerate isoniazid or who are thought or known to be infected with isoniazid-resistant organisms.

MECHANISM OF ACTION Ethambutol at standard doses is bacteriostatic against M. tuberculosis. Its primary mechanism of action appears to be inhibition of an arabinosyltransferase that mediates the polymerization of arabinose into arabinogalactan within the cell wall.

PHARMACOLOGY After oral administration, 75 to 80% of a dose of ethambutol is absorbed from the gastrointestinal tract. Peak serum levels of 2 to 4 μg/mL are achieved 2 to 4 h after the standard adult daily dose of 15 mg/kg. The drug’s distribution throughout the body is adequate except in the CSF, where it reaches only low levels. However, ethambutol can reach CSF levels up to 50% as high as peak plasma levels when administered at a daily dosage of 25 mg/kg (which may be given in one dose) for the first 2 months, with subsequent reduction to 15 mg/kg. In cases of drug-resistant tuberculosis or where re-treatment is necessary, the higher dose may be given for the duration. For intermittent therapy, the dosage is 50 mg/kg twice weekly or 30 mg/kg thrice weekly. The dosage must be lowered for patients with renal insufficiency (a creatinine clearance rate of <50 mL/min) to prevent drug accumulation and toxicity.

ADVERSE EFFECTS Ethambutol is usually well tolerated. Retinal optic neuritis is the most serious adverse effect; axial or central neuritis—the only form reported in patients taking doses of <30 mg/kg—involves the papillomacular bundle of fibers and results in reduced visual acuity, central scotoma, and loss of ability to see green. Symptoms of ocular toxicity typically develop several months after initiation of therapy, but rapid-onset optic neuritis has been reported. The risk of optic neuritis depends on the dose and duration of therapy: this reaction develops in 5% of patients receiving a daily dose of 25 mg/kg but in fewer than 1% of patients given a daily dose of 15 mg/kg. Patients taking the lower dose should be tested at baseline and whenever there is a subjective visual change for visual acuity and red-green color discrimination. Patients taking the higher dose should be tested at baseline, monthly thereafter, and whenever there is subjective visual change. Intermittent (three times weekly) administration of ethambutol at 25 mg/kg per dose appears to be better tolerated than daily administration of 15 mg/kg, especially in elderly populations being treated for M. avium complex infection. Optic neuritis with associated visual loss is usually reversible, but recovery may take >6 months.

Other adverse effects of ethambutol are infrequent. Hyperuricemia occurs but is usually asymptomatic. Peripheral sensory neuropathy occurs in rare instances. Optic neuritis is rare at the low dose in children; however, the use of ethambutol in very young children is problematic because visual complications are difficult to monitor.

RESISTANCE Ethambutol resistance in M. tuberculosis most commonly relates to missense mutations in the embB gene that encodes for arabinosyltransferase. Such mutations have been found in 70% of resistant strains and involve amino acid replacements at position 306 or 406 in ~90% of cases. Species of NTM that are intrinsically resistant to ethambutol have variant amino acids in this region of the gene, while susceptible species have the same amino acid sequences as M. tuberculosis.

Streptomycin An aminoglycoside isolated from Streptomyces griseus, streptomycin is available for intramuscular and intravenous administration only. In the United States, it is the least-used first-line supplemental drug for tuberculosis because of its toxicity, the difficulty in obtaining adequate CSF levels, and the inconvenience of parenteral administration. In developing countries, however, streptomycin is frequently used because of its low cost. The drug is active against untreated strains of M. tuberculosis, M. kansasi, and M. marinum and against some strains of the M. avium complex at achievable serum levels.

MECHANISM OF ACTION Streptomycin inhibits protein synthesis by disruption of ribosomal function.

PHARMACOLOGY Serum levels of streptomycin peak at 25 to 40 μg/mL after a 1.0-g dose. Streptomycin is bactericidal for rapidly dividing extracellular mycobacteria but is ineffective in the acidic environment within the macrophage. It diffuses poorly into the meninges and, in patients with meningitis, reaches CSF levels that are only 20% of serum levels.

The usual adult dose of streptomycin for a 70-kg patient is 0.5 to 1.0 g (10 to 15 mg/kg) given intramuscularly daily or five times per week; the pediatric dose is 20 to 40 mg/kg daily, with a maximum of 1 g/d. Because streptomycin is eliminated almost exclusively by the kidneys, the dosage must be lowered and the frequency of administration reduced (to only two or three times per week) in most patients >50 years of age and in any patient with renal impairment (Table 149-1) or reduced body weight. Although this approach is not approved by the FDA, streptomycin can be given intravenously.

ADVERSE EFFECTS (Table 149-3) Adverse reactions to streptomycin therapy occur in 10 to 20% of recipients. Otoxicity and renal toxicity are the most common and the most serious. Renal toxicity, usually manifested as nonoliguric renal failure, is less common with streptomycin than with other frequently used aminoglycosides, such as gentamicin. Ototoxicity involves both hearing loss and vestibular dysfunction. The latter is more common and includes loss of balance, vertigo, and tinnitus. Patients receiving streptomycin must be monitored carefully for these adverse effects. Less serious reactions include perioral paresthesia, cosinophilia, rash, and drug fever.

RESISTANCE Spontaneous resistance to streptomycin occurs in 1 in 106 to 108 organisms. In two-thirds of streptomycin-resistant strains of M. tuberculosis, mutations have been identified in one of two targets: a 16S rRNA gene (rrs) or the gene encoding ribosomal protein S12 (rpsL). Both targets are believed to be involved in streptomycin ribosomal binding. No mutational change has been identified in the other one-third of resistant isolates. Strains of M. tuberculosis resistant to streptomycin are not cross-resistant to capreomycin or amikacin.
SECOND-LINE ANTITUBERCULOUS DRUGS  Second-line and/or newer antituberculosis agents are used either when tuberculosis is drug resistant or when first-line supplemental drugs are not available. The more important second-line drugs are discussed below in their general (descending) order of usefulness.

Quinolones  A surprisingly large number of fluorinated quinolones are being developed and studied as inhibitors of mycobacteria. Their mode of action presumably is the prevention of DNA synthesis through the inhibition of DNA gyrase. Ofloxacin, levofloxacin, ciprofloxacin, gatifloxacin, and moxifloxacin are active against many mycobacteria, including M. tuberculosis, M. leprae, M. marinum, M. kansasi, and M. fortuitum. These drugs are well absorbed orally, reach high serum levels, and distribute well to body tissues and fluids. While not approved for antituberculosis therapy in the United States, ofloxacin—used in combination with isoniazid and rifampin for the treatment of pulmonary tuberculosis—has been as active and safe as ethambutol in initial trials. Adverse effects are relatively uncommon, occurring in 0.5 to 10% of cases and consisting mostly of benign reactions such as gastrointestinal intolerance, rashes, dizziness, and headache. However, more serious adverse effects are being reported and include confusion, seizures, interstitial nephritis, skin vasculitis, and acute renal failure. The quinolones are rapidly becoming some of the most important and effective drugs for the treatment of tuberculosis resistant to first-line essential drugs. Some experts would classify the quinolones as first-line supplemental agents. The quinolones can also be administered intravenously.

Mycobacterial resistance to the fluoroquinolones develops rapidly. Its molecular basis is complex; only some strains exhibit missense mutations in the A subunit (gyrA gene) of DNA gyrase. Fluoroquinolone-resistant tuberculosis is a source of growing concern. Antituberculous therapy with quinolones should be reserved for patients with multidrug resistance and for those who cannot tolerate first-line drugs.

Capreomycin  Capreomycin, a complex cyclic polypeptide antibiotic derived from Streptomyces capreolus, is similar to streptomycin in terms of dosing, mechanism of action, pharmacology, and toxicity. It is administered only by the intramuscular route in doses of 10 to 15 mg/kg daily or five times per week (maximal daily dose, 1 g), with peak blood levels of 20 to 40 μg/mL. After 2 to 4 months, the dosage should be reduced to 1 g two or three times a week. Cross-resistance to kanamycin and amikacin—but not to streptomycin—is common. After streptomycin, capreomycin is the injectable drug of choice for tuberculosis.

Rifabutin  Rifabutin, a semisynthetic rifamycin spiroperidyl derivate, shares many characteristics with rifampin, including its activity against M. tuberculosis. Rifabutin is also active against some strains of rifampin-resistant M. tuberculosis and is more active than rifampin against the M. avium complex and other NTM. To date, rifabutin has been most useful in the prophylaxis of disseminated MAI infection and in the treatment of drug-resistant tuberculosis. Because it is able to exhibit more antituberculous activity than rifampin in vitro and in animals, its possible clinical advantages over rifapentine are being evaluated. In a multinational trial in which either rifampin (600 mg/d) or rifabutin (150 mg/d) was administered in combination with isoniazid plus a 2-month regimen of pyrazinamide and ethambutol, the two rifamycins were equally effective and well tolerated in the treatment of newly diagnosed pulmonary tuberculosis. Rifabutin is recommended in place of rifampin for the treatment of HIV-positive individuals who are also taking a protease inhibitor because its effect on these agents is less pronounced (Table 149-2).

MECHANISM OF ACTION  In Escherichia coli and Bacillus subtilis, rifabutin inhibits DNA-dependent RNA polymerase in the same manner as rifampin. Its mode of action against mycobacteria is believed to be the same.

PHARMACOLOGY  The pharmacology of rifabutin is dramatically different from that of rifampin. Rifabutin is readily absorbed after a single oral dose of 300 mg and reaches peak serum levels (0.35 μg/mL) in 2 to 4 h. This lipophilic drug distributes best to tissues; tissue levels are 5 to 10 times higher than plasma levels. CSF concentrations are 30 to 70% of plasma levels in HIV-infected patients who have meningitis. The drug’s slow clearance via hepatic metabolism and renal excretion results in a mean serum half-life of 45 h, which is much longer than the 3- to 5-h half-life of rifampin. Clarithromycin (but not azithromycin) and fluconazole appear to block the hepatic metabolism of rifabutin, with consequent increases in serum levels. When rifabutin is administered orally with food, its rate of absorption is slowed but the extent of absorption is unchanged. Adjustment of dosage is usually unnecessary in elderly patients and in patients with reduced hepatic or renal function (Table 149-1).

ADVERSE EFFECTS  The majority of rifabutin’s adverse effects are dose related and occur most frequently in patients receiving >300 mg/d. Discontinuation of therapy because of adverse drug reactions is reported in 16% of patients receiving rifabutin as opposed to 8% of those receiving a placebo. The most common symptoms are gastrointestinal; other reactions include rash, headache, asthenia, chest pain, myalgia, and insomnia. Like those taking rifampin, most patients taking rifabutin have discolored (orange to tan) urine and other body fluids. Less common adverse reactions include fever, chills, a flulike syndrome, hepatitis, Clostridium difficile–associated diarrhea, a diffuse polymyalgia syndrome, and a yellow skin discoloration (“pseudojaundice”). After a rifabutin dose of 450 or 600 mg in combination with clarithromycin, anterior uveitis is reported in up to 40% of patients; also common at these high doses are hyperpigmentation and the polymyalgia/arthritis syndrome. All of these conditions are reversible when treatment is discontinued. Laboratory abnormalities include neutropenia, leukopenia, thrombocytopenia, and increased levels of liver enzymes.

Rifabutin induces the hepatic cytochrome P450 enzymes but does so much less strongly than rifampin. Drugs whose metabolism is enhanced by rifabutin include anticoagulants, quinidine, oral contraceptives, sulfonyleureas, analgesics, dapsone, narcotics, glucocorticoids, clarithromycin, zidovudine, protease inhibitors, nonnucleoside reverse transcriptase inhibitors, and cardiac glycosides.

RESISTANCE  Resistance to rifabutin is attributable to the same mechanism as that to rifampin—i.e., mutations involving the rpoB gene. However, of the 14 mutant rpoB alleles that confer resistance to rifampin, only 9 confer high-level resistance to rifabutin, while the remaining 5 result in only small changes in rifabutin MICs, which remain at ≥0.5 μg/mL. The MIC of rifabutin for susceptible strains of M. tuberculosis is low (<0.06 μg/mL), and the drug is considered clinically active against partially resistant strains that are inhibited by plasma levels of ≥0.5 μg/mL. Thus rifabutin inhibits about one-quarter of rifampin-resistant strains of M. tuberculosis.

Amikacin  This well-known aminoglycoside is bactericidal to extracellular organisms. Amikacin is active against M. tuberculosis and several of the nontuberculosis species, including the rapidly growing mycobacteria, M. kansasi, M. leprae, and the M. avium complex. The usual adult dosage is 7 to 10 mg/kg intramuscularly or intravenously three to five times per week (generally no more than 500 to 750 mg/d). Resistance relates to a single A→G base-pair change at position 1408 in the 16S ribosomal RNA gene.

Ethionamide  Like isoniazid and pyrazinamide, ethionamide is a derivative of isonicotinic acid. This agent is bacteriostatic against metabolizing M. tuberculosis and some NTM. It is most useful in the treatment of multidrug-resistant tuberculosis. However, its use is severely limited by its toxicity and frequent side effects, which include intense gastrointestinal intolerance (anorexia, vomiting, and dysgeusia), serious neurologic reactions, reversible hepatitis (5% of cases), hypersensitivity reactions, and hypothyroidism. Ethionamide is well
Para-Aminosalicylic Acid PAS as a calcium or sodium salt inhibits the growth of *M. tuberculosis* by impairing folate synthesis. It is rarely indicated for the treatment of tuberculosis because of its low level of antituberculous activity and its high level of gastrointestinal toxicity (manifesting as nausea, vomiting, and diarrhea). Enteric-coated PAS granules (4 g every 8 h) may be better tolerated than other formulations and produce higher therapeutic blood levels. PAS is well absorbed after oral administration but reaches only low concentrations in the CSF. The drug has a short half-life (1 h), and 80% of the dose is excreted in the urine.

Cycloserine Cycloserine (D-4-amino-3-isoxazolidinone) is produced by *Streptomyces orchidaceus* and is active against a broad spectrum of bacteria, including *M. tuberculosis*. Cycloserine is well absorbed after oral administration and is widely distributed throughout body fluids, including the CSF. Serious side effects limit the use of this drug and include psychosis (with suicide in some cases), seizures, peripheral neuropathy, headaches, somnolence, and allergic reactions. Cycloserine should not be given to patients with epilepsy, active alcohol abuse, severe renal insufficiency, or a history of depression or psychosis.

NEWER ANTITUBERCULOUS DRUGS A number of drugs are being evaluated for their antituberculous activity. This group includes rifapentine, the newer 8-methoxyfluoroquinolones gatifloxacin and moxifloxacin, clarithromycin, linezolid and other oxazolidinones, and rifamycins not yet approved by the FDA, such as KRM-1648 (benzoxazinorifamycin).

Rifapentine A semisynthetic cyclopentyl rifamycin antibiotic, rifapentine has received accelerated approval from the FDA for the treatment of tuberculosis. It is the first new drug approved for tuberculosis in the United States in 25 years. While similar to rifampin, rifapentine is lipophilic and longer acting—characteristics that enhance patient compliance; the drug can be administered at a dose of 600 mg once or twice weekly. It is active against *M. tuberculosis* but has undergone only minimal testing against NTM. Rifapentine has not yet been approved for the treatment of patients with HIV disease because rifapentine/rifampin monoresistance frequently develops in HIV-positive patients receiving isoniazid plus once-weekly rifapentine. Like rifampin, rifapentine is active against many nonmycobacterial organisms, including *Haemophilus influenzae*, *Bordetella pertussis*, *Bordetella parapertussis*, *Brucella* spp., *Legionella* spp., *Neisseria* spp., streptococci, and staphylococci.

In a randomized comparative study, 672 Chinese patients received isoniazid plus either rifapentine or rifampin. The isoniazid/rifapentine group had a higher relapse rate than the isoniazid/rifampin group (10% vs 5%). Nevertheless, this disadvantage was considered acceptable in light of the lower rate of adverse effects and the less frequent administration for isoniazid/rifapentine.

**MECHANISM OF ACTION** Rifapentine exerts its bactericidal effect by inhibiting DNA-dependent RNA polymerase in susceptible bacteria. The MICs of rifapentine for rifampin-susceptible strains of *M. tuberculosis* range from 0.03 to 0.12 μg/mL.

**PHARMACOLOGY** Food enhances the oral absorption of rifapentine, whereas antacids impair its absorption. After oral administration with food, this drug reaches peak serum concentrations in 5 to 6 h and achieves a steady state in 10 days. The half-life of rifapentine and its active metabolite 25-desacetyl rifapentine is ~13 h. The administered dose is excreted via the liver (70%). Oral clearance is more rapid in males than in females (2.51 vs 1.69 L/h), but the clinical significance of this difference is unknown.

**ADVERSE EFFECTS** Rifapentine demonstrates an adverse-event pattern similar to that of rifampin. Both drugs are frequently associated with hyperuricemia when administered with pyrazinamide and with elevated hepatocellular enzyme levels in 3 to 4% of patients when administered with other antituberculous agents. Liver enzyme levels should be monitored in patients receiving rifapentine who already have elevated liver enzyme concentrations or known liver disease. Like rifampin, rifapentine causes an orange-red discoloration of body fluids, including urine, saliva, and tears, and stains contact lenses.

Rifapentine induces the hepatic cytochrome P450 enzymes CYP3A4 and 2C8/9. Current induction studies suggest that its potential for drug-drug interaction may be less than that of rifampin but greater than that of rifabutin. Other drugs potentially affected by concomitant administration of rifapentine are listed in Table 149-2.

Rifapentine is in category C for use in pregnancy (Table 149-1) because of its teratogenesis in rats and rabbits. There are insufficient data concerning use of this drug in pregnant and breast-feeding patients.

**RESISTANCE** Strains of *M. tuberculosis* resistant to rifapentine, rifampin, and rifabutin all involve spontaneous point mutations in the rpoB gene. All strains resistant to rifampin are also resistant to rifapentine.

**LEPROSY (HANSEN’S DISEASE)** Therapy for leprosy remains difficult, especially in developing countries. Obstacles include the long courses of drug therapy required, the high cost and low availability of most drugs, the frequency of adverse drug reactions, the difficulty of determining a treatment endpoint, and (given that *M. leprae* still cannot be grown in vitro) the difficulty of conducting susceptibility testing. While many drugs are active against *M. leprae*, efficacy in the treatment of leprosy has been established only for dapsone, rifampin, clofazimine, and ethionamide. Initiation of multidrug treatment has reduced the problem of acquired drug resistance seen previously with dapsone monotherapy.

**Rifampin** Rifampin is considered the most active agent for the treatment of leprosy. Its worldwide use is limited only by its cost. This drug is highly bactericidal against *M. leprae* and reduces the number of viable bacilli in patients’ tissues faster than any other available agent. Rifampin must be combined with other antileprosy drugs to forestall resistance. For cost reasons, the drug dose of 600 mg is given once a month (supervised) outside the United States, but it is given daily in the United States. For details on pharmacology, adverse events, and resistance, see relevant sections under “Tuberculosis.” Allergic interstitial nephritis is a rare but significant complication of rifampin use in Hansen’s disease.

**Dapsone** Dapsone (4,4’-diaminodiphenylsulfone) inhibits bacterial folic acid synthesis. It is now considered the second most active drug (after rifampin) in the treatment of Hansen’s disease because of its ready availability, low cost, and low toxicity and the susceptibility of untreated strains of *M. leprae* to low concentrations.

**PHARMACOLOGY** Dapsone is well absorbed orally and distributes well throughout the body. The usual daily dosage is 100 mg for adults and 0.9 to 1.4 mg/kg for children. Plasma concentrations peak within 1 to 3 h. The median elimination half-life is 22 h. Dapsone is cleared by acetylation in the liver, with genetic variation similar to that documented for the acetylation of isoniazid. The drug is 70% bound to plasma protein. Usual daily doses produce serum concentrations of 10 to 15 μg/mL, which far exceed the MIC for *M. leprae* (0.01 to 0.001 μg/mL).

**ADVERSE EFFECTS** Hemolysis and methemoglobinemia are common untoward reactions to dapsone. Patients should be screened for glucose-6-phosphate dehydrogenase deficiency to prevent serious drug-induced hemolysis. However, most patients tolerate dapsone therapy well with adequate clinical and laboratory supervision. Other side effects include gastrointestinal intolerance, headache, pruritus, peripheral neuropathies, nephrotic syndrome, fever, and rash. In lepromatous and borderline lepromatous leprosy, erythema nodosum leprosum (ENL) may occur. ENL and other reactions of leprosy may be difficult...
to distinguish from drug reactions and the infectious mononucleosis—like syndrome due to dapsone.

Clofazimine A phenazine iminiquinone dye, clofazimine is weakly bactericidal against *M. lepraemurium*. It is useful in treating dapsone-resistant leprosy and may lessen the severity of ENL. Clofazimine’s mode of action is not well understood, but the drug may inhibit DNA binding. It is absorbed orally and distributed to the fatty tissues and the reticuloendothelial system. Its serum half-life is ~60 to 70 days; only a small proportion of the dose is excreted daily into the urine or bile. Bactericidal activity is very slow and is evident for ~50 days after administration. The usual adult dosage is 50 to 100 mg/d, 100 mg three times a week, or (for treatment of ENL) 300 mg/d. Untoward effects include skin discoloration and, less commonly, gastrointestinal intolerance. Clofazimine was reported to be responsible for a case of cardiotoxicity induced via ventricular arrhythmia. Even though clofazimine-resistant disease has been reported only rarely when this agent is used alone, it should be used with other effective antibiotics. Clofazimine is active in vitro against some NTM species, including *M. kansasii*, *M. simiae*, and *M. abscessus*.

Ethionamide While ethionamide (250 mg/d) has not been approved by the FDA for the treatment of leprosy, it is sometimes used in the United States in combination with rifampin (600 mg/d) to treat dapsone-resistant leprosy in patients who cannot accept the skin-pigmentation effect of clofazimine. Because resistance to ethionamide develops quickly when the drug is used alone, it must be used with other effective agents. Patients should be monitored closely for hepatotoxicity when taking ethionamide (especially in combination with rifampin), and treatment should be discontinued if the patient’s ALT levels exceed 2.5 times the normal value. Prothionamide, a congener of ethionamide that is not available in the United States, has pharmacologic properties similar to those of ethionamide and is widely used throughout the world.

Other Agents A number of other drugs exhibit significant activity against *M. lepraemurium*, but clinical experience with these agents is lacking. Thalidomide is now approved by the FDA for treatment of ENL. This drug is sedating and extremely teratogenic and should never be taken by anyone who is or may become pregnant. Physicians wishing to prescribe thalidomide must register with the System for Thalidomide Education and Prescription Safety (S.T.E.P.S) at 1-888-423-5436 (Celgene Corporation); the sole exceptions to this registration requirement are physicians at Hansen’s disease clinics that are receiving medication support from the national Hansen’s disease program. It is noteworthy that ENL may be a presenting feature of Hansen’s disease before treatment. It is not considered an adverse drug reaction but may be confused with drug reaction states.

The newer macrolide antibiotics (particularly clarithromycin), macrolides (long-acting tetracycline), and a number of fluoroquinolones (including ofloxacin, sparfloxacin, and pefloxacin) have shown promising bactericidal activity against *M. lepraemurium*. Ofloxacin and macrolides are being investigated with rifampin in short-course regimens for lepromatous disease. All of these newer leprosy drugs have low toxicity profiles, modes of action different from those of the established agents, and bactericidal activity against *M. lepraemurium*. However, their levels of bactericidal activity are lower than that of rifampin.

**NONTUBERCULOUS MYcobacteria**

Although less pathogenic than *M. tuberculosis*, NTM can cause pulmonary, skin, bone, joint, lymph node, and soft tissue infection as well as disseminated disease in immunocompromised hosts, including patients with AIDS. MAI and *M. kansasii* are the two most common causes of NTM pulmonary infection. Up to 40% of AIDS patients with CD4+ cell counts of ~50/μL develop disseminated disease due to *M. avium* unless they are receiving specific *M. avium* prophylaxis.

**Clarithromycin** Clarithromycin (6-O-methylerythromycin) is a newer macrolide that is similar to erythromycin in its mechanism of action. It is well absorbed with or without meals and elicits little gastrointestinal intolerance at low doses. Clarithromycin distributes well into body tissues and fluids and is highly concentrated in macrophages. The drug is metabolized in the liver, with ~30% of a given dose excreted in the urine. The dosage should be reduced if the creatinine clearance rate is ≤30 mL/min. Like erythromycin, clarithromycin binds with plasma proteins (65 to 70%) and can raise the levels of drugs such as theophylline and carbamazepine. Serum levels of clarithromycin are reduced by rifampin and, to a lesser degree, by rifabutin; clarithromycin increases serum levels of rifabutin and some antibiotics (e.g., terfenadine), thus potentially increasing their toxicity. Clarithromycin and (probably) azithromycin are the most active agents for the treatment of MAI infections; one of these drugs is considered an essential component of any regimen for this purpose. However, because of the risk of mutational drug resistance, clarithromycin should be given in combination with other agents, such as ethambutol and rifampin or rifabutin. The drug is also highly active against almost all other NTM, including *M. marinum*, *M. kansasi*, *M. haemophilum*, *M. genavense*, *M. xenopi*, *M. abscessus*, *M. chelonae*, and most isolates of *M. fortuitum*. Standard antimycobacterial doses have been 500 mg twice daily or, in the case of MAI pulmonary disease, three times weekly. The more common side effects of high doses include nausea, vomiting, and (occasionally) abnormal liver function tests. A bitter taste is common even with routine doses. Most gastrointestinal side effects can be minimized by reducing the dose. Clarithromycin is teratogenic in laboratory animals and is in category C for use in pregnancy (Table 149-1). Resistance results from point mutations involving adenine at positions 2058 or 2059 in the 23S ribosomal RNA gene macrolide binding site. Mutational resistance occurs in 1 in 10^5 to 10^6 organisms and develops with monotherapy, especially for all slowly growing species and the rapid growers *M. chelonae* and *M. abscessus*, which have only a single copy of the ribosomal genes.

**Azithromycin** Azithromycin is a macrolide that belongs to the family of azalides. This drug reaches much lower serum levels than clarithromycin (usually ≤0.5 μg/mL), but its high tissue and macrophage concentrations and longer half-life suggest the feasibility of intermittent therapy. Azithromycin is involved in few drug interactions since it does not affect the cytochrome P450 system. The usual doses are 250 to 500 mg three times weekly (MAI therapy) or 1200 mg once a week (prophylaxis for disseminated *M. avium*). No alteration in dose is required in renal failure. The most common side effects are gastrointestinal symptoms and reversible hearing loss. Azithromycin appears to be less active than clarithromycin for both pulmonary and disseminated MAI disease. Resistance to azithromycin develops by the same mechanism as that to clarithromycin, with cross-resistance between the two macrolides.

**Therapy for Specific NTM Infections**

**MAI** Therapy for MAI lung disease in the adult usually involves the administration of clarithromycin (500 mg morning and night), ethambutol (25 mg/kg), and rifampin (600 mg) on a Monday-Wednesday-Friday schedule. Therapy is generally continued until cultures have been negative for 12 months.

For disseminated disease in AIDS, daily administration of one of the newer macrolides (clarithromycin or azithromycin) and ethambutol (15 mg/kg) is considered an essential component of any treatment regimen, with rifabutin (300 mg) commonly used third drug. Other alternative drugs include streptomycin and amikacin. Clofazimine appears to increase mortality and should be avoided. For prophylaxis of disseminated MAI disease, rifabutin (300 mg/d), clarithromycin (500 mg twice daily), and azithromycin (1200 mg once weekly) have all been demonstrated to be effective in controlled or comparative clinical trials. Once-weekly azithromycin is the drug most often used.

**MYCOBACTERIUM KANSASII** *M. kansasi* is usually susceptible to most antituberculous drugs except for pyrazinamide. Current ATS recommendations for the treatment of *M. kansasi* pulmonary disease are 18 to 24 months of daily isoniazid (300 mg), rifampin (600 mg), and etham-
butyl (15 mg/kg). In patients taking protease inhibitors, rifabutin (150 mg/d) or clarithromycin (500 mg twice daily) should be substituted for rifampin. The potential advantages of the highly active rifabutin and the newer macrolides in immunocompetent patients have not been studied.

RAPIDLY GROWING MYCOBACTERIA The *M. fortuitum* group, *M. abscessus*, and *M. chelonea* account for more than 80% of cases of clinical disease due to rapidly growing mycobacteria. These organisms are resistant to antituberculous agents other than amikacin but are variably susceptible to several traditional antibiotics. Clarithromycin has dramatically changed the approach to therapy for infection with these organisms, as it inhibits all rapidly growing mycobacteria (except for 20% of *M. fortuitum* strains and most *M. smegmatis* strains) at concentrations of ≤4 μg/mL. Other drugs with good activity include amikacin (which inhibits 80 to 100% of strains), cefoxitin (80% of *M. abscessus* and *M. fortuitum* strains), doxycycline (50% of *M. fortuitum* strains), imipenem (100% of *M. fortuitum* strains, 70% of *M. chelonea* strains, and 70% of *M. abscessus* strains), the fluoroquinolones (100% of *M. fortuitum* strains), sulfonamides (90% of *M. fortuitum* strains), and linezolid (>90% of isolates of *M. chelonea* and *M. fortuitum*).

**MYCOBACTERIUM MARINUM** *M. marinum*, a cause of postrheumatic localized skin infection, is typically susceptible to minocycline, rifampin, ethambutol, clarithromycin, and trimethoprim-sulfamethoxazole and is resistant to isoniazid.

**MYCOBACTERIUM HAEMOPHILUM** Infection due to *M. haemophilum* occurs most commonly as disseminated cutaneous disease in immunocompromised patients with or without AIDS. Isolates typically show in vitro resistance to most drugs but may be susceptible to rifampin, rifabutin, quinolones, and clarithromycin.

**MYCOBACTERIUM XENOPI** In the United States, *M. xenopi* is best known as a cause of nosocomial pseudoinfections associated with contamination of the hospital’s hot-water system. Drug therapy for *M. xenopi* infection is difficult. *M. xenopi* is often resistant to first-line antituberculous agents but susceptible to the newer macrolides, quinolones, streptomycin, and ethionamide. Patients usually respond to multidrug regimens that include clarithromycin, but relapses are common.

---

**MYCOBACTERIUM GENAVENSE** *M. genavense* is a fastidious organism that grows only in liquid media, such as BACTEC 12B or 13A, after prolonged incubation. This organism almost exclusively infects AIDS patients, causing disseminated disease and being isolated from blood, bone marrow, liver, lymph node, spleen, and intestinal cultures. The in vitro susceptibility profile of *M. genavense* has not been well established. Some isolates are susceptible to amikacin, clarithromycin, ofloxacin, rifampin, and rifabutin. Isolates generally respond to macrolide-containing regimens similar to those used for disseminated *M. avium* infection.

**MYCOBACTERIUM SIMIAE** *M. simiae* is a cause of chronic lung disease, especially in Texas and other southwestern states. It is highly drug resistant, and no satisfactory treatment regimen has yet been established.

**TUBERCULOSIS**

**DEFINITION** Tuberculosis, one of the oldest diseases known to affect humans, is caused by bacteria belonging to the *Mycobacterium tuberculosis* complex. The disease usually affects the lungs, although in up to one-third of cases other organs are involved. If properly treated, tuberculosis caused by drug-susceptible strains is curable in virtually all cases. If untreated, the disease may be fatal within 5 years in more than half of cases. Transmission usually takes place through the airborne spread of droplet nuclei produced by patients with infectious pulmonary tuberculosis.

**ETIOLOGIC AGENT** Mycobacteria belong to the family Mycobacteriaceae and the order Actinomycetales. Of the pathogenic species belonging to the *M. tuberculosis* complex, the most frequent and important agent of human disease is *M. tuberculosis*. The complex includes *M. bovis* (the bovine tubercle bacillus, once an important cause of tuberculosis transmitted by unpasteurized milk and currently the cause of a small percentage of cases in developing countries), *M. africanum* (isolated from cases in West, Central, and East Africa), *M. microti* (the “vole” bacillus, a less virulent and rarely encountered organism), and *M. canettii* (a very rare isolate in African cases).

*M. tuberculosis* is a rod-shaped, non-spore-forming, thin aerobic bacterium measuring 0.5 μm by 3 μm. Mycobacteria, including *M. tuberculosis*, are often neutral on Gram’s staining. However, once stained, the bacilli cannot be decolorized by acid alcohol, a characteristic justifying their classification as acid-fast bacilli (AFB; Fig. 150-1). Acid fastness is due mainly to the organisms’ high content of mycolic acids, long-chain cross-linked fatty acids, and other cell-wall lipids. Microorganisms other than mycobacteria that display some acid fastness include species of *Nocardia* and *Rhodococcus*, *Legionella micdadei*, and the protozoa *Isospora* and *Cryptosporidium*. In the mycobacterial cell wall, lipids (e.g., mycolic acids) are linked to underlying arabinogalactan and peptidoglycan. This structure confers very low permeability of the cell wall, thus reducing effectiveness of most antibiotics. Another molecule in the mycobacterial cell wall, lipoarabinomannan, is involved in the pathogen-host interaction and facilitates the survival of *M. tuberculosis* within macrophages. The several proteins characteristic of *M. tuberculosis* include those in purified protein derivative (PPD) tuberculin, a precipitate of non-species-specific molecules obtained from filtrates of heat-sterilized, concentrated broth cultures. The complete genome sequence of *M. tuberculosis* comprises ~4000 genes and has a high guanine-plus-cytosine content. A large proportion of genes are devoted to the production of enzymes involved in cell wall metabolism.

**EPIDEMIOLOGY** More than 3.8 million new cases of tuberculosis—all forms (pulmonary and extrapulmonary), 90% of them from developing countries—were reported to the World Health Organization (WHO) in 2001. However, because of a low level of case detection and incomplete notifications, reported cases represent only a fraction of the total. It is estimated that 8.5 million new cases of tuberculosis occurred worldwide in 2001, 95% of them in developing countries of Asia (5 million), Africa (2 million), the Middle East (0.6 million), and Latin
America (0.4 million). It is also estimated that 1.8 million deaths from tuberculosis occurred in 2000, 98% of them in developing countries. Estimates of tuberculosis incidence rates (per 100,000 population) and numbers of tuberculosis-related deaths in 2001 are depicted in Fig. 150-2 and Fig. 150-3, respectively.

After an increase in the late 1980s, numbers of cases have declined during the past few years in several industrialized countries, including the United States. The increases in the 1980s were largely related to immigration from countries with a high prevalence of tuberculosis; infection with HIV; social problems, such as poverty, homelessness, and drug abuse; and dismantling of tuberculosis services. In the United States, with the implementation of stronger control programs, the decrease resumed in 1993. In 2002, 15,075 cases of tuberculosis (5.2 cases per 100,000 population) were reported to the U.S. Centers for Disease Control and Prevention (CDC)—a 43% decrease from the 1992 peak.

In the United States, tuberculosis is uncommon among young adults of European descent, who have only rarely been exposed to \( M. tuberculosis \) infection during recent decades. In contrast, because of a high risk in the past, the prevalence of \( M. tuberculosis \) infection is relatively high among elderly Caucasians, who remain at increased risk of developing active tuberculosis. Tuberculosis in the United States is also a disease of young adult members of the HIV-infected, immigrant, and disadvantaged/marginalized populations. Similarly, in Europe, tuberculosis has reemerged as an important public health problem, mainly as a result of cases among immigrants from high-prevalence countries.

Recent tuberculosis trends in developing countries indicate a stable situation, with almost no decline. There are two exceptions. First, in sub-Saharan Africa, the spread of the HIV epidemic has resulted in doubling or tripling of the number of reported cases of tuberculosis during the past 15 years. Second, in countries of the former Soviet Union and in Romania, numbers of cases have increased by two- or threefold in the past 10 years, largely as the result of deterioration in socioeconomic conditions and the health care infrastructure.

From Exposure to Infection \( M. tuberculosis \) is most commonly transmitted from a patient with infectious pulmonary tuberculosis to other persons by droplet nuclei, which are aerosolized by coughing, sneezing, or speaking. The tiny droplets dry rapidly; the smallest (<10 μm in diameter) may remain suspended in the air for several hours and may gain direct access to the terminal air passages when inhaled. There may be as many as 3000 infectious nuclei per cough. Other routes of transmission of tubercle bacilli, such as through the skin or the placenta, are uncommon and of no epidemiologic significance.

The probability of contact with a case of tuberculosis, the intimacy and duration of that contact, the degree of infectiousness of the case, and the shared environment of the contact are all important determinants of transmission. Several studies of close contacts have clearly demonstrated that tuberculosis patients whose sputum contains AFB visible by microscopy play the greatest role in the spread of infection. These patients often have cavitary pulmonary disease or tuberculosis of the respiratory tract (endobronchial or laryngeal tuberculosis) and...
produce sputa containing as many as \(10^5\) AFB/mL. Patients with sputum smear–negative/culture-positive tuberculosis are less infectious, and those with culture-negative pulmonary disease and extrapulmonary tuberculosis are essentially noninfectious. The frequent absence of cavities among HIV-infected patients may reduce their infectiousness. Crowding in poorly ventilated rooms is one of the most important factors in the transmission of tubercle bacilli, since it increases the intensity of contact with a case.

In short, the risk of acquiring \(M.\) \(tuberculosis\) infection is determined mainly by exogenous factors. Because of delays in seeking care and in diagnosis, it is estimated that up to 20 contacts may be infected by each AFB-positive case before detection in high-prevalence settings.

**From Infection to Disease** Unlike the risk of acquiring infection with \(M.\) \(tuberculosis\), the risk of developing disease after being infected depends largely on endogenous factors, such as the individual’s innate susceptibility to disease and level of function of cell-mediated immunity. Clinical illness directly following infection is classified as *primary tuberculosis* and is common among children up to 4 years of age. Although this form may be severe and disseminated, it is usually not transmissible. When infection is acquired later in life, the chance of the immune system containing it, at least temporarily. The majority of infected individuals who ultimately develop tuberculosis do so within the first year or two after infection. Dormant bacilli, however, may persist for years before reactivating to produce secondary (or postprimary) tuberculosis, which is often infectious. Overall, it is estimated that \(~10\%\) of persons infected in their youth will eventually develop active tuberculosis. This risk, however, is greatly increased among HIV-infected persons. Reinfection of a previously infected individual, which is common in areas with high rates of tuberculosis transmission, may also favor the development of disease. Molecular typing and comparison of strains of \(M.\) \(tuberculosis\) have suggested that up to one-third of cases of active tuberculosis in U.S. inner-city communities are due to recent transmission rather than to reactivation of latent infection.

Age is an important determinant of the risk of disease after infection. Among infected persons, the incidence of tuberculosis is highest during late adolescence and early adulthood; the reasons are unclear. The incidence among women peaks at 25 to 34 years of age. In this age group rates among women are usually higher than those among men, while at older ages the opposite is true. The risk may increase in the elderly, possibly because of waning immunity and comorbidity. A variety of diseases and conditions favor the development of active tuberculosis (Table 150-1). The most potent risk factor for tuberculosis among infected individuals is clearly HIV co-infection, which suppresses cellular immunity. The risk that latent \(M.\) \(tuberculosis\) infection will proceed to active disease is directly related to the patient’s degree of immunosuppression. In a study of HIV-infected, PPD-positive persons, this risk varied from 2.6 to 13.3 cases per 100 person-years and depended upon the CD4+ cell count.

* Old infection \(\sim 1\).
of large numbers of activated macrophages at the site of the primary lesion, granulomatous lesions (tubercles) are formed. These lesions consist of lymphocytes and activated macrophages, such as epithelioid cells and giant cells. Initially, the newly developed tissue-damaging response is the only event capable of limiting mycobacterial growth within macrophages. This response, mediated by various bacterial products, not only destroys macrophages but also produces early solid necrosis in the center of the tubercle. Although \textit{M. tuberculosis} can survive, its growth is inhibited within this necrotic environment by low oxygen tension and low pH. At this point, some lesions may heal by fibrosis and calcification, while others undergo further evolution.

Cell-mediated immunity is critical at this early stage. In the majority of infected individuals, local macrophages are activated when bacillary antigens processed by macrophages stimulate \textbf{T} lymphocytes to release a variety of lymphokines. These activated cells aggregate around the lesion’s center and effectively neutralize tubercle bacilli without causing further tissue destruction. In the central part of the lesion, the necrotic material resembles soft cheese (\textit{caseous necrosis})—a phenomenon that may also be observed in other conditions, such as neoplasms. Even when healing takes place, viable bacilli may remain dormant within macrophages or in the necrotic material for years or even throughout the patient’s lifetime. These “healed” lesions in the lung parenchyma and hilar lymph nodes may later undergo calcification.

In a minority of cases, the macrophage-activating response is weak, and mycobacterial growth can be inhibited only by intensified DTH reactions, which lead to tissue destruction. The lesion tends to enlarge further, and the surrounding tissue is progressively damaged. At the center of the lesion, the caseous material liquefies. Bronchial walls as well as blood vessels are invaded and destroyed, and cavities are formed. The liquefied caseous material, containing large numbers of bacilli, is drained through bronchi. Within the cavity, tubercle bacilli multiply well and spread into the airways and the environment through expectorated sputum.

In the early stages of infection, bacilli are usually transported by macrophages to regional lymph nodes, from which they disseminate widely to many organs and tissues. The resulting lesions may undergo the same evolution as those in the lungs, although most tend to heal. In young children with poor natural immunity, hematogenous dissemination may result in fatal miliary tuberculosis or tuberculous meningitis.

Cell-mediated immunity confers partial protection against \textit{M. tuberculosis}, while humoral immunity has no defined role in protection. Two types of cells are essential: macrophages, which directly phagocytize tubercle bacilli, and \textbf{T} cells (mainly CD4+ lymphocytes), which induce protection through the production of lymphokines, especially interferon-\gamma (IFN-\gamma).

After infection with \textit{M. tuberculosis}, alveolar macrophages secrete a number of cytokines: interleukin (IL) 1 contributes to fever; IL-6 contributes to hyperglobulinemia; and tumor necrosis factor \alpha (TNF-\alpha) contributes to the killing of mycobacteria, the formation of granulomas, and a number of systemic effects, such as fever and weight loss. Macrophages are also critical in processing and presenting antigens to T lymphocytes; the result is a proliferation of CD4+ lymphocytes, which are crucial to the host’s defense against \textit{M. tuberculosis}. Qualitative and quantitative defects of CD4+ T cells explain the inability of HIV-infected individuals to contain mycobacterial proliferation. Reactive CD4+ lymphocytes produce cytokines of the Th1 pattern and participate in MHC class II–restricted killing of cells infected with \textit{M. tuberculosis}. Th1 CD4+ cells produce IFN-\gamma and IL-2 and promote cell-mediated immunity. Th2 cells produce IL-4, IL-5, and IL-10 and promote humoral immunity. The interplay of these various cytokines and their cross-regulation determine the host’s response. The role of cytokines in promoting intracellular killing of mycobacteria has not been entirely elucidated. IFN-\gamma may induce release of nitric oxide, and TNF-\alpha also seems to be important. Observations in transgenic knockout mice suggest that other T cell subsets (especially CD8+ cells) restricted by alternative antigen-presenting molecules containing a B2-microglobulin subunit may play an important role. Lipids have been involved in mycobacterial recognition by the innate immune system, and lipoproteins have been proven to trigger potent signals through Toll-like receptors. Finally, a recently described subset of T cells capable of recognizing lipid elements of the bacillus presented by CD1 molecules may be implicated in protection.

\textit{M. tuberculosis} possesses various protein antigens. Some are present in the cytoplasm and cell wall; others are secreted. That the latter are more important in eliciting a T lymphocyte response is suggested by experiments documenting the appearance of protective immunity in animals after immunization with live, protein-secreting mycobacteria. Among the antigens with a potential protective role are the 30-kDa (or 85B) and the ESAT-6 antigens. Protective immunity is probably the result of reactivity to a large number of different mycobacterial antigens.

Coincident with the appearance of immunity, DTH to \textit{M. tuberculosis} develops. This reactivity is the basis of the PPD skin test, which is used primarily for the detection of \textit{M. tuberculosis} infection in persons without symptoms. The cellular mechanisms responsible for PPD reactivity are related mainly to previously sensitized CD4+ lymphocytes, which are attracted to the skin-test site. There, they proliferate and produce cytokines.

While DTH is associated with protective immunity (PPD-positive persons being less susceptible to a new \textit{M. tuberculosis} infection than PPD-negative persons), it by no means guarantees protection against reactivation. In fact, severe cases of active tuberculosis are often accompanied by strongly positive skin-test reactions.

**CLINICAL MANIFESTATIONS** Tuberculosis is classified as pulmonary or extrapulmonary. Before the recognition of HIV infection, >80% of all cases of tuberculosis were limited to the lungs. However, up to two-thirds of HIV-infected patients with tuberculosis may have both pulmonary and extrapulmonary disease or extrapulmonary disease alone.

**Pulmonary Tuberculosis** Pulmonary tuberculosis can be categorized as primary or postprimary (secondary).

**PRIMARY DISEASE** Primary pulmonary tuberculosis results from an initial infection with tubercle bacilli. In areas of high tuberculosis prevalence, this form of disease is often seen in children and is frequently localized to the middle and lower lung zones. The lesion forming after infection is usually peripheral and accompanied by hilar or paratracheal lymphadenopathy, which may not be detectable on chest radiography. In the majority of cases, the lesion heals spontaneously and may later be evident as a small calcified nodule (\textit{Ghon lesion}).

In children and in persons with impaired immunity (e.g., those with malnutrition or HIV infection), primary pulmonary tuberculosis may progress rapidly to clinical illness. The initial lesion increases in size and can evolve in different ways. Pleural effusion, a frequent finding, results from the penetration of bacilli into the pleural space from an adjacent subpleural focus. In severe cases, the primary site rapidly enlarges, its central portion undergoes necrosis, and acute cavitation develops (progressive primary tuberculosis). Tuberculosis in young children is almost invariably accompanied by hilar or mediastinal lymphadenopathy due to the spread of bacilli from the lung parenchyma through lymphatic vessels. Enlarged lymph nodes may compress bronchi, causing obstruction and subsequent segmental or lobar collapse. Partial obstruction may cause obstructive emphysema, and bronchiectasis may also develop. Hematogenous dissemination, which is common and is often asymptomatic, may result in the most severe manifestations of primary \textit{M. tuberculosis} infection. Bacilli reach the bloodstream from the pulmonary lesion or the lymph nodes and disseminate into various organs, where they may produce granulomatous lesions. Although healing frequently takes place, immunocompromised persons (e.g., patients with HIV infection) may develop miliary tuberculosis and/or tuberculous meningitis.
POSTPRIMARY DISEASE Also called adult-type, reactivation, or secondary tuberculosis, postprimary disease results from endogenous reactivation of latent infection and is usually localized to the apical and posterior segments of the upper lobes, where the high oxygen concentration favors mycobacterial growth. In addition, the superior segments of the lower lobes are frequently involved. The extent of lung parenchymal involvement varies greatly, from small infiltrates to extensive cavitary disease. With cavity formation, liquefied necrotic contents are ultimately discharged into the airways, resulting in satellite lesions within the lungs that may in turn undergo cavitation (Fig. 150–4). Massive involvement of pulmonary segments or lobes, with coalescence of lesions, produces tuberculous pneumonia. While up to one-third of untreated patients reportedly succumb to severe pulmonary tuberculosis within a few weeks or months after onset, others undergo a process of spontaneous remission or proceed along a chronic, progressively debilitating course (“consumption”). Under these circumstances, some pulmonary lesions become fibrotic and may later calcify, but cavities persist in other parts of the lungs. Individuals with such chronic disease continue to discharge tubercle bacilli into the environment. Most patients respond to treatment, with defervescence, decreasing cough, weight gain, and a general improvement in well-being within several weeks.

Early in the course of disease, symptoms and signs are often nonspecific and insidious, consisting mainly of fever and night sweats, weight loss, anorexia, general malaise, and weakness. However, in the majority of cases, cough eventually develops—often initially nonproductive and subsequently accompanied by the production of purulent sputum. Blood streaking of the sputum is frequently documented. Massive hemoptysis may ensue as a consequence of the erosion of a fully patent vessel located in the wall of a cavity. Hemoptysis, however, may also result from rupture of a dilated vessel in a cavity (Rasmussen’s aneurysm) or from aspergilloma formation in an old cavity. Pleuritic chest pain sometimes develops in patients with subpleural parenchymal lesions but can also result from muscle strain due to persistent coughing. Extensive disease may produce dyspnea and (occasionally) adult respiratory distress syndrome (ARDS).

Physical findings are of limited use in pulmonary tuberculosis. Many patients have no abnormalities detectable by chest examination, while others have detectable rales in the involved areas during inspiration, especially after coughing. Occasionally, ronchi due to partial bronchial obstruction and classic amorphic breath sounds in areas with large cavities may be heard. Systemic features include fever (often low-grade and intermittent) and wasting. In some cases, pallor and finger clubbing develop. The most common hematologic findings are mild anemia and leukocytosis. Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has also been reported.

Extrapulmonary Tuberculosis In order of frequency, the extrapulmonary sites most commonly involved in tuberculosis are the lymph nodes, pleura, genitourinary tract, bones and joints, meninges, peritoneum, and pericardium. However, virtually all organ systems may be affected. As a result of hematogenous dissemination in HIV-infected individuals, extrapulmonary tuberculosis is seen more commonly today than in the past.

LYMPH-NODE TUBERCULOSIS (TUBERCULOUS LYMPHADENITIS) The most common presentation of extrapulmonary tuberculosis (documented in >25% of cases), lymph-node disease is particularly frequent among HIV-infected patients. In the United States, children and women (particularly non-Caucasians) also seem to be especially susceptible. Once caused mainly by M. bovis, tuberculous lymphadenitis is today due largely to M. tuberculosis. Lymph-node tuberculosis presents as painless swelling of the lymph nodes, most commonly at cervical and supraclavicular sites (a condition often referred to as scrofula). Lymph nodes are usually discrete in early disease but may be inflamed and have a fistulous tract draining caseous material. Systemic symptoms are usually limited to HIV-infected patients, and concomitant lung disease may or may not be present. The diagnosis is established by fine-needle aspiration or surgical biopsy. AFB are seen in up to 50% of cases, cultures are positive in 70 to 80%, and histologic examination shows granulomatous lesions. Among HIV-infected patients, granulomas are usually not seen. Differential diagnosis includes a variety of infectious conditions as well as neoplastic diseases such as lymphomas or metastatic carcinomas.

PLEURAL TUBERCULOSIS Involvement of the pleura is common in primary tuberculosis and results from penetration by tubercle bacilli into the pleural space. Depending on the extent of reactivity, the effusion may be small, remain unnoticed, and resolve spontaneously or may be sufficiently large to cause symptoms such as fever, pleuritic chest pain, and dyspnea. Physical findings are those of pleural effusion: dullness to percussion and absence of breath sounds. A chest radiograph reveals the effusion and, in no more than one-third of cases, also shows a parenchymal lesion. Thoracentesis is required to ascertain the nature of the effusion. The fluid is straw colored and at times hemorrhagic; it is an exudate with a protein concentration >50% of that in serum, a normal to low glucose concentration, a pH that is generally <7.2, and detectable white blood cells (usually 500 to 2500/µL). Neutrophils may predominate in the early stage, while mononuclear cells are the typical finding later. Mesothelial cells are generally rare or absent. AFB are very rarely seen on direct smear, but cultures may be positive for M. tuberculosis in up to one-third of cases. Needle biopsy of the pleura is often required for diagnosis and reveals granulomas and/or yields a positive culture in up to 70% of cases. This form of pleural tuberculosis responds well to chemotherapy and may resolve spontaneously. The usefulness of glucocorticoids is debatable.

Tuberculous empyema is a less common complication of pulmonary tuberculosis. It is usually the result of the rupture of a cavity, with delivery of a large number of organisms into the pleural space, or of a bronchopleural fistula from a pulmonary lesion. A chest radiograph may show pyopneumothorax with an air-fluid level. The effusion is purulent and thick and contains large numbers of lymphocytes. An acid-fast smear of pleural fluid is often found to be positive when examined by microscopy, as is culture of the pleural fluid. Surgical drainage is usually required as an adjunct to chemotherapy. Tuberculous empyema may result in severe pleural fibrosis and restrictive lung disease.
TUBERCULOSIS OF THE UPPER AIRWAYS  Nearly always a complication of advanced cavitary pulmonary tuberculosis, tuberculosis of the upper airways may involve the larynx, pharynx, and epiglottis. Symptoms include hoarseness and dysphagia in addition to chronic productive cough. Findings depend on the site of involvement, and ulcerations may be seen on laryngoscopy. Acid-fast smear of the sputum is often positive, but biopsy may be necessary in some cases to establish the diagnosis. Cancer may have similar features but is usually painless.

GENITOURINARY TUBERCULOSIS  Genitourinary tuberculosis accounts for 15% of all extrapulmonary cases; may involve any portion of the genitourinary tract, and is usually due to hematogenous seeding following primary infection. Local symptoms predominate. Urinary frequency, dysuria, hematuria, and flank pain are common presentations. However, patients may be asymptomatic and the disease discovered only after severe destructive lesions of the kidneys have developed. Urinalysis gives abnormal results in 90% of cases, revealing pyuria and hematuria. The documentation of culture-negative pyuria in acidic urine raises the suspicion of tuberculosis. An intravenous pyelogram helps in diagnosis. Calcifications and ureteral strictures are suggestive findings. Culture of three morning urine specimens yields a definitive diagnosis in nearly 90% of cases. Severe ureteral strictures may lead to hydronephrosis and renal damage.

Genital tuberculosis is diagnosed more commonly in female than in male patients. In female patients, it affects the fallopian tubes and the endometrium and may cause infertility, pelvic pain, and menstrual abnormalities. Diagnosis requires biopsy or culture of specimens obtained by dilatation and curettage. In male patients, tuberculosis preferentially affects the epididymis, producing a slightly tender mass that may drain externally through a fistulous tract; orchitis and prostatitis may also develop. In almost half of cases of genitourinary tuberculosis, urinary tract disease is also present. Genitourinary tuberculosis responds well to chemotherapy.

SKELETAL TUBERCULOSIS  In the United States, tuberculosis of the bones and joints is responsible for 10% of extrapulmonary cases. In bone and joint disease, pathogenesis is related to reactivation of hematogenous foci or to spread from adjacent paravertebral lymph nodes. Weight-bearing joints (spine, hips, and knees—in that order) are affected most commonly. Spinal tuberculosis (Pott’s disease or tuberculous spondylitis; Fig. 150-5) often involves two or more adjacent vertebral bodies. While the upper thoracic spine is the most common site of spinal tuberculosis in children, the lower thoracic and upper lumbar vertebrae are usually affected in adults. From the anterior superior or inferior angle of the vertebral body, the lesion reaches the adjacent body, also destroying the intervertebral disk. With advanced disease, collapse of vertebral bodies results in kyphosis (gibbus). A paravertebral “cold” abscess may also form. In the upper spine, this abscess may track to the chest wall as a mass; in the lower spine, it may reach the inguinal ligaments or present as a psaas abscess. Computed tomography (CT) or magnetic resonance imaging (MRI) reveals the characteristic lesion and suggests its etiology, although the differential diagnosis includes other infections and tumors. Aspiration of the abscess or bone biopsy confirms the tuberculous etiology, as cultures are usually positive and histologic findings highly typical. A catastrophic complication of Pott’s disease is paraplegia, which is usually due to an abscess or a lesion compressing the spinal cord. Paraparesis due to a large abscess is a medical emergency and requires abscess drainage. Tuberculosis of the hip joints causes pain and limping; tuberculosis of the knee produces pain and swelling and sometimes follows trauma. If the disease goes unrecognized, the joints may be destroyed. Skeletal tuberculosis responds to chemotherapy, but severe cases may require surgery.

TUBERCULOUS MENINGITIS AND TUBERCULOMA  Tuberculosis of the central nervous system accounts for 5% of extrapulmonary cases. It is seen most often in young children but also develops in adults, especially those who are infected with HIV. Tuberculous meningitis results from the hematogenous spread of primary or postprimary pulmonary disease or from the rupture of a subependymal tubercle into the subarachnoid space. In more than half of cases, evidence of old pulmonary lesions or a military pattern is found on chest radiography. The disease may present subtly as headache and mental changes or acutely as confusion, lethargy, altered sensorium, and neck rigidity. Typically, the disease evolves over 1 or 2 weeks, a course longer than that of bacterial meningitis. Paralysis of cranial nerves (ocular nerves in particular) is a frequent finding, and the involvement of cerebral arteries may produce focal ischemia. Hydrocephalus is common. Lumbar puncture is the cornerstone of diagnosis. In general, examination of the cerebrospinal fluid (CSF) reveals a high leukocyte count (usually with a predominance of lymphocytes but often with a predominance of neutrophils in the early stage), a protein content of 1 to 8 g/L (100 to 800 mg/dL), and a low glucose concentration; however, any of these three parameters can be within the normal range. AFB are seen on direct smear of CSF sediment in only 20% of cases, but repeated lumbar punctures increase the yield. Culture of CSF is diagnostic in up to 80% of cases. Imaging studies (CT and MRI) may show hydrocephalus and abnormal enhancement of basal cisterns or ependyma. If unrecognized, tuberculous meningitis is uniformly fatal. This disease responds to chemotherapy; however, neurologic sequelae are documented in 25% of treated cases, in most of which the diagnosis has been delayed. Clinical trials have demonstrated that patients treated with adjunctive glucocorticoids experience a significantly faster resolution of CSF abnormalities and elevated CSF pressure. Adjuvant glucocorticoids (e.g., dexamethasone, up to 12 mg/d for 4 to 6 weeks) enhance the chances of survival and reduce the frequency of neurologic sequelae.

Tuberculoma, an uncommon manifestation of tuberculosis, presents as one or more space-occupying lesions and usually causes seizures and focal signs. CT or MRI reveals contrast-enhanced ring lesions, but biopsy is necessary to establish the diagnosis.

GASTROINTESTINAL TUBERCULOSIS  Any portion of the gastrointestinal tract may be affected by tuberculosis. Various pathogenetic mechanisms are involved: swallowing of sputum with direct seeding, hematogenous spread, or (although rare today) ingestion of milk from cows affected by bovine tuberculosis. The terminal ileum and the cecum are the sites most commonly involved. Abdominal pain (at times similar to that associated with appendicitis), diarrhea, obstruction, hematochezia, and a palpable mass in the abdomen are common findings at presentation. Fever, weight loss, and night sweats are also frequent. With intestinal-wall involvement, ulcersations and fistulae may simulate Crohn’s disease. Anal fistulae should prompt an evaluation for rectal tuberculosis. As surgery is required in most cases, the diagnosis can be established by histologic examination and culture of specimens obtained intraoperatively.

Tuberculous peritonitis follows either the direct spread of tubercle bacilli from ruptured lymph nodes and intraabdominal organs or hematogenous seeding. Nonspecific abdominal pain, fever, and ascites
should raise the suspicion of tuberculous peritonitis. The coexistence of cirrhosis (Chap. 288) in patients with tuberculous peritonitis complicates the diagnosis. In tuberculous peritonitis, paracentesis reveals an exudative fluid with a high protein content and leukocytosis that is usually lymphocytic (although neutrophils occasionally predominate). The yield of direct smear and culture is relatively low; culture of a large volume of ascitic fluid can increase the yield, but peritoneal biopsy is often needed to establish the diagnosis.

**PERICARDIAL TUBERCULOSIS (TUBERCULOSIS PERICARDITIS)** Due to direct progression of a primary focus within the pericardium, to reactivation of a latent focus, or to rupture of an adjacent lymph node, pericardial tuberculosis has often been a disease of the elderly in countries with low tuberculosis prevalence but also develops frequently in HIV-infected patients. Case-fatality rates are as high as 40% in some series. The onset may be subacute, although an acute presentation, with fever, dull retrosternal pain, and a friction rub, is possible. An effusion eventually develops in many cases; cardiovascular symptoms and signs of cardiac tamponade may ultimately appear (Chap. 222). In the presence of effusion detected on chest radiography, tuberculous pericarditis must be suspected if the patient belongs to a high-risk population (HIV-infected, originating in a high-prevalence country), if there is evidence of previous tuberculosis or disease in other organs, or if echocardiography shows thick strands crossing the pericardial space. Diagnosis can be facilitated by pericardiocentesis under echocardiographic guidance. The pericardial fluid must be submitted for biochemical, cytologic, and microbiologic study. The effusion is exudative in nature, with a high count of leukocytes (predominantly mononuclear cells). Hemorrhagic effusion is frequent. Culture of the fluid reveals *M. tuberculosis* in ~30% of cases, while biopsy has a higher yield. High levels of adenine deaminase and IFN-γ may also suggest a tubercular etiology. Without treatment, pericardial tuberculosis is usually fatal. Even with treatment, complications may develop, including chronic constrictive pericarditis with thickening of the pericardium, fibrosis, and sometimes calcification, which may be visible on a chest radiograph. A course of glucocorticoid treatment (e.g., prednisone, 20 to 60 mg/day for up to 6 weeks) is useful in the management of acute disease, reducing effusion, facilitating hemodynamic recovery, and thus decreasing mortality. Progression to chronic constrictive pericarditis, however, seems unaffected by such therapy.

**Miliary or Disseminated Tuberculosis** Miliary tuberculosis is due to hematogenous spread of tubercle bacilli. Although in children it is often the consequence of a recent primary infection, in adults it may be due to either recent infection or reactivation of old disseminated foci. Lesions are usually yellowish granulomas 1 to 2 mm in diameter that resemble millet seeds (thus the term *miliary*, coined by nineteenth-century pathologists).

Clinical manifestations are nonspecific and protean, depending on the predominant site of involvement. Fever, night sweats, anorexia, weakness, and weight loss are presenting symptoms in the majority of cases. At times, patients have a cough and other respiratory symptoms due to pulmonary involvement as well as abdominal symptoms. Physical findings include hepatomegaly, splenomegaly, and lymphadenopathy. Eye examination may reveal choroidal tubercles, which are pathognomonic of miliary tuberculosis, in up to 30% of cases. Menigitis occurs in ~10% of cases.

A high index of suspicion is required for the diagnosis of miliary tuberculosis. Frequently, chest radiography reveals a miliary reticulonodular pattern (more easily seen on underpenetrated film), although no radiographic abnormality may be evident early in the course and among HIV-infected patients. Other radiologic findings include large infiltrates, interstitial infiltrates (especially in HIV-infected patients), and pleural effusion. A sputum smear is negative in 80% of cases. Various hematologic abnormalities may be seen, including anemia with leukopenia, neutrophilic leukocytosis and leukemoid reactions, and polycythemia. Disseminated intravascular coagulation has been reported. Elevation of alkaline phosphatase levels and other abnormal values in liver function tests are detected in patients with severe hepatic involvement. The PPD test may be negative in up to half of cases, but reactivity may be restored during chemotherapy. Bronchoalveolar lavage and transbronchial biopsy are more likely to permit bacteriologic confirmation, and granulomas are evident in liver or bone-marrow biopsy specimens from many patients. If it goes unrecognized, miliary tuberculosis is lethal; with proper treatment, however, it is amenable to cure.

A rare presentation seen in the elderly is *cryptic miliary tuberculosis*, which has a chronic course characterized by mild intermittent fever, anemia, and—ultimately—meningeal involvement preceding death. An acute septicemic form, *nonreactive miliary tuberculosis*, occurs very rarely and is due to massive hematogenous dissemination of tubercle bacilli. Pancytopenia is common in this form of disease, which is rapidly fatal. At postmortem examination, multiple necrotic but nongranulomatous (“nonreactive”) lesions are detected.

**LESS COMMON EXTRAPULMONARY FORMS** Tuberculosis may cause chorioretinitis, uveitis, panophthalmitis, and painful hypersensitivity-related phlyctenular conjunctivitis. Tuberculous oitis is rare and presents as hearing loss, otorrhea, and tympanic membrane perforation. In the nasopharynx, tuberculosis may simulate Wegener’s granulomatosis. Cutaneous manifestations of tuberculosis include primary infection due to direct inoculation, abscesses and chronic ulcers, scrofuloderma, lupus vulgaris, miliary lesions, and erythema nodosum. Adrenal tuberculosis is a manifestation of advanced disease presenting as signs of adrenal insufficiency. Finally, congenital tuberculosis results from transplacental spread of tubercle bacilli to the fetus or from ingestion of contaminated amniotic fluid. This rare disease affects the liver, spleen, lymph nodes, and various other organs.

**HIV-Associated Tuberculosis** (See also Chap. 173) Tuberculosis is an important opportunistic disease among HIV-infected persons worldwide. In some African countries, the rate of HIV infection among tuberculosis patients may reach 70 to 80% in certain urban settings. A person with skin test–documented *M. tuberculosis* infection who acquires HIV infection has a 3 to 15% annual risk of developing active tuberculosis.

Tuberculosis can appear at any stage of HIV infection, and its presentation varies with the stage. When cell-mediated immunity is only partially compromised, pulmonary tuberculosis presents as a typical pattern (Fig. 150-4) of upper lobe infiltrates and cavitation, without significant lymphadenopathy or pleural effusion. In late stages of HIV infection, a primary tuberculosis—like pattern, with diffuse interstitial or miliary infiltrates, little or no cavitation, and intrathoracic lymphadenopathy, is more common. Overall, sputum smears may be positive less frequently among tuberculosis patients with HIV infection than among those without; thus the diagnosis of tuberculosis may be unusually difficult, especially in view of the variety of HIV-related pulmonary conditions mimicking tuberculosis.

Extrapulmonary tuberculosis is common among HIV-infected patients. In various series, extrapulmonary tuberculosis—alone or in association with pulmonary disease—has been documented in 40 to 60% of all cases in HIV co-infected individuals. The most common forms are lymphatic, disseminated, pleural, and pericardial. Mycobacteremia and meningitis are also frequent, particularly in advanced HIV disease. The diagnosis of tuberculosis in HIV-infected patients may be difficult not only because of the increased frequency of sputum-smear negativity (up to 40% in culture-proven pulmonary cases) but also because of atypical radiographic findings, a lack of classic granuloma formation in the late stages, and negative results in PPD skin tests. Delays in treatment may prove fatal.

Recommendations for the prevention and treatment of tuberculosis in HIV-infected individuals are provided below.

**DIAGNOSIS** The key to the diagnosis of tuberculosis is a high index of suspicion. Diagnosis is not difficult with a high-risk patient—e.g., a homeless alcoholic who presents with typical symptoms and a classic chest radiograph showing upper lobe infiltrates with cavities (Fig.
150-4). On the other hand, the diagnosis can easily be missed in an elderly nursing-home resident or a teenager with a focal infiltrate.

Often, the diagnosis is first entertained when the chest radiographic of a patient being evaluated for respiratory symptoms is abnormal. If the patient has no complicating medical conditions that favor immunosuppression, the chest radiograph may show the typical picture of upper lobe infiltrates with cavitation (Fig. 150-4). The longer the delay between the onset of symptoms and the diagnosis, the more likely is the finding of cavitary disease. In contrast, immunosuppressed patients, including those with HIV infection, may have “atypical” findings on chest radiography—e.g., lower-zone infiltrates without cavity formation.

**AFB Microscopy**  A presumptive diagnosis is commonly based on the finding of AFB on microscopic examination of a diagnostic specimen such as a smear of expectorated sputum or of tissue (for example, a lymph node biopsy). Most modern laboratories processing large numbers of diagnostic specimens use auramine-rhodamine staining and fluorescence microscopy. The more traditional method—light microcopy of specimens stained with Kinyoun or Ziehl-Neelsen basic fuchsin dyes—is satisfactory, although more time-consuming. For patients with suspected pulmonary tuberculosis, three sputum specimens, preferably collected early in the morning, should be submitted to the laboratory for AFB smear and mycobacteriology culture. If tissue is obtained, it is critical that the portion of the specimen intended for culture not be put in formaldehyde. The use of AFB microscopy on urine or gastric lavage fluid is limited by the presence of mycobacterial commensals, which can cause false-positive results.

**Mycobacterial Culture**  Definitive diagnosis depends on the isolation and identification of *M. tuberculosis* from a diagnostic specimen—in most cases, a sputum specimen obtained from a patient with a productive cough. Specimens may be inoculated onto egg- or agar-based medium (e.g., Löwenstein-Jensen or Middlebrook 7H10) and incubated at 37°C under 5% CO₂. Because most species of mycobacteria, including *M. tuberculosis*, grow slowly, 4 to 8 weeks may be required before growth is detected. Although *M. tuberculosis* may be presumptively identified on the basis of growth time and colony pigmentation and morphology, a variety of biochemical tests have traditionally been used to speciate mycobacterial isolates. In today’s laboratories, the use of liquid media for isolation and speciation by nucleic acid probes or high-pressure liquid chromatography of mycolic acids has replaced the traditional methods of isolation on solid media and identification by biochemical tests. These new methods have decreased the time required for bacteriologic confirmation to 2 to 3 weeks.

**Nucleic Acid Amplification**  Several test systems based on amplification of mycobacterial nucleic acid are available. These systems permit the diagnosis of tuberculosis in as little as several hours. However, their applicability is limited by low sensitivity (lower than culture, but higher than AFB smear microscopy) and high cost. At present, these tests are most useful for the rapid confirmation of tuberculosis in persons with AFB-positive sputa. However, they may also have utility for the diagnosis of AFB-negative pulmonary and extrapulmonary tuberculosis in selected patients.

**Drug Susceptibility Testing**  In general, the initial isolate of *M. tuberculosis* should be tested for susceptibility to isoniazid, rifampin, and ethambutol. In addition, expanded susceptibility testing is mandatory when resistance to one or more of these drugs is found or the patient either fails to respond to initial therapy or has a relapse after the completion of treatment (see below). Susceptibility testing may be conducted directly (with the clinical specimen) or indirectly (with mycobacterial cultures) on solid or liquid medium. Results are obtained most rapidly by direct susceptibility testing on liquid medium, with an average reporting time of 3 weeks. With indirect testing on solid medium, results may not be available for >8 weeks. Molecular methods for the rapid identification of drug resistance are becoming available. One of the most promising uses polymerase chain reaction (PCR) to detect mutations in the *rpoB* gene associated with resistance to rifampin.

**Radiographic Procedures**  As noted above, the initial suspicion of pulmonary tuberculosis is often based on abnormal chest radiographic findings in a patient with respiratory symptoms. Although the “classic” picture is that of upper lobe disease with infiltrates and cavities (Fig. 150-4), virtually any radiographic pattern—from a normal film or a solitary pulmonary nodule to diffuse alveolar infiltrates in a patient with ARDS—may be seen. In the era of AIDS, no radiographic pattern can be considered pathognomonic.

**PPD Skin Testing and Diagnosis of Latent Tuberculosis Infection**  In 1891, Robert Koch discovered components of *M. tuberculosis* in a concentrated liquid culture medium. Subsequently named “old tuberculin” (OT), this material was initially believed to be useful in the treatment of tuberculosis (although this idea was later disproved). It soon became clear that OT was capable of eliciting a skin reaction when injected subcutaneously into patients with tuberculosis. In 1932, Seibert and Munday purified this product by ammonium sulfate precipitation. The result was an active protein fraction known as *tuberculin PPD*. However, the complexity and diversity of the constituents of PPD rendered its standardization difficult. PPD-S, developed by Seibert and Glenn in 1941, was chosen as the international standard. Later, the WHO and UNICEF sponsored large-scale production of a master batch of PPD, termed *RT23*, and made it available for general use. The greatest limitation of PPD is its lack of mycobacterial species specificity, a property that is due to the large number of proteins in this product that are highly conserved in the various species of mycobacteria.

Skin testing with PPD is most widely used in screening for *M. tuberculosis* infection (see below). The test is of limited value in the diagnosis of active tuberculosis because of its low sensitivity and specificity. False-negative reactions are common in immunosuppressed patients and in those with overwhelming tuberculosis. Positive reactions are obtained when patients have been infected with *M. tuberculosis* but do not have active disease and when persons have been sensitized by nontuberculous mycobacteria (Chap. 152) or bacille Calmette-Guérin (BCG) vaccination. Although BCG vaccine is not used in the United States for tuberculosis prevention, many immigrants will have received it. In the absence of a history of BCG vaccination, a positive skin test may provide additional support for the diagnosis of tuberculosis in culture-negative cases.

Because results of anergy testing in HIV-infected populations do not seem useful to clinicians making decisions about preventive therapy, anergy testing based on other DTH antigens is no longer recommended as a routine component of tuberculosis screening among HIV-infected persons. However, some experts support the use of anergy testing to help guide individual decisions regarding preventive therapy, and some recommend that PPD skin testing be performed for patients previously classified as anergic if evidence indicates that these patients’ immune systems have responded to therapy with antiretroviral drugs.

**Cytokine Release Assays**  A commercially available whole-blood cytokine assay, the QuantiFERON-TB test (Cellestis Ltd), has been approved by the U.S. Food and Drug Administration (FDA) as an aid in the diagnosis of latent tuberculosis infection. The test requires overnight incubation of a peripheral-blood sample with PPD and control antigens followed by measurement of IFN-γ released by sensitized lymphocytes in an enzyme-linked immunosorbent assay (ELISA). A multicenter study conducted by the CDC indicated good agreement between this assay and the PPD skin test, although the assay’s ability to predict the development of active tuberculosis is not known. At present, the QuantiFERON-TB test is recommended for screening for latent tuberculosis infection in populations at low to moderate risk of tuberculosis. Studies are under way to assess the performance of this test in contact investigations, persons with suspected tuberculosis disease, HIV-infected persons, and children. The test’s performance will probably be enhanced by the use of antigens such as ESAT-6 and CFP-
The introduction of rifampin in the early 1970s heralded the era of effective short-course chemotherapy, with a treatment duration of <12 months. The discovery that pyrazinamide, which was first used in the 1950s, augmented the potency of isoniazid/rimipin regimens led to the use of a 6-month course of this triple-drug regimen as standard therapy.

**DRUGS** Four major drugs are considered the first-line agents for the treatment of tuberculosis: isoniazid, rifampin, pyrazinamide, and ethambutol (Table 150-2). These drugs are well absorbed after oral administration, with peak serum levels at 2 to 4 h and nearly complete elimination within 24 h. These agents are recommended on the basis of their bactericidal activity (ability to rapidly reduce the number of viable organisms and render patients noninfectious), their sterilizing activity (ability to kill all bacilli and sterilize the affected organ, measured in terms of the ability to prevent relapses), and their low rate of induction of drug resistance. Rifampin and rifabutin, two drugs related to rifampin, are also available in the United States and are useful for selected patients. →For a detailed discussion of the drugs used for the treatment of tuberculosis, see Chap. 149.

Because of a lower degree of efficacy and a higher degree of tolerability and toxicity, a number of second-line drugs are generally used only for the treatment of patients with tuberculosis resistant to first-line drugs. Included in this group are the injectable drugs streptomycin (formerly a first-line agent), kanamycin, amikacin, and capreomycin and the oral agents ethionamide, cycloserine, and PAS. Recently, fluoroquinolone antibiotics have become the most commonly used second-line drugs. Of available agents, oxolinic acid is the most widely used, but levofloxacin, gatifloxacin, and moxifloxacin are the most active. Other drugs of doubtful efficacy that have been used in the treatment of patients with resistance to most of the first- and second-line agents include clofazimine, amithiazine (thiacetazone, still used in less wealthy countries but not marketed in North America or Europe), amoxicillin/clavulanate, and linezolid.

**REGIMENS** Short-course regimens are divided into an initial, or bactericidal, phase and a continuation, or sterilizing, phase. During the initial phase, the majority of the tubercle bacilli are killed, symptoms resolve, and the patient becomes noninfectious. The continuation phase is required to eliminate persisting mycobacteria and prevent relapse.

The treatment regimen of choice for virtually all forms of tuberculosis in both adults and children consists of a 2-month initial phase of isoniazid, rifampin, pyrazinamide, and ethambutol followed by a 4-month continuation phase of isoniazid and rifampin (Table 150-3). Treatment may be given daily throughout the course or intermittently (either three times weekly throughout the course or twice weekly following an initial phase of daily therapy). A continuation phase of once-weekly rifapentine and isoniazid is equally effective for HIV-

**TREATMENT** The two aims of tuberculosis treatment are to interrupt tuberculosis transmission by rendering patients noninfectious and to prevent morbidity and mortality by curing patients with tuberculosis disease. Chemotherapy for tuberculosis became possible with the discovery of streptomycin in the mid-1940s. Randomized clinical trials clearly indicated that the administration of streptomycin to patients with chronic tuberculosis reduced mortality and led to cure in the majority of cases. However, monotherapy with streptomycin was frequently associated with the development of resistance to this drug and the attendant failure of treatment. With the discovery of para-aminosalicylic acid (PAS) and isoniazid, it became axiomatic that cure of tuberculosis required the concomitant administration of at least two agents to which the organism was susceptible. Furthermore, early clinical trials demonstrated that a long period of treatment—i.e., 12 to 24 months—was required to prevent the recurrence of tuberculosis.

* Dosages for children are similar, except that some authorities recommend higher doses of isoniazid (10–15 mg/kg daily; 20–30 mg/kg intermittently) and rifampin (10–20 mg/kg).

* Dosages for twice-weekly administration are the same for isoniazid and rifampin but are higher for pyrazinamide (50 mg/kg, with a maximum of 4 g/d) and ethambutol (40–50 mg/d).

* In certain settings, streptomycin (15 mg/kg daily, with a maximum dose of 1 g; or 25–30 mg/kg thrice weekly, with a maximum dose of 1.5 g) can replace ethambutol in the initial phase of treatment. However, streptomycin is no longer considered a first-line drug by the ATS, the IDSA, or the CDC.

seronegative patients with noncavitary pulmonary tuberculosis who have negative sputum cultures at 2 months. Intermittent treatment is especially useful for patients whose therapy is being directly observed (see below). Patients with cavitary pulmonary tuberculosis and delayed sputum-culture conversion (i.e., those who remain culture-positive at 2 months) should have their treatment extended by 3 months, for a total course of 9 months. For patients with sputum culture–negative pulmonary tuberculosis, the duration of treatment may be reduced to a total of 4 months. To prevent isoniazid-related neuropathy, pyridoxine (10 to 25 mg/d) should be added to the regimen given to persons at high risk of vitamin B6 deficiency (e.g., alcoholics; malnourished persons; pregnant and lactating women; and patients with conditions such as chronic renal failure, diabetes, and HIV infection or AIDS, which are also associated with neuropathy). A full course of therapy (completion of treatment) is defined more accurately by the total number of doses taken than by the length of treatment. Specific recommendations on the required numbers of doses for each of the various treatment regimens have been published jointly by the American Thoracic Society (ATS), the Infectious Diseases Society of America (IDSA), and the CDC.

Lack of adherence to treatment is recognized worldwide as the most important impediment to cure. Moreover, the tubercle bacilli infecting patients who do not adhere to the prescribed regimen are likely to become drug resistant. Both patient- and provider-related factors may affect compliance. Patient-related factors include a lack of belief that the illness is significant and/or that treatment will have a beneficial effect; the existence of concomitant medical conditions (notably substance abuse); lack of social support; and poverty, with attendant joblessness and homelessness. Provider-related factors that may promote compliance include the education and encouragement of patients, the offering of convenient clinic hours, and the provision of incentives and enablers such as meals and bus tokens.

In addition to specific measures addressing noncompliance, two other strategic approaches are used: direct observation of treatment and provision of fixed-drug-combination (FDC) products. Because it is difficult to predict which patients will adhere to the recommended treatment, all patients should have their therapy directly supervised, especially during the initial phase. In the United States, personnel to supervise therapy are usually available through tuberculosis control programs of local public health departments. Supervision increases the proportion of patients completing treatment and greatly lessens the chances of relapse and acquired drug resistance. FDC products (e.g., isoniazid/rifampin, ethionamide/pyrazinamide, and streptomycin/pyrazinamide, and isoniazid/ethambutol) are available (except, in the United States, for the four-drug FDC) and strongly recommended as a means of minimizing the likelihood of prescription error and of the development of drug resistance as the result of monotherapy. In some formulations of these combination products, the bioavailability of rifampin has been found to be substandard. In North America and Europe, regulatory authorities ensure that combination products are of good quality; however, this type of quality assurance cannot be assumed to take place in less affluent countries. Alternative regimens for patients who exhibit drug intolerance or adverse reactions are listed in Table 150-3. However, severe side effects prompting discontinuation of any of the first-line drugs and use of these alternative regimens are uncommon.

**MONITORING TREATMENT RESPONSE AND DRUG TOXICITY** Bacteriologic evaluation is the preferred method of monitoring the response to treatment for tuberculosis. Patients with pulmonary disease should have their sputum examined monthly until cultures become negative. With the recommended regimen, >80% of patients will have negative sputum cultures at the end of the second month of treatment. By the end of the third month, virtually all patients should be culture-negative. In some patients, especially those with extensive cavitary disease and large numbers of organisms, AFB smear conversion may follow culture conversion. This phenomenon is presumably due to the expectation and microscopic visualization of dead bacilli. As noted above, patients with cavitary disease who do not achieve sputum culture conversion by 2 months require extended treatment. When a patient’s sputum cultures remain positive at ≥3 months, treatment failure and drug resistance should be suspected (see below). A sputum specimen should be collected by the end of treatment to document cure. If mycobacterial cultures are not practical, then monitoring by AFB smear examination should be undertaken at 2, 5, and 6 months. Smears positive after 5 months are indicative of treatment failure.

Bacteriologic monitoring of patients with extrapulmonary tuberculosis is more difficult and often is not feasible. In these cases, the response to treatment must be assessed clinically.

Monitoring of the response to treatment during chemotherapy by serial chest radiographs is not recommended, as radiographic changes may lag behind bacteriologic response and are not highly sensitive. After the completion of treatment, neither sputum examination nor chest radiography is recommended for follow-up purposes. However, a chest radiograph may be obtained at the end of treatment and used for comparative purposes should the patient develop symptoms of recurrent tuberculosis months or years later. Patients should be instructed

Patients with pulmonary disease should have their sputum examined monthly until cultures become negative. With the recommended regimen, >80% of patients will have negative sputum cultures at the end of the second month of treatment. By the end of the third month, virtually all patients should be culture-negative. In some patients, especially those with extensive cavitary disease and large numbers of organisms, AFB smear conversion may follow culture conversion. This phenomenon is presumably due to the expectation and microscopic visualization of dead bacilli. As noted above, patients with cavitary disease who do not achieve sputum culture conversion by 2 months require extended treatment. When a patient’s sputum cultures remain positive at ≥3 months, treatment failure and drug resistance should be suspected (see below). A sputum specimen should be collected by the end of treatment to document cure. If mycobacterial cultures are not practical, then monitoring by AFB smear examination should be undertaken at 2, 5, and 6 months. Smears positive after 5 months are indicative of treatment failure. Bacteriologic monitoring of patients with extrapulmonary tuberculosis is more difficult and often is not feasible. In these cases, the response to treatment must be assessed clinically. Monitoring of the response to treatment during chemotherapy by serial chest radiographs is not recommended, as radiographic changes may lag behind bacteriologic response and are not highly sensitive. After the completion of treatment, neither sputum examination nor chest radiography is recommended for follow-up purposes. However, a chest radiograph may be obtained at the end of treatment and used for comparative purposes should the patient develop symptoms of recurrent tuberculosis months or years later. Patients should be instructed
to report promptly for medical assessment should they develop any such symptoms.

During treatment, patients should be monitored for drug toxicity (Table 149-3). The most common adverse reaction of significance is hepatitis. Patients should be carefully educated about the signs and symptoms of drug-induced hepatitis (e.g., dark urine, loss of appetite) and should be instructed to discontinue treatment promptly and seek their health care provider should these symptoms occur. Although biochemical monitoring is not routinely recommended, all adult patients should undergo baseline assessment of liver function (e.g., measurement of serum levels of hepatic aminotransferases and serum bilirubin). Older patients, those with concomitant diseases, those with a history of hepatic disease, and those using alcohol daily should be monitored especially closely (i.e., monthly) with repeated measurements of aminotransferases, during the initial phase of treatment. Up to 20% of patients have small increases in aspartate aminotransferase (up to three times the upper limit of normal) that are accompanied by no symptoms and are of no consequence. For patients with symptomatic hepatitis and those with marked (five- to sixfold) elevations in serum levels of aspartate aminotransferase, treatment should be stopped and drugs reintroduced one at a time after liver function has returned to normal.

Hypersensitivity reactions usually require the discontinuation of all drugs and rechallenge to determine which agent is the culprit. Because of the variety of regimens available, it is usually not necessary—although it is possible—to desensitize patients. Hyperuricemia and arthralgia caused by pyrazinamide can usually be managed by the administration of acetylsalicylic acid; however, pyrazinamide treatment should be stopped if the patient develops gouty arthritis. Individuals who develop autoimmune thrombocytopenia secondary to rifampin therapy should not receive the drug thereafter. Similarly, the occurrence of optic neuritis with ethambutol is an indication for permanent discontinuation of this drug. Other common manifestations of drug intolerance, such as pruritus and gastrointestinal upset, can generally be managed without the interruption of therapy.

**TREATMENT FAILURE AND RELAPSE**

As stated above, treatment failure should be suspected when a patient’s sputum cultures remain positive after 3 months or when AFB smears remain positive after 5 months. In the management of such patients, it is imperative that the current isolate be tested for susceptibility to first- and second-line agents. When the results of susceptibility testing are expected to become available within a few weeks, changes in the regimen can be postponed until that time. However, if the patient’s clinical condition is deteriorating, an earlier change in regimen may be indicated. A cardinal rule in the latter situation is always to add more than one drug at a time to a failing regimen: at least two and preferably three drugs that have never been used and to which the bacilli are likely to be susceptible should be added. The patient may continue to take isoniazid and rifampin along with these new agents pending the results of susceptibility tests.

The mycobacterial strains infecting patients who experience a relapse after apparently successful treatment are less likely to have acquired drug resistance (see below) than are strains from patients in whom treatment has failed. However, if the regimen administered initially does not contain rifampin (and thus is not a short-course regimen), the probability of isoniazid resistance is high. Acquired resistance is uncommon among strains from patients who relapse after completing a short-course regimen. However, it is prudent to begin the treatment of all relapses with all five first-line drugs pending the results of susceptibility testing. In less affluent countries and other settings where facilities for culture and drug susceptibility testing are not available, a standard regimen should be used in all instances of relapse and treatment failure (Table 150-3).

**HIV-ASSOCIATED TUBERCULOSIS**

In general, the standard treatment regimens are equally efficacious in HIV-negative and HIV-positive patients. However, adverse drug effects may be more pronounced in HIV-infected patients. Since these effects may include serious or even fatal skin reactions to amithiozone (thiacetazone), this drug, which has been used in place of ethambutol in developing countries, is no longer recommended by WHO.

There are three important considerations relevant to tuberculosis treatment in HIV-infected patients: an increased frequency of paradoxical reactions, drug interactions between HAART and rifamycins, and development of rifampin monoresistance with widely spaced intermittent treatment. Exacerbations in symptoms, signs, and laboratory or radiographic manifestations of tuberculosis—termed *paradoxical reactions*—have been associated with the administration of HAART regimens. The presumed pathogenesis of paradoxical reactions is an immune response to antigens released as bacilli are killed by effective chemotherapy. In patients in whom HAART has recently been started, paradoxical reactions may be due to improving immune function. The first priority in the management of a possible paradoxical reaction is to ensure that the clinical syndrome does not represent a failure of tuberculosis treatment or the development of another infection. Mild paradoxical reactions can be managed with symptom-based treatment. Glucocorticoids have been used for more severe reactions, although this practice has not been formally evaluated in clinical trials.

Most HIV-infected tuberculosis patients are candidates for HAART, although the optimal timing for antiretroviral treatment is not known. Rifampin, a potent inducer of enzymes of the cytochrome P450 system, lowers serum levels of many HIV protease inhibitors and some nonnucleoside reverse transcriptase inhibitors, essential drugs used in HAART regimens. In such cases, rifabutin, which has much less enzyme-inducing activity, has been recommended in place of rifampin. However, dose adjustments for rifabutin and/or the antiretroviral drugs may be necessary. Because recommendations are frequently updated, consultation of the CDC website is advised (www.cdc.gov/nchstp/bb).

Several clinical trials of HIV-associated tuberculosis have found that patients with advanced immunosuppression (CD4+ cell counts of <100) are prone to treatment failure and relapse with rifampin-resistant organisms when treated with “highly intermittent” (i.e., once- or twice-weekly) rifamycin-containing regimens. Consequently, it is recommended that these patients receive daily or thrice-weekly therapy for the entire course.

**DRUG-RESISTANT TUBERCULOSIS**

Strains of *M. tuberculosis* resistant to individual drugs arise by spontaneous point mutations in the mycobacterial genome, which occur at low but predictable rates. Because there is no cross-resistance among the commonly used drugs, the probability that a strain will be resistant to two drugs is the product of the probabilities of resistance to each drug and thus is low. The development of drug-resistant tuberculosis is invariably the result of monotherapy—i.e., the failure of the health care provider to prescribe at least two drugs to which the bacilli are susceptible or of the patient to take properly prescribed therapy.

Drug-resistant tuberculosis may be either primary or acquired. Primary drug resistance is that in a strain infecting a patient who has not previously been treated. Acquired resistance develops during treatment with an inappropriate regimen. In North America and Europe, rates of primary resistance are generally low, and isoniazid resistance is most common. In the United States, while primary isoniazid resistance was stable at about 7 to 8% between 1993 and 2002, the rate of primary multidrug-resistant (MDR) tuberculosis declined from 2.5% to 1%. Resistance rates are higher among foreign-born and HIV-infected patients. Worldwide, MDR tuberculosis is a serious problem in some regions, especially in the former Soviet Union and parts of Asia. As noted above, drug-resistant tuberculosis can be prevented by adherence to the principles of sound therapy: the inclusion of at least two bactericidal drugs to which the organism is susceptible and the verification that patients complete the prescribed course.

Although the 6-month regimen described in Table 150-3 is generally effective for patients with initial isoniazid-resistant disease, it is
prudent to include ethambutol and pyrazinamide for the full 6 months. In such cases, isoniazid probably does not contribute to a successful outcome and should be omitted. MDR tuberculosis is more difficult to manage than is disease caused by a drug-susceptible organism, especially because resistance to other first-line drugs as well as to isoniazid and rifampin is common. For strains resistant to isoniazid and rifampin, combinations of a fluoroquinolone, ethambutol, pyrazinamide, and streptomycin (or, for those resistant to streptomycin as well, another injectable agent such as amikacin), given for 18 to 24 months and for at least 9 months after spu tum culture conversion, may be effective. For patients with bacilli resistant to all of the first-line agents, cure may be attained with a combination of four second-line drugs, including one injectable agent (Table 150-3). The optimal duration of treatment in this situation is not known; however, a duration of 24 months is recommended. For patients with localized disease and sufficient pulmonary reserve, lobectomy or pneumonectomy may be helpful. Because the management of patients with MDR tuberculosis is complicated by both social and medical factors, care of these patients should be restricted to specialists and tuberculosis control programs.

**SPECIAL CLINICAL SITUATIONS** Although comparative clinical trials of treatment for extrapulmonary tuberculosis are limited, the available evidence indicates that most forms of disease can be treated with the 6-month regimen recommended for patients with pulmonary disease. The American Academy of Pediatrics recommends that children with bone and joint tuberculosis, tuberculous meningitis, or miliary tuberculosis receive 9 to 12 months of treatment.

Treatment for tuberculosis may be complicated by underlying medical problems that require special consideration (Table 149-1). As a rule, patients with chronic renal failure should not receive aminoglycosides and should receive ethambutol only if serum levels can be monitored. Isoniazid, rifampin, and pyrazinamide may be given in the usual doses in cases of mild to moderate renal failure, but the dosages of isoniazid and pyrazinamide should be reduced for all patients with severe renal failure except those undergoing hemodialysis. Patients with hepatic disease pose a special problem because of the hepatotoxicity of isoniazid, rifampin, and pyrazinamide. Patients with severe hepatic disease may be treated with ethambutol and streptomycin and, if required, with isoniazid and rifampin under close supervision. The use of pyrazinamide by patients with liver failure should be avoided. Silver treatment necessitates the extension of therapy by at least 2 months. The regimen of choice for pregnant women (Tables 149-1 and 150-3) is 9 months of treatment with isoniazid and rifampin supplemented by ethambutol for the first 2 months. When required, pyrazinamide may be given, although there are no data concerning its safety in pregnancy. Streptomycin is contraindicated because it is known to cause eighth-cranial-nerve damage in the fetus. Treatment for tuberculosis is not a contraindication to breast feeding; most of the drugs administered will be present in small quantities in breast milk, albeit at concentrations far too low to provide any therapeutic or prophylactic benefit to the child.

**PREVENTION** By far the best way to prevent tuberculosis is to diagnose infectious cases rapidly and administer appropriate treatment until cure. Additional strategies include BCG vaccination and treatment of persons with latent tuberculosis infection who are at high risk of developing active disease.

**BCG Vaccination** BCG was derived from an attenuated strain of *M. bovis* and was first administered to humans in 1921. Many BCG vaccines are available worldwide; all are derived from the original strain, but the vaccines vary in efficacy. In fact, estimates of efficacy from randomized, placebo-controlled trials have ranged from 80% to nil. A similar range of efficacy was found in recent observational studies (case-control, historic cohort, and cross-sectional) in areas where infants are vaccinated at birth. These studies also found higher rates of efficacy in the protection of infants and young children from relatively serious forms of tuberculosis, such as tuberculous meningitis and miliary tuberculosis.

BCG vaccine is safe and rarely causes serious complications. The local tissue response begins 2 to 3 weeks after vaccination, with scar formation and healing within 3 months. Side effects—most commonly, ulceration at the vaccination site and regional lymphadenitis—occur in 1 to 10% of vaccinated persons. Some vaccine strains have caused osteomyelitis in ~1 case per million doses administered. Disseminated BCG infection and death have occurred in 1 to 10 cases per 10 million doses administered, although this problem is restricted almost exclusively to persons with impaired immunity, such as children with severe combined immunodeficiency syndrome or adults with HIV infection. BCG vaccination induces PPD reactivity, which tends to wane with time. The presence or size of PPD skin-test reactions after vaccination does not predict the degree of protection afforded.

BCG vaccine is recommended for routine use at birth in countries with high tuberculosis prevalence. However, because of the low risk of transmission of tuberculosis in the United States and the unreliable protection afforded by BCG, the vaccine has never been recommended for general use in the United States. The CDC has recommended that HIV-infected adults and children not receive BCG vaccine, although the WHO has recommended that asymptomatic HIV-infected children residing in tuberculosis-endemic areas receive BCG.

**Tuberculin Reaction Size, Treatment of Latent Tuberculosis Infection** A major component of tuberculosis control in the United States is the treatment of selected persons with latent tuberculosis infection to prevent active disease. This intervention (formerly called preventive chemotherapy or chemoprophylaxis) is based on the results of a large number of randomized, placebo-controlled clinical trials demonstrating that a 6- to 12-month course of isoniazid reduces the risk of active tuberculosis in infected people by ≥90%. Analysis of available data indicates that the optimal duration of treatment is 9 to 10 months. In the absence of reinfection, the protective effect is believed to be lifelong. Clinical trials have also shown that isoniazid reduces rates of tuberculosis among PPD-positive persons with HIV infection. Studies in HIV-infected patients have demonstrated the effectiveness of shorter courses of rifampin-based treatment.

In most cases, candidates for treatment of latent tuberculosis (Table 150-4) are identified by PPD skin testing of persons in defined high-risk groups. For skin testing, 5 tuberculin units of polysorbate-stabilized PPD should be injected intradermally into the volar surface of the forearm (Mantoux method). Multipuncture tests, which may be useful for screening large populations, are not recommended for this purpose; any positive reaction to a multipuncture test must be confirmed by Mantoux testing. Reactions are read at 48 to 72 h as the transverse diameter in millimeters of induration; the diameter of erythema is not considered. In some persons, PPD reactivity wanes with time but can be recalled by a second skin test administered ≥1 week after the first (i.e., two-step testing). For persons undergoing periodic treatment for extrapulmonary tuberculosis.

a Tuberculin-negative contacts, especially children, should receive prophylaxis for 2 to 3 months after contact ends and should then be retested with PPD. Those whose results remain negative should discontinue prophylaxis. HIV-infected contacts should receive a full course of treatment regardless of PPD results.

b Includes diabetes mellitus, some hematologic and reticuloendothelial diseases, injection drug use (with HIV seronegativity), end-stage renal disease, and clinical situations associated with rapid weight loss.

c Decision to treat should be based on individual risk/benefit considerations.
PPD skin testing, such as health care workers and individuals admitted to long-term-care institutions, initial two-step testing may preclude subsequent misclassification of persons with boosted reactions as PPD converters.

The cutoff for a positive skin test (and thus for treatment) is related both to the probability that the reaction represents true infection and to the likelihood that the individual, if truly infected, will develop tuberculosis (Table 150–4). Thus positive reactions for close contacts of infectious cases, persons with HIV infection, persons receiving drugs that suppress the immune system, and previously untreated persons whose chest radiographs is consistent with healed tuberculosis are defined as an area of induration ≥5 mm in diameter.

A 10-mm cutoff is used to define positive reactions in most other at-risk persons. For persons with a very low risk of developing tuberculosis if infected, a cutoff of 15 mm is used. Treatment should be considered for persons from tuberculosis-endemic countries who have a history of BCG vaccination.

Some PPD-negative individuals are also candidates for treatment. Infants and children who have come into contact with infectious cases should be treated and should have a repeat skin test 2 or 3 months after contact ends. Those whose test results remain negative should discontinue treatment. HIV-infected persons who have been exposed to an infectious tuberculosis patient should receive treatment regardless of the PPD test result.

Isoniazid is administered at a daily dose of 5 mg/kg (up to 300 mg/ d) for 9 months (Table 150–5). On the basis of cost-benefit analyses, a 6-month period of treatment has been recommended in the past and may be considered for HIV-negative adults with normal chest radiographs when financial considerations are important. When supervised treatment is desirable and feasible, isoniazid may be given at a dose of 15 mg/kg (up to 900 mg) twice weekly. An alternative regimen for adults is 4 months of daily rifampin. A previously recommended regimen of 2 months of rifampin and pyrazinamide has been associated with serious and fatal hepatotoxicity and is now generally not recommended for use. The rifampin regimen should be considered for persons who are likely to have been infected with an isoniazid-resistant strain.

Isoniazid should not be given to persons with active liver disease. All persons at increased risk of hepatotoxicity (e.g., those abusing alcohol daily and those with a history of liver disease) should undergo baseline and then monthly assessment of liver function. All patients should be carefully educated about hepatitis and instructed to discontinue use of the drug immediately should any symptoms develop. Moreover, patients should be seen and questioned monthly during therapy, be educated about reactions and should be given no more than 1 month’s supply of drug at each visit.

It may be more difficult to ensure compliance when treating persons with latent infection than when treating those with active tuberculosis. If family members of active cases are being treated, compliance and monitoring may be easier. When feasible, twice-weekly supervised therapy may increase the likelihood of completion. As in active cases, the provision of incentives may also be helpful.

### BASICS OF CONTROL

The highest priority in any tuberculosis control program is the prompt detection of cases and the provision of short-course chemotherapy to all tuberculosis patients under proper case-management conditions, including directly observed therapy, with emphasis on the cure of sputum smear–positive cases. In addition, in low-prevalence countries with adequate resources, screening of high-risk groups (such as immigrants from high-prevalence countries and HIV-seropositive persons) is recommended. Identification of active cases of tuberculosis should be followed by treatment. PPD-positive high-risk persons should be treated for latent infection. Contact investigation is an important component of efficient tuberculosis control. In the United States, a great deal of attention has been given to the transmission of tuberculosis (particularly in association with HIV infection) in institutional settings such as hospitals, homeless shelters, and prisons. Measures to limit such transmission include respiratory isolation of persons with suspected tuberculosis until they are proven to be noninfectious (i.e., by spumum AFB smear negativity), proper ventilation in rooms of patients with infectious tuberculosis, use of ultraviolet lights in areas of increased risk of tuberculosis transmission, and

† Strength of the recommendation: A. Both strong evidence of efficacy and substantial clinical benefit support recommendation for use. Should always be offered. B. Moderate evidence for efficacy or strong evidence for efficacy, but only limited clinical benefit, supports recommendation for use. Should generally be offered. C. Evidence for efficacy is insufficient to support a recommendation for or against use, or evidence for efficacy might not outweigh adverse consequences (e.g., drug toxicity, drug interactions) or cost of the treatment or alternative approaches. Optional. D. Moderate evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should generally not be offered. E. Good evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should never be offered.

‡ Quality of evidence supporting the recommendation: I. Evidence from at least one properly randomized controlled trial. II. Evidence from at least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), from multiple time-series studies, or from dramatic results in uncontrolled experiments. III. Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.

§ Recommended regimen for persons aged ≥18 years.

‖ Recommended regimen for pregnant women.

Leprosy, first described in ancient Indian texts from the sixth century B.C., is a nonfatal, chronic infectious disease caused by Mycobacterium leprae, whose clinical manifestations are largely confined to the skin, peripheral nervous system, upper respiratory tract, eyes, and testes. The unique tropism of M. leprae for peripheral nerves (from large nerve trunks to microscopic dermal nerves) and certain immunologically mediated reactional states are the major causes of morbidity in leprosy. The propensity of the disease, when untreated, to result in characteristic deformities and the recognition in most cultures that the disease is communicable from person to person have resulted historically in a profound social stigma. Today, with early diagnosis and the institution of appropriate and effective antimicrobial therapy, patients can lead productive lives in the community, and deformities and other visible manifestations can largely be prevented.

**ETIOLOGY** M. leprae is an obligate intracellular bacillus (0.3 to 1 μm wide and 1 to 8 μm long) that is acid-fast, indistinguishable microscopically from other mycobacteria, and ideally detected in tissue sections by a modified Fite stain. Strain variability was recently discovered in this organism. M. leprae produces no known toxins and is well adapted to penetrate and reside within macrophages, yet it may survive outside the body for months. In untreated patients, only ~1% of M. leprae organisms are viable. The morphologic index (MI), a measure of the number of acid-fast bacilli (AFB) in skin scrapings that stain uniformly bright, correlates with viability. The bacteriologic index (BI), a logarithmic-scaled measure of the density of M. leprae in the dermis, may be as high as 4+ to 6+ in untreated patients, falling by one unit per year during effective therapy; the rate of fall is independent of the relative potency of effective antimicrobial therapy. A rising MI or BI suggests relapse and perhaps—if the patient is being treated—drug resistance; the latter possibility can be confirmed or excluded in the mouse model.

As a result of reductive evolution, almost half of the M. leprae genome contains nonfunctional genes; only 1605 genes encode for proteins. In contrast, M. tuberculosis uses 91% of its genome to encode for 4000 proteins. Among the lost genes in M. leprae are those for catabolic and respiratory pathways; transport systems; purine, methionine, and glutamine synthesis; and nitrogen regulation. The genome of M. leprae provides a metabolic rationale for its obligate intracellular existence and reliance on host biochemical support, a template for targets of drug development, and ultimately a pathway to cultivation. The recent finding of strain variability among M. leprae isolates provides a powerful tool with which to address anew the organism’s epidemiology and pathobiology. The bacterium’s complex cell wall has a peptidoglycan backbone, which is linked to arabinogalactan and mycolic acids. Lipoarabinomannan is a key component of the cell membrane, and the outer capsule contains large amounts of an M. leprae–specific phenolic glycolipid (PGL-1), which is detected in serologic tests.

Among the mycobacteria, M. leprae is unique in exhibiting dopa oxidase activity and an acid-fastness that is pyridine-extractable. Although it was the first bacterium to be etiologically associated with human disease, M. leprae remains one of the few bacterial species that still has not been cultivated on artificial medium or tissue culture. The multiplication of M. leprae in mouse footpads (albeit limited, with a doubling time of ~2 weeks) has provided a means to evaluate antimicrobial agents, monitor clinical trials, and screen vaccines. M. leprae grows best in cooler tissues (the skin, peripheral nerves, anterior chamber of the eye, upper respiratory tract, and testes), sparing warmer areas of the skin (the axilla, groin, scalp, and midline of the back).

**EPIDEMIOLOGY** Leprosy is almost exclusively a disease of the developing world, affecting areas of Asia, Africa, Latin America, and the Pacific. While Africa has the highest disease prevalence, Asia has the most cases. More than 80% of the world’s cases occur in a few countries: India, China, Myanmar, Indonesia, Brazil, Nigeria, Madagascar, and Nepal. Within endemic locales, the distribution of leprosy is quite uneven, with areas of high prevalence bordering on areas with little or no disease. In Brazil the majority of cases occur in the Amazon basin and two western states, while in Mexico leprosy is mostly confined to the Pacific coast. Except as imported cases, leprosy is largely absent from the United States, Canada, and northwestern Europe. In the United States, ~4000 persons have leprosy and 100 to 200 new cases are reported annually, most of them in California, Texas, New York, and Hawaii among immigrants from Mexico, Southeast Asia, the Philippines, and the Caribbean.

The global prevalence of leprosy is difficult to assess, given that many of the locales with high prevalence lack a significant medical or public health infrastructure. Estimates range from 0.6 to 8 million affected individuals. The lower estimate includes only persons who have not completed chemotherapy, excluding those who may be physi...
ically or psychologically damaged from leprosy and who may yet relapse or develop immune-mediated reactions; the higher figure includes patients whose infections probably are already cured and many who have no leprosy-related deformity or disability. Although the figures on the worldwide prevalence of leprosy are debatable, it is generally agreed that the annual incidence of new cases is rising (529,000 estimated new cases in 1995 and 719,000 in 2001, with 60% of the latter number from India alone).

Leprosy is associated with poverty and rural residence. It appears not to be associated with AIDS, perhaps because of leprosy’s long incubation period. Most people appear to be naturally immune to leprosy and do not develop disease manifestations following exposure. The time of peak onset is in the second and third decades of life. The most severe polar form of leprosy is twice as common among men as among women and is rarely encountered in children. The frequency of the polar forms of leprosy in different countries varies widely and may in part be genetically determined; certain HLA associations are known for both polar forms of leprosy (see below). In India and Africa, 90% of cases are tuberculoid; in Southeast Asia, 50% are tuberculoid and 50% lepromatous; and in Mexico, 90% are lepromatous. (For definitions of disease types, see Table 151-1 and “Clinical, Histologic, and Immunologic Spectrum,” below).

Transmission The route of transmission of leprosy remains uncertain and may be multiple: nasal droplet infection, contact with infected soil, and even insect vectors have been considered the prime candidates. Aerosolized M. leprae can cause infection in immunosuppressed mice, and a sneeze from an untreated lepromatous patient may contain >1010 AFB. Furthermore, both IgA antibody to M. leprae and genes of M. leprae—demonstrable by polymerase chain reaction (PCR)—have been found in the nose of individuals without signs of leprosy from endemic areas and in 19% of occupational contacts of lepromatous patients.

Several lines of evidence implicate soil transmission of leprosy: (1) in endemic countries such as India, leprosy is primarily a rural and not an urban disease; (2) M. leprae products have been demonstrated to be resident in soil in endemic locales; and (3) direct dermal inoculation (e.g., during tattooing) may transmit M. leprae, and common sites of leprosy in children are the buttocks and thighs, suggesting that microinoculation of infected soil may transmit the disease.

Evidence for insect vectors of leprosy includes the demonstration that bedbugs and mosquitoes in the vicinity of leprosaria regularly harbor M. leprae and that experimentally infected mosquitoes can transmit infection to mice. Skin-to-skin contact is generally not considered an important route of transmission.

In endemic countries, ~50% of leprosy patients have a history of intimate contact with an infected person (often a household member), while, for unknown reasons, leprosy patients in nonendemic locales can identify such contact only 10% of the time. Moreover, household contact with an infected lepromatous case carries an eventual risk of disease acquisition of ~10% in endemic areas as opposed to only 1% in nonendemic locales. Contact with a tuberculoid case carries a very low risk. Physicians and nurses caring for leprosy patients and the coworkers of these patients are not at risk for leprosy.

M. leprae causes disease primarily in humans. However, in Texas and Louisiana, 15% of nine-banded armadillos are infected, and armadillo contact occasionally results in human disease; armadillos develop a disseminated infection following intravenous inoculation of live M. leprae.

**CLINICAL, HISTOLOGIC, AND IMMUNOLOGIC SPECTRUM**

The incubation period prior to manifestation of clinical disease can vary between 2 and 40 years, although it is generally 5 to 7 years in duration. Leprosy presents as a spectrum of clinical manifestations that have bacteriologic, pathologic, and immunologic counterparts. The spectrum from polar tuberculoid (TT) to borderline tuberculoid (BT) to mid-borderline (BB, which is rarely encountered) to borderline lepromatous (BL) to polar lepromatous (LL) disease is associated with an evolution from asymmetric localized macules and plaques to nodular and indurated symmetric generalized skin manifestations, an increasing bacterial

load, and loss of M. leprae–specific cellular immunity (Table 151-1). Distinguishing dermatopathologic characteristics include the number of lymphocytes, giant cells, and AFB as well as the nature of epithelioid cell differentiation. Where a patient presents on the clinical spectrum largely determines prognosis, complications, reactional states, and the intensity of antimicrobial therapy required.

**Tuberculoid Leprosy** At the less severe end of the spectrum is tuberculoid leprosy, which encompasses TT and BT disease. In general, these forms of leprosy result in symptoms confined to the skin and peripheral nerves. The skin lesions of tuberculoid leprosy consist of one or a few hypopigmented macules or plaques that are sharply demarcated and hyposthetic, often have erythematous or raised borders, and are devoid of the normal skin organs (sweat glands and hair follicles) and thus are dry, scaly, and anhidrotic. AFB are generally absent or few in number. Tuberculoid leprosy patients may have asymmetric enlargement of one or a few peripheral nerves. Indeed, leprosy and certain rare hereditary neuropathies are the only human diseases associated with peripheral-nerve enlargement. Although any peripheral nerve may be enlarged (including small digital and supraclavicular nerves), those most commonly affected are the ulnar, posterior auricular, peroneal, and posterior tibial nerves, with associated hypopigesis and myopathy. TT leprosy is the most common form of the disease encountered in India and Africa but is virtually absent in Southeast Asia, where BT leprosy is frequent.

In tuberculoid leprosy, T cells breach the perineurium, and destruction of Schwann cells and axons may be evident, resulting in fibrosis of the epineurium, replacement of the endoneurium with epithelial granulomas, and occasionally caceous necrosis. Such invasion and destruction of nerves in the dermis by T cells are pathognomonic for leprosy.

Circulating lymphocytes from patients with tuberculoid leprosy readily recognize M. leprae and its constituent proteins, and patients have positive lepromin skin tests (see “Diagnosis,” below). In tuberculoid leprosy tissue, there is a 2:1 predominance of helper CD4+ over CD8+ T lymphocytes. Tuberculoid tissues are rich in the mRNAs of the proinflammatory T, family of cytokines: interleukin (IL) 2, interferon (IFN) γ (IFN-γ), and IL-12; in contrast, IL-4, IL-5, and IL-10 mRNAs are scarce.

**Lepromatous Leprosy** Lepromatous leprosy patients present with symmetrically distributed skin nodules, raised plaques, or diffuse dermal infiltration, which, when on the face, results in leonine facies. Late manifestations include loss of eyebrows (initially the lateral margins only; Fig. 151-1) and eyelashes, pendulous earlobes, and dry scaling skin, particularly on the feet. In LL leprosy, bacilli are numerous in the skin (as many as 10⁹/g), where they are often found in large clumps (globi), and in peripheral nerves, where they initially invade Schwann cells, resulting in foamy degenerative myelination and axonal degeneration and later in Wallerian degeneration. In addition, bacilli are plentiful in circulating blood and in all organ systems except the lungs and the central nervous system. Nevertheless, patients are afebrile, and there is no evidence of major organ system dysfunction. Almost exclusively found in western Mexico and the Caribbean is a form of lepromatous leprosy without visible skin lesions but with diffuse dermal infiltration and a demonstrably thickened dermis, termed diffuse lepromatosis. In lepromatous leprosy, nerve enlargement and damage tend to be symmetric, result from actual bacillary invasion, and are more insidious but ultimately more extensive than in tuberculoid leprosy. Patients with LL leprosy have acral, distal, symmetric peripheral neuropathy and a tendency toward symmetric nerve-trunk enlargement. They may also have signs and symptoms related to involvement of the upper respiratory tract, the anterior chamber of the eye, and the testes.

In untreated LL patients, lymphocytes regularly fail to recognize either M. leprae or its protein constituents, and lepromin skin tests are negative (see “Diagnosis,” below). This loss of protective cellular immunity appears to be antigen-specific, as patients are not unusually susceptible to opportunistic infections, cancer, or AIDS and maintain delayed-type hypersensitivity to Candida, Trichophyton, mumps, tetanus toxoid, and even purified protein derivative of tuberculin. At times, M. leprae–specific anergy is reversible with effective chemotherapy. In LL tissues, there is a 2:1 ratio of CD8+ to CD4+ T lymphocytes. LL tissues demonstrate a T, cytokine profile, being rich in mRNAs for IL-4, IL-5, and IL-10 and poor in those for IL-2, IFN-γ, and IL-12. It appears that cytokines mediate a protective tissue response in leprosy, as injection of IFN-γ or IL-2 into lepromatous lesions causes a loss of AFB and histopathologic conversion toward a tuberculoid pattern. Macrophages of lepromatous leprosy patients appear to be functionally intact; circulating monocytes exhibit normal microbialic function and responsiveness to IFN-γ.

**Reactive States** Leprosy reactions comprise several common immunologically mediated inflammatory states that cause considerable morbidity. Some of these reactions precede diagnosis and the institution of effective antimicrobial therapy. Indeed, these reactions may precipitate presentation for medical attention and diagnosis; others occur after the initiation of appropriate chemotherapy. In the latter circumstances, patients often lose confidence in conventional therapy, perceiving that their leprosy is worsening. Only by warning patients of the potential for these reactions and describing their manifestations can physicians treating leprosy patients ensure continued credibility.

**TYPE 1 LEPRA REACTIONS (DOWNGRADING AND REVERSAL REACTIONS)** These reactions occur in almost half of patients with borderline forms of leprosy but not in patients with polar disease. Manifestations include classic signs of inflammation within previously involved macules, papules, and plaques and, on occasion, the appearance of new skin lesions, neuritis, and (less commonly) fever—generally low-grade. The nerve trunk most commonly involved in this process is the ulnar nerve at the elbow, which may be painful and exquisitely tender. If patients with affected nerves are not treated promptly with glucocorticoids (see below), irreversible nerve damage may result in as little as 24 h. The most dramatic manifestation is footdrop, which occurs when the peroneal nerve is involved.

When type 1 lepra reactions precede the initiation of appropriate antimicrobial therapy, they are termed downgrading reactions, and the case becomes histologically more lepromatous; when they occur after the initiation of therapy, they are termed reversal reactions, and the case becomes more tuberculoid. Reversal reactions often occur in the first months or years after the initiation of therapy but may also develop several years thereafter.

Edema is the most characteristic microscopic feature of type 1 lepra...
lesions, whose diagnosis is primarily clinical. Reversal reactions are typified by a T_4/T_8 cytokine profile, with an influx of CD4+ helper cells and increased levels of IFN-γ and IL-2. In addition, type 1 reactions are associated with large numbers of T cells bearing γ/δ receptors—a unique feature of leprosy.

**TYPE 2 LEPROREACTIONS** (ERYTHEMA NODOSUM LEPROTICUM, ENL) ENL occurs exclusively in patients near the lepromatous end of the leprosy spectrum (BL-LL), affecting nearly 50% of this group. Although ENL may precede leprosy diagnosis and initiation of therapy—sometimes, in fact, prompting the diagnosis—in 90% of cases it follows the institution of chemotherapy, generally within 2 years. The most common features of ENL are crops of painful erythematous papules that resolve spontaneously in a few days to a week but may recur; malaise; and fever that can be profound. However, patients may also experience symptoms of neuritis, lymphadenitis, uveitis, orchitis, and glomerulonephritis and may develop anemia, leukocytosis, and abnormal liver function tests, particularly increased aminotransferase levels. Individual patients may have either a single bout of ENL or chronic recurrent manifestations. Bouts may be either mild or severe and generalized; in rare instances, ENL results in death.

Skin biopsy of ENL papules reveals vasculitis or panniculitis, sometimes with many lymphocytes but characteristically with polymorphonuclear leukocytes as well.

Elevated levels of circulating tumor necrosis factor (TNF) have been demonstrated in ENL; thus, TNF may play a central role in the pathobiology of this syndrome. ENL is thought to be a consequence of immune complex deposition, given its T_H1 cytokine profile and its high levels of IL-6 and IL-8. However, in ENL tissue, the presence of HLA Dr framework antigen of epidermal cells—considered a marker for a delayed-type hypersensitivity response—and evidence for higher levels of IL-2 and IFN-γ than are usually seen in polar lepromatous disease suggest an alternative mechanism.

**LUCIO’S PHENOMENON** This unusual reaction is seen exclusively in patients from the Caribbean and Mexico who have the diffuse lepromatous form of lepromatous leprosy, most often those who are untreated. Patients with this reaction develop recurrent crops of large, sharply margined, ulcerative lesions—particularly on the lower extremities—that may be generalized and, when so, are frequently fatal as a result of secondary infection and consequent septic bacteremia. Histologically, the lesions are characterized by ischemic necrosis of the epidermis and superficial dermis, heavy parasitism of endothelial cells with AFB, and endothelial proliferation and thrombus formation in the larger vessels of the deeper dermis. Like ENL, the Lucio phenomenon is probably mediated by the immune complex.

**Complications**

**THE EXTREMITIES** Complications of the extremities in leprosy patients are primarily a consequence of neuropathy leading to insensitivity and myopathy. Insensitivity affects fine touch, pain, and heat receptors but generally spares position and vibration appreciation. The most commonly affected nerve trunk is the ulnar nerve at the elbow, whose involvement results in clawing of the fourth and fifth fingers, loss of dorsal interosseous musculature in the affected hand, and loss of sensation in these distributions. Median nerve involvement in leprosy impairs thumb opposition and grasp, while radial nerve dysfunction, though rare in leprosy, leads to wristdrop. Tendon transfers can restore hand function but should not be performed until 6 months after the initiation of antimicrobial therapy and the conclusion of episodes of acute neuritis.

Plantar ulceration, particularly at the metatarsal heads, is probably the most frequent complication of leprosy neuropathy. Therapy requires careful debridement; administration of appropriate antibiotics; avoidance of weight-bearing until ulcerations are healed, with slowly progressive ambulation thereafter; and wearing of specialized shoes to prevent recurrence.

Footdrop as a result of peroneal nerve palsy should be treated with a simple nonmetallic brace within the shoe or surgical correction attained by tendon transfers. Although uncommon, Charcot’s joints, particularly of the foot and ankle, may result from leprosy.

**THE NOSE** In lepromatous leprosy, bacillary invasion of the nasal mucosa can result in chronic nasal congestion and epistaxis. Saline nose drops may relieve these symptoms. Long-untreated LL leprosy may further result in destruction of the nasal cartilage, with consequent saddle-nose deformity or anosmia (more common in the preantibiotic era than at present). Nasal reconstructive procedures can ameliorate significant cosmetic defects.

**THE EYE** Owing to cranial nerve palsies, lagophthalmus and corneal insensitivity may complicate leprosy, resulting in trauma, secondary infection, and (without treatment) corneal ulcerations and opacities. For patients with these conditions, eyepatches during the day and ointments at night provide some protection from such consequences. Furthermore, in LL leprosy, the anterior chamber of the eye is invaded by bacilli, and ENL may result in uveitis, with consequent cataracts and glaucoma. Thus leprosy is a major cause of blindness in the developing world. Slit-lamp evaluation of LL patients often reveals “corneal beading,” representing globi of *M. leprae*.

**THE TESTES** *M. leprae* invades the testes, while ENL may cause orchitis. Thus males with lepromatous leprosy often manifest mild to severe testicular dysfunction, with an elevation of luteinizing and follicle-stimulating hormones, decreased testosterone, and aspermatia or hypospermatia in 85% of LL patients but in only 25% of BL patients. LL patients may become impotent and infertile. Impotence is sometimes responsive to testosterone replacement.

**AMYLOIDOSIS** Secondary amyloidosis is a complication of LL leprosy and ENL that is encountered infrequently in the antibiotic era. This complication may result in abnormalities of hepatic and particularly renal function.

**NERVE ABSCESSES** Patients with various forms of leprosy, but particularly those with the BT form, may develop abscesses of nerves (most commonly the ulnar) with an adjacent cellulitic appearance of the skin. In such conditions, the affected nerve is swollen and exquisitely tender. Although glucocorticoids may reduce signs of inflammation, rapid surgical decompression is necessary to prevent irreversible sequelae.

**DIAGNOSIS** Leprosy most commonly presents with both characteristic skin lesions and skin histopathology. Thus the disease should be suspected when a patient from an endemic area has suggestive skin lesions or peripheral neuropathy; the diagnosis should be confirmed by histopathology. In tuberculoid leprosy, lesional areas—preferably the advancing edge—must be biopsied because normal-appearing skin does not have pathologic features. In lepromatous leprosy, nodules, plaques, and indurated areas are optimal biopsy sites, but biopsies of normal-appearing skin are also generally diagnostic. Lepromatous leprosy is associated with diffuse hyperglobulinemia, which may result in false-positive serologic tests (e.g., VDRL, RA, ANA) and therefore may cause diagnostic confusion. On occasion, tuberculoid lesions may not (1) appear typical, (2) be hypereutic, and (3) contain granulomas but only nonspecific lymphocytic infiltrates. In such instances, two of these three characteristics are considered sufficient for a diagnosis. It is preferable to overtreat leprosy rather than to allow a patient to remain untreated.

IgM antibodies to PGL-1 are found in 95% of untreated lepromatous leprosy patients; the titer decreases with effective therapy. However, in tuberculoid leprosy—the form of disease most often associated with diagnostic uncertainty owing to the absence or paucity of AFB—patients have significant antibodies to PGL-1 only 60% of the time; moreover, in endemic locales, exposed individuals without
clinical leprosy may harbor antibodies to PGL-1. Thus PGL-1 serology is of little diagnostic utility in tuberculoid leprosy. Heat-killed *M. leprae* (lepromin) has been used as a skin test reagent. It generally elicits a reaction in tuberculoid leprosy patients, may do so in individuals without leprosy, and gives negative results in lepromatous leprosy patients; consequently, it is likewise of little diagnostic value. Unfortunately, PCR of the skin for *M. leprae*, although positive in LL and BL leprosy, yields negative results in 50% of tuberculoid leprosy cases, again offering little diagnostic assistance.

Included in the differential diagnosis of lesions that resemble leprosy are sarcoidosis, leishmaniasis, lupus vulgaris, lymphoma, syphilis, yaws, granuloma annulare, and various other disorders causing hypopigmentation. Sarcoidosis may result in perineural inflammation, but actual granuloma formation within dermal nerves is pathognomonic for leprosy. In lepromatous leprosy, sputum specimens may be loaded with AFB—a finding that can be inappropriately interpreted as representing pulmonary tuberculosis.

### TREATMENT

**Antimicrobial Therapy**

- **ACTIVE AGENTS**

  Established agents used to treat leprosy include dapsone (50 to 100 mg/d), clofazimine (50 to 100 mg/d; 100 mg three times weekly, or 300 mg monthly), and rifampin (600 mg daily or monthly). Of these drugs, only rifampin is bactericidal. The sulfones (folate antagonists), the foremost of which is dapsone, were the first antimicrobials found to be effective for the treatment of leprosy and are still the mainstay of therapy. With sulfone treatment, skin lesions resolve and numbers of viable bacilli in the skin are reduced. Although primarily bacteriostatic, dapsone monotherapy results in only a 2.5% resistance-related relapse rate; after ≥18 years of therapy and subsequent discontinuation, only another 10% of patients relapse, developing new, usually asymptomatic, shiny, “histoid” nodules. Dapsone is generally safe and inexpensive. Individuals with glucose-6-phosphate dehydrogenase deficiency who are treated with dapsone may develop severe hemolytic crisis; those without this deficiency also have reduced red cell survival and a hemoglobin decrease averaging 1 g/dL. Dapsone’s usefulness is limited occasionally by allergic dermatitis and rarely by the sulfone syndrome (including high fever, anemia, exfoliative dermatitis, and a mononucleosis-type blood picture). It must be remembered that rifampin induces microsomal enzymes, necessitating increased doses of medications such as glucocorticoids and oral birth control regimens. Clofazimine is often cosmetically unacceptable to light-skinned leprosy patients because it causes a red-black skin discoloration that accumulates, particularly in lesional areas, and makes the patient’s diagnosis obvious to members of the community.

  Other antimicrobial agents active against *M. leprae* in animal models and at the usual daily doses used in clinical trials include ethionamide/prothionamide; the aminoglycosides streptomycin, kanamycin, and amikacin (but not gentamicin or tobramycin); minocycline; clarithromycin; and several fluoroquinolones, particularly ofloxacin. Next to rifampin, minocycline, clarithromycin, and ofloxacin appear to be most bactericidal for *M. leprae*, but these drugs have not been used extensively in leprosy control programs. Most recently, rifampentine and moxifloxacin have been found to be especially potent against *M. leprae*.

### CHOICE OF REGIMENS

Antimicrobial therapy for leprosy must be individualized, depending on the clinical/pathologic form of the disease encountered. Tuberculoid leprosy, which is associated with a low bacterial burden and a protective cellular immune response, is the easier form to treat and can be reliably cured with a finite course of chemotherapy. In contrast, lepromatous leprosy may have a higher bacillary load than any other human bacterial disease, and the absence of a salutary T cell repertoire requires prolonged or even lifelong chemotherapy. Hence, careful classification of disease prior to therapy is important. In developed countries, clinical experience with leprosy classification is limited; fortunately, however, the resources needed for skin biopsy are highly accessible and pathologic interpretation is readily available. In developing countries, clinical expertise is greater but is now waning substantially as the care of leprosy patients is integrated into general health services. In addition, access to dermatopathology services is often limited. In such instances, skin smears may prove useful, but in many locales access to the resources needed for their preparation and interpretation may also be unavailable. Use of skin smears is no longer encouraged by the World Health Organization (WHO) and is often replaced by mere counting of lesions, which, together with the lack of histopathology, may negatively affect decisions about chemotherapy, increase the potential for reactions, and worsen the ultimate prognosis.

A reasoned approach to the treatment of leprosy is confounded by these and several other issues:

1. Even without therapy, TT leprosy may heal spontaneously, and prolonged dapsone monotherapy (even for LL leprosy) is generally curative in 80% of cases.
2. In tuberculoid disease, there are often no bacilli found in the skin prior to therapy, and thus there is no objective measure of therapeutic success. Furthermore, despite adequate treatment, TT and particularly BT lesions often resolve little or incompletely, while relapse and late type 1 lepra reactions can be difficult to distinguish.
3. LL leprosy patients commonly harbor viable persistent *M. leprae* organisms after prolonged intensive therapy; the propensity of these organisms to initiate clinical relapse is unclear. Because relapse in LL patients after discontinuation of rifampin-containing regimens usually begins only after 7 to 10 years, follow-up over the very long term is necessary to assess ultimate clinical outcomes.
4. Even though primary dapsone resistance is exceedingly rare and multidrug therapy is generally recommended (at least for lepromatous leprosy), there is a paucity of information from experimental animals and clinical trials on the optimal combination of antimicrobials, dosing schedule, or duration of therapy.

In 1982, the WHO made recommendations for “the chemotherapy of leprosy for control programs.” These recommendations came on the heels of the demonstration of the relative success of long-term dapsone monotherapy and in the context of concerns about dapsone resistance. Other complicating considerations included the limited resources available for leprosy care in the very areas where it is most prevalent and the frustration and discouragement of patients and program managers with the previous requirement for lifelong therapy for many leprosy patients. The WHO delineated for the first time a finite duration of therapy for all forms of leprosy and—given the prohibitive cost of daily rifampin treatment in developing countries—encouraged the monthly administration of this agent as part of a multidrug regimen.

Over the ensuing years, these WHO recommendations have been broadly implemented, and the duration of therapy required, particularly for lepromatous leprosy, has been progressively shortened. For treatment purposes, the WHO classifies patients as paucibacillary and multibacillary. Previously, patients without demonstrable AFB in the dermis were classified as paucibacillary and those with AFB as multibacillary. Currently, owing to the perceived unreliability of skin smears in the field, patients are classified as multibacillary if they have six or more skin lesions and as paucibacillary if they have fewer. The WHO recommends that paucibacillary adults be treated with 100 mg of dapsone daily and 600 mg of rifampin monthly (supervised) for 6 months (Table 151-2). For patients with single-lesion paucibacillary leprosy, the WHO recommends as an alternative a single dose of rifampin (600 mg), ofloxacin (400 mg), and minocycline (100 mg). Multibacillary adults should be treated with 100 mg of dapsone plus 50 mg of clofazimine daily (unsupervised) and with 600 mg of rifampin plus 150 mg of clofazimine monthly (supervised). Originally, the WHO recommended that lepromatous patients be treated for 2 years or until smears became negative (generally in ~5 years); subsequently,
the acceptable course was reduced to 1 year—a change that remains especially controversial in the absence of supporting clinical trials.

Several factors have caused many authorities to question the WHO recommendations and to favor a more intensive approach. Among these factors are—for multibacillary patients—a high (double-digit) relapse rate in three locales (reaching 20 to 40% in one locale, with the rate directly related to the initial bacterial burden) and—for paucibacillary patients—demonstrable lesional activity for years in fully half of patients after the completion of therapy. The more intensive approach (Table 151-2) calls for tuberculoid leprosy to be treated with dapsone (100 mg/d) for 5 years and for lepromatous leprosy to be treated with rifampin (600 mg/d) for 3 years and with dapsone (100 mg/d) throughout life.

On effective antimicrobial therapy, new skin lesions and signs and symptoms of peripheral neuropathy cease appearing. Nodules and plaques of lepromatous leprosy noticeably flatten in 1 to 2 months and resolve in 1 year or a few years, while tuberculoid skin lesions may disappear, improve, or remain relatively unchanged. Although the peripheral neuropathy of leprosy may improve somewhat in the first few months of therapy, rarely is it significantly ameliorated by treatment.

**Therapy for Reactions**

**TYPE 1** Type 1 lepra reactions are best treated with glucocorticoids (e.g., prednisone, initially at doses of 40 to 60 mg/d). As the inflammation subsides, the glucocorticoid dose can be tapered, but steroid therapy must be continued for at least 3 months lest recurrence supervene. Because of the myriad toxicities of prolonged glucocorticoid therapy, the indications for its initiation are strictly limited to lesions whose intense inflammation poses a threat of ulceration; lesions at cosmetically important sites, such as the face; and cases in which neuritis is present. Mild to moderate lepra reactions that do not meet these criteria should be tolerated and glucocorticoid treatment withheld. Thalidomide is ineffective against type 1 lepra reactions; clofazimine (200 to 300 mg/d) is of questionable benefit but in any event is far less efficacious than glucocorticoids.

**TYPE 2** Treatment of ENL must be individualized. If ENL is mild (i.e., without fever or other organ involvement, with occasional crops of only a few skin papules), it may be treated with antipyretics alone. However, in cases with many skin lesions, fever, malaise, and other tissue involvement, brief courses (1 to 2 weeks) of glucocorticoids (initially 40 to 60 mg/d) are often effective. With or without therapy, individual inflamed papules last for >1 week. Successful therapy is defined by the cessation of skin lesion development and the disappearance of other systemic signs and symptoms. If, despite two courses of glucocorticoid therapy, ENL appears to be recurring and persisting, treatment with thalidomide (100 to 300 mg nightly) should be initiated, with the dose depending on the initial severity of the reaction. Because even a single dose of thalidomide administered early in pregnancy may result in severe birth defects, including phocomelia, the use of this drug in the United States for the treatment of fertile female patients is tightly regulated and requires informed consent, prior pregnancy testing, and maintenance of birth control measures. Although the mechan-
The designation *nontuberculous mycobacteria* (NTM) encompasses the mycobacterial species other than organisms of the *Mycobacterium tuberculosis* complex and *M. leprae*. The NTM are distributed widely in the environment, are typically acquired from environmental sources, and therefore are also referred to as environmental mycobacteria. Most species are less virulent for humans than is *M. tuberculosis*. Thus symptomatic infections are often associated with local or generalized defects in host defenses. Because isolation of an NTM species from a clinical specimen may represent true infection, colonization, or environmental contamination, strict criteria are required to assess the clinical significance of a positive culture. Although the >90 species of NTM have been associated with a wide variety of infections, most NTM infections are due to a relatively limited number of species that cause characteristic patterns of disease (Table 152-1).

**Microbiology**  Similar to *M. tuberculosis*, NTM organisms resist decolorization after staining and are referred to as acid-fast bacilli (AFB). NTM have conventionally been characterized by the time required for clinical specimens to yield visible growth on solid media. Rapidly growing NTM species, such as *M. abscessus*, *M. fortuitum*, and *M. chelonea*, appear within 7 days. These organisms grow on standard microbiologic media and thus may be reported even when the clinician has not explicitly requested cultures for mycobacteria. Slow-growing species, in contrast, often take 2 to 3 weeks to grow on solid media and require special mycobacterial media such as Lowenstein-Jensen or Middlebrook. Accordingly, slow-growing NTM species are usually isolated only when the clinician specifically requests cultures for mycobacteria. Representative species include *M. avium*, *M. kansasi*, *M. ulcerans*, and *M. marinum*. Automated broth culture systems are now used in many laboratories and may permit isolation of slow-growing NTM organisms within 10 to 14 days, thus tending to blur species distinctions based on growth rate.

Further classification based on colony pigmentation (Runyon classification) has been replaced by the use of DNA probes for identification of common species such as *M. avium*, *M. intracellulare*, *M. gordonae* (which is rarely pathogenic), and *M. kansasii*. Less common species may be identified rapidly on the basis of fatty acid composition or DNA sequencing. Molecular strain typing (“fingerprinting”) based on analysis of polymorphisms among large restriction fragments can be used to determine whether two or more isolates are genotypically—and, by implication, epidemiologically—related. This technique has been useful for identifying common-source outbreaks of infection or contamination.

Antibiotic susceptibility testing should be performed for rapidly growing NTM species. However, susceptibility testing of slow-growing species is of limited value: testing methods are not well standardized, and the relevance of the results to outcome is uncertain since patients are usually treated with multiple-drug regimens. Testing of *M. avium* or *M. kansasii* for susceptibility to specific drugs may be useful in certain situations (see below).

**Distribution**  NTM have a waxy, hydrophobic, triple-layered cell wall that renders them unusually resistant to physical conditions and chemical agents (including disinfectants such as chlorine at concentrations used in drinking water). These organisms can make use of a wide variety of carbon and nitrogen sources and can survive in nutrient-poor environments. Thus they are widely distributed in water, biofilms, and soil as well as in numerous animal species. Optimal growth temperatures vary and may influence distribution. For example, *M. avium* and *M. intracellulare* are often isolated from potable hot-water sources, whereas *M. marinum* is found in the cooler water of fish tanks. Most species of NTM are obligate aerobes and grow best at acid pH. Soil and natural water samples from most regions of the world contain numerous species of NTM, which are as common in northern regions (e.g., Finland) as they are in more temperate areas (e.g., the southern United States).

**Epidemiology**  Asymptomatic infections with NTM are common in humans and are probably acquired most often from childhood contact with soil, water, and possibly animals. Studies with skin tests derived from NTM indicate that 30 to 40% of adults in the northern and southern United States have had prior unrecognized or asymptomatic infection with NTM—most often with organisms of the *M. avium* complex (MAC). Since latent infection is not a recognized characteristic of NTM, most symptomatic infections are thought to represent recent exposure. Molecular methods have identified clusters of infections and pseudoinfections associated with potable water as well as with clinical procedures such as endoscopy and surgery. Environmental exposures are assumed to cause most symptomatic infections; however, this point has been difficult to document by molecular methods, presumably because there are many potential exposures (some of which are sporadic) and because a specific NTM species may be present only transiently or in low numbers in any given source.

a Symbols indicate relative prevalence among NTM infections of the indicated species and pattern of disease: +++, most common; ++, common; +, reported but uncommon; –, rare or not reported.
PATHOGENESIS  NTM may be acquired through cutaneous, respiratory, gastrointestinal, or (rarely) parenteral exposure. Organisms are ingested by host macrophages and may survive within these cells to replicate and cause symptomatic infection. Disease manifestations in immunocompetent hosts are due to host cellular immune responses and the formation of granulomas. Intracellular killing of mycobacteria, with ultimate control of infection, requires the action of cellular immune mechanisms including proliferation of CD4+ T lymphocytes and elaboration of interferon γ (IFN-γ) and interleukin 12. Deficiencies in CD4+ T cell function due to HIV infection and inherited deficiencies in the production of or response to IFN-γ are associated with disseminated NTM infection (Chap. 173).

There is no convincing evidence that NTM can establish latent infection with subsequent clinical reactivation—a pattern characteristic of M. tuberculosis. Asymptomatic infection with NTM in a healthy host may induce beneficial immunity; persons with skin-test reactivity to NTM antigens (e.g., M. intracellulare) are at decreased risk for the subsequent development of tuberculosis. Likewise, immunization with bacille Calmette-Guérin (BCG) from (United States), M. abscessus (Europe, Canada), and M. kansasii (Europe, Canada, and South Africa) are the most commonly involved species. Cutaneous disease, but numerous other organisms (e.g., M. abscessus) can be cultured from 13% of cystic fibrosis patients in the United States (Chap. 241); however, not all of these patients appear to have invasive NTM disease. Although invasive disease is particularly strongly suspected when the same NTM species is isolated on multiple occasions from a patient with lung disease, even persistent organisms may represent colonization or slowly progressive disease apparent only on long-term follow-up. Additional laboratory tests (e.g., immunologic assessments) are of no value in the diagnosis.

Although treatment should be considered in patients who meet clinical, radiologic, and microbiologic criteria for disease (Table 152-2), several other factors require consideration. For example, species such as M. kansasi are usually pathogenic, and a single isolate may be significant, while species such as M. gordonae are rarely pathogenic, even when isolated repeatedly. In addition, in some patients with true invasive disease, infection may progress so slowly that it is unlikely to have much impact on longevity determined by such factors as age or comorbid illness. Since therapy for NTM requires prolonged administration of multiple drugs and is associated with significant side effects, the decision to institute treatment in patients with noncavitary disease who do not have clearly progressive pulmonary disease should be made with careful deliberation after a period of clinical and radiologic follow-up.

Disseminated Disease  Patients with disseminated infection present with fever, weight loss, and fatigue and sometimes with hepatosplenomegaly or lymphadenopathy. Chest radiographs are typically normal in infection with M. avium (although they may show a miliary pattern) but are usually abnormal in that with M. kansasi. Laboratory studies may show demyelinating disease due to an elevated level of alkaline phosphatase in serum. Disseminated disease is characterized by the widespread presence of foamy macrophages with AFB, which may be demonstrated
in biopsy samples of bone marrow, intestine, or liver. Granulomas are typically absent in patients with impaired cellular immunity. In most cases, the diagnosis can be established by one or two sets of mycobacterial blood cultures, which will be positive for the etiologic mycobacteria in 2 to 3 weeks. Treatment requires long-term administration of a multiple-drug antimycobacterial regimen and attempts to ameliorate the defect in cellular immunity (e.g., institution of antiretroviral therapy, discontinuation of glucocorticoid administration).

Other Disease NTM species have been associated with disease at numerous other anatomical locations, including ocular infections, mastoiditis, sinusitis, mastitis, catheter site infections, endocarditis, meningitis, peritonitis, appendicitis, pericarditis, pyelonephritis, prostatitis, tenosynovitis, bursitis, septic arthritis, osteomyelitis, and lymphadenitis (especially in children). Accumulating data support an association between infection with M. avium subspecies paratuberculosis and Crohn's disease.

ORGANISMS

M. AVIUM COMPLEX ■ Pulmonary Disease MAC organisms (M. avium, M. intracellulare, and genetically related unnamed species) are more common than M. tuberculosis as a cause of mycobacterial pulmonary disease among persons born in the United States. Epidemiologic data support a marked increase in the incidence of MAC infection over the past two to three decades. Two patterns of MAC disease are recognized: a primary form in apparently healthy nonsmokers and a secondary form in patients with preexisting pulmonary disease (Table 152-3). The description of subtle defects in cellular immune responses and body morphology in patients with primary disease raises the possibility of an as-yet-undefined immune defect predisposing to MAC infection. Patients with secondary disease include those with chronic obstructive pulmonary disease, prior tuberculosis, cystic fibrosis, or pulmonary alveolar proteinosis. The sources of infection have not been identified.

CLINICAL FEATURES AND DIAGNOSIS Symptoms and diagnostic studies are described above (see “Clinical Syndromes”). CT identifies characteristic cylindrical bronchiectasis with nodule formation, documents the extent of disease, and establishes a baseline for possible treatment. Standard diagnostic criteria should be applied (Table 152-2), and antibiostatic susceptibility testing should be reserved for patients with prolonged prior macrolide exposure and for those in whom treatment fails.

TREATMENT

Treatment should be initiated in most patients with cavitary disease and those with documented progression of a pulmonary process who meet diagnostic criteria for NTM infection. A period of observation prior to consideration of treatment may be useful when there is no evidence of an otherwise-explainable progressive pulmonary process and when the patient’s age or underlying disease is likely to be the critical determinant of survival over the next few years.

Recommended treatment for pulmonary disease includes daily ethambutol and rifabutin plus a macrolide (either clarithromycin or thrice-weekly azithromycin; Table 152-4). Concomitant streptomycin therapy for the first 2 months should be considered in patients with extensive or cavitary disease. As many as 30% of patients treated with standard drugs and doses are unable to tolerate therapy, generally because of gastrointestinal side effects. Rifabutin appears to have the highest rate of side effects. Thus, doses often need to be reduced or drugs eliminated or replaced with alternatives. A fluoroquinolone may be considered as a substitute drug, although clinical data on this option are limited.

For patients with positive sputum cultures who receive a macrolide-containing regimen, treatment should be continued for at least 12 months after cultures revert to negative—typically for ≥18 months. The duration of therapy with other regimens may need to be extended to 24 months. In some cases, cough and radiographic findings may improve after several months; in others, treatment may serve only to prevent the progression of disease. Approximately 20% of patients experience treatment failure or relapse; some apparent treatment failures may actually represent reinfection. Surgical resection is an option for patients with localized disease who are intolerant or unresponsive to multiple-drug therapy; however, this approach is associated with postoperative complications in as many as 20% of patients and should be undertaken only by surgeons who have considerable experience with this intervention.

Disseminated Disease Disseminated MAC disease occurs principally among patients with advanced HIV disease who live in developed countries but are not receiving antiretroviral therapy. Almost all cases occur at CD4+ T cell counts of <100/μL, and the risk is ~20% per year for untreated patients with CD4+ T cell counts of <50/μL. The risk of disease is essentially eliminated for patients given highly active antiretroviral therapy (HAART) who have an increase in CD4+ T cell count to >100/μL for 3 months. Most cases are due to M. avium, and molecular studies indicate that as many as 25% of disseminated infections involve more than one strain. Strains causing bacteremia differ genetically from those typically isolated from respiratory sources or the environment. Molecular techniques have documented nosocomial acquisition from potable hot water and have demonstrated common genotypes among isolates from humans and those from peat used in potting soil. Epidemiologic studies have demonstrated an increased risk associated with consumption of untreated spring water and of raw or partially cooked fish or shellfish and a decreased risk associated with showering. Overall, sources of acquisition appear to be diverse and exposure is probably unavoidable; at this time, no specific behavioral changes are recommended for at-risk patients.

CLINICAL FEATURES AND DIAGNOSIS Disseminated M. avium infection in AIDS is associated with fever, weakness, and weight loss and usually presents as a wasting syndrome in patients who are not receiving HAART or chemoprophylaxis for M. avium (Chap. 173). Untreated disease shortens the survival period of patients with advanced AIDS by 4 to 5 months. Laboratory findings may include anemia, hypoalbuminemia, and elevated serum levels of alkaline phosphatase and lactate dehydrogenase. HIV-infected patients with prior disseminated MAC infection or unrecognized or subclinical MAC infection may experience an immune reconstitution syndrome when they start to receive HAART (Chap. 173). This syndrome presents 1 to 12 weeks after the institution of HAART and manifests as localized (or generalized) culture-positive lymphadenitis with negative blood cultures for M. avium.

TREATMENT

Disseminated M. avium disease requires treatment with the combination of clarithromycin and ethambutol, with or without rifabutin (Table 152-3).
Prevention
Chemoprophylaxis is highly effective for the prevention of disseminated M. avium infection in AIDS. Weekly azithromycin administration should be instituted when the CD4+ \( T \) cell count is <50/\( \mu L \) or when a patient with HIV infection has had an AIDS-defining opportunistic infection (e.g., Pneumocystis infection). Chemoprophylaxis may be discontinued when the CD4+ \( T \) cell count has been >100/\( \mu L \) for >6 months.

**M. KANSASII** Pulmonary Disease Pulmonary disease due to *M. kansasii* has been reported from many areas of the world, including North America, Europe, and South Africa. In the United States, *M. kansasii* is the second most common cause of lung disease due to NTM and is distributed largely in central and southern states and California. The average age of onset is 60 years, and most patients have predisposing factors, such as chronic obstructive pulmonary disease, carcinoma of the lung, silicosis, or prior tuberculosis. However, pulmonary infection sometimes occurs in persons without predisposing disease and has also been associated with poverty. Disease may sometimes wax and wane over many years; this pattern is assumed to represent chronic infection rather than reactivation. Localized pulmonary infection has been described in South African miners with early HIV infection and preserved CD4+ \( T \) cell counts. The source of infection has not been identified, although *M. kansasii* has been isolated from both potable and natural water sources.

**Clinical Features and Diagnosis** *M. kansasii* is the most pathogenic non-tuberculous mycobacterial species affecting the lung, and the clinical features of *M. kansasii* disease resemble those of tuberculosis. Most cases include cough and sputum production; 30% include frank hemoptysis. Systemic signs and symptoms, including fever, night sweats, and weight loss, are reported by as many as 50% of patients. However, symptoms may be subtle or absent in patients with underlying malignancy. Chest radiographs show cavitation in 50% of patients, pleural scarring in 40%, and infiltrates in 30%; abnormalities are most prominent in the apices. Clinical and radiographic effects progress in the absence of treatment.

Sputum samples should be obtained for AFB staining and mycobacterial culture. The isolation of *M. kansasii* sometimes represents colonization; the diagnostic criteria in Table 152-2 are useful when multiple sputum samples can be obtained. However, the growth of *M. kansasii* from even a single sputum culture should be considered to have potential clinical significance, especially in HIV-positive patients. Testing of *M. kansasii* isolates for susceptibility to rifampin is recommended.

### Treatment

For susceptible strains of *M. kansasii*, rifampin is the foundation of a multiple-drug regimen. The recommended regimen consists of daily rifampin (600 mg), isoniazid (300 mg), and ethambutol (25 mg/kg for the initial 2 months, 15 mg/kg subsequently) for at least 18 months. Sputum cultures almost always become negative by 4 months; patients with delayed conversion should be treated for at least 12 months after the last positive culture. Resistance to rifampin may develop, in which case clarithromycin or azithromycin may be substituted.

### Disseminated Disease
Disseminated *M. kansasii* disease occurs principally among patients with advanced AIDS and CD4+ \( T \) cell counts of <100/\( \mu L \). It has also been reported in patients with leukemia, lymphoma, or solid-organ transplantation.

### Clinical Features and Diagnosis
Symptoms are similar to those reported for disseminated MAC infection, although cough is more common with disseminated *M. kansasii* infection and chest radiographs often demonstrate alveolar or interstitial infiltrates or cavities. An immune reconstitution syndrome may occur after the institution of HAART in HIV-infected patients and manifests as cervical or mediastinal lymphadenitis (Chap. 173).

The diagnosis is established by the isolation of *M. kansasii* from a normally sterile parenchymal site or from blood. In one series of cases, concurrent disseminated infection with a second NTM species (most often *M. avium*), was found in one-third of patients. The isolation of *M. kansasii* from sputum from a patient with advanced HIV disease suggests possible disseminated infection and is an indication for mycobacterial blood culture.

### Regimens for Prevention and Treatment of Disease Due to the M. avium Complex

<td>Primary prevention</td>
<td>Azithromycin 1200 mg PO weekly or clarithromycin 500 mg PO bid</td>
<td>Treat when CD4+ ( T ) cell count is &lt;50/( \mu L ). Discontinue if CD4+ ( T ) cell count exceeds 100/( \mu L ) for &gt;3 months during HAART.</td>
</tr>
<tr>
<td>Secondary prevention</td>
<td>Clarithromycin 500 mg PO bid (or azithromycin 500 mg/d) plus ethambutol 15 mg/kg per day</td>
<td>Discontinue if disease resolves with &gt;12 months of MAC therapy and CD4+ ( T ) cell count exceeds 100/( \mu L ) for &gt;6 months during HAART.</td>
</tr>
<tr>
<td>Treatment</td>
<td>Clarithromycin 500 mg PO (or azithromycin 600 mg 3 times/week), ethambutol 15 mg/kg/d, and rifabutin 150–300 mg/d; consider adding streptomycin 500–1000 mg 2 or 3 times/week for first 2 months</td>
<td>Treat for 18 months or until 12 months after conversion of sputum culture.</td>
</tr>
</tbody>
</table>

### Notes

* Azithromycin is preferred to clarithromycin in pregnancy.
* Concomitant rifabutin (150–300 mg/d) may protect against the development of clarithromycin resistance and improve survival but can cause interactions with antiretroviral therapy.

**Abbreviation**: HAART, highly active antiretroviral therapy.

### Treatment

Antimycobacterial treatment of disseminated *M. kansasii* disease is the same as that for pulmonary disease due to this organism. Patients with AIDS who are receiving HAART should have rifabutin (150 mg/d) or clarithromycin (500 mg twice daily) substituted for rifampin because of drug interactions. Untreated disease is associated with shortened survival, and the response to treatment is good in patients who do not have rapidly progressive HIV infection. HIV-positive patients who experience clearing of systemic symptoms and have positive cultures with sustained recovery of the CD4+ \( T \) cell count can probably have treatment discontinued (as described above for *M. avium* infection), although there are no clinical data on this point. Azithromycin prophylaxis for disseminated *M. avium* infection may also be effective in preventing disseminated *M. kansasii* infection.

### M. ABBESISSUS, M. CHELONEA, AND M. FORTUITUM

Three rapidly growing NTM species are prominent in reports of human infection and colonization: *M. abscessus*, *M. chelonae*, and *M. fortuitum*. These organisms are acquired from water, soil, or nosocomial sources. The most common clinical manifestation of infection is disseminated cutaneous...
disease in patients who have defects in cellular immunity or are receiving glucocorticoid therapy. Normal hosts develop localized cutaneous infection in surgical or traumatic wounds, from contaminated injections, or after body piercing. Cutaneous lesions are cellulitic or nodular; are typically erythematous, indurated, and tender; and may progress to ulceration and purulent drainage. Proximal sporotrichoid spread has also been reported. Pulmonary infections (usually due to \textit{M. abscessus}) are the next most common manifestation and occur principally in patients with underlying lung disease, such as cystic fibrosis. The rapidly growing NTM species may be isolated from clinical specimens submitted for routine microbiologic testing. However, reliable evaluation requires inoculation onto special mycobacterial media and an extended incubation period. Because rapidly growing NTM species are also common laboratory contaminants, numerous false alarms in the form of pseudoepidemics have been reported.

**TREATMENT**

Treatment varies with the patient group and with the species of rapidly growing NTM. Susceptibility tests should be performed and used to guide antibiotic selection. All three species are usually susceptible to clarithromycin and amikacin; \textit{M. abscessus} and \textit{M. fortuitum} are also susceptible to cefoxitin. Other agents that may be active include imipenem, doxycycline, and fluoroquinolones. Patients with localized cutaneous disease may respond to a single active agent (e.g., clarithromycin, 500 mg twice daily by mouth for \( \approx 2 \) weeks). Up to 6 months of therapy may be optimal for bacteremic or disseminated cutaneous disease, and a second agent should be added on the basis of susceptibility tests. Pulmonary disease is especially difficult to treat since prolonged therapy is required and the most active drugs require parenteral administration. Current recommendations are to administer intravenous amikacin (5 to 7.5 mg/kg every 12 h) and cefoxitin (3 g every 6 h) with oral clarithromycin (500 mg twice daily) and to continue treatment for 6 to 12 months. Surgery can be considered for localized disease.

\textit{M. marinum} \textit{M. marinum} is widely distributed in water and causes chronic cutaneous infection when an open cutaneous lesion is exposed to a colonized water source. Most infections are due to hand or upper-extremity exposure to fish tanks, and some are due to shellfish or marine exposures. Swimming pools are no longer a common source of infection because of current chlorination standards. \textit{M. marinum} grows optimally at 30°C—a lower temperature than is optimal for most pathogenic mycobacteria. After a median incubation period of 21 days (\( \approx 30 \) days in 35% of cases), a granulomatous or ulcerating skin lesion develops at the site of entry with subsequent sporotrichoid spread in many cases. In some patients, especially those with serious underlying disease and those receiving immunosuppressive therapy, infection may extend to deeper structures, producing tenosynovitis or osteomyelitis. The diagnosis is established by mycobacterial culture of a biopsied lesion or by demonstration of granulomas or AFB in a biopsy sample from a patient with a compatible exposure history.

**TREATMENT**

Antimicrobial therapy has not yet been shown to be beneficial, although rifampin, dapsone, clarithromycin, streptomycin, and amikacin display in vitro activity against \textit{M. ulcerans}. Surgical treatment is primary and may require skin grafting. Immunization with BCG reduces the risk of disease by \( \approx 50\% \).

**FURTHER READING**

- \textit{M. ulcerans} \textit{M. ulcerans} causes cutaneous infection (“Buruli ulcer”) in endemic regions of Central and West Africa, Central and South America, Malaysia, Indonesia, Papua New Guinea, and Australia. The organism is closely related to \textit{M. marinum}, has a similar temperature for optimal growth, and has been isolated from natural bodies of water. Most cases of human infection occur on the bare arms or legs of children or young adults living near rivers, lakes, or swamps. Transmission is thought to result from minor trauma or the bite of an aquatic insect. The initial lesion is a small painless nodule that progresses to a deep ulcer. The ulcer expands, resulting in sloughing of skin and subcutaneous tissue; osteomyelitis may also occur. Stellate scarring and deforming contractures may result from extensive necrosis.

- Biopsy analyses demonstrate extracellular AFB in early lesions, with a limited inflammatory reaction. Tissue destruction extends beyond the area of demonstrable bacterial infection and has been attributed to a unique mycobacterial toxin, mycolactone.

**TREATMENT**

- Treatment consists of the combination of clarithromycin and ethambutol, with administration continuing for 1 to 2 months after resolution of lesions—typically 3 to 4 months in total. Surgical debridement may be necessary in extensive or deep disease; however, in contrast to pyogenic infections, routine incision and drainage are not helpful. Persons with occupational or avocational exposure to fish tanks or salt water should wear waterproof gloves to prevent infection of open cutaneous lesions.

- Other NTM species Numerous other NTM species have been associated with human disease, although they may represent contaminants in clinical specimens. Species and sites of possible infection include \textit{M. celatum} (lung, lymph nodes), \textit{M. genavense} (disseminated), \textit{M. gordonae} (skin, contaminant), \textit{M. haemophilum} (skin, disseminated), \textit{M. malmoense} (lung), \textit{M. simiae} (lung, disseminated), \textit{M. scrofulaceum} (lymphadenitis), \textit{M. szulgai} (skin, lung), and \textit{M. xenopi} (lung, disseminated).

SYphilis
Sheila A. Lukehart

DEFINITION
Syphilis, a chronic systemic infection caused by Treponema pallidum subspecies pallidum, is usually sexually transmitted and is characterized by episodes of active disease interrupted by periods of latency. After an incubation period averaging 2 to 6 weeks, a primary lesion appears, often associated with regional lymphadenopathy. A secondary bacteremic stage, associated with generalized mucocutaneous lesions and generalized lymphadenopathy, is followed by a latent period of subclinical infection lasting many years. In about one-third of untreated cases, the tertiary stage is characterized by progressive destructive mucocutaneous, musculoskeletal, or parenchymal lesions; aortitis; or symptomatic central nervous system (CNS) disease.

ETIOLOGY
The Spirochaetales include three genera that are pathogenic for humans and for a variety of other animals: Leptospira, which causes human leptospirosis (Chap. 155); Borrelia, which causes relapsing fever and Lyme disease (Chaps. 156 and 157); and Treponema, which causes the diseases known as treponematoses (see also Chap. 154). The genus Treponema includes T. pallidum subspecies pallidum, which causes venereal syphilis; T. pallidum subspecies pertenue, which causes yaws; T. pallidum subspecies endemicum, which causes endemic syphilis or bejel; and T. carateum, which causes pinta. Until recently, the subspecies were distinguished primarily by the clinical syndromes they produce. Researchers have now identified molecular signatures that can differentiate T. pallidum subspecies pallidum from the other pathogenic T. pallidum subspecies by culture-independent, polymerase chain reaction (PCR)—based methods. Other Treponema species found in the human mouth, genital mucosa, and gastrointestinal tract have no proven pathogenic role in human disease. These spirochetes can be confused with T. pallidum on dark-field examination.

T. pallidum subspecies pallidum (hereafter referred to in this chapter simply as T. pallidum), a thin delicate organism with 6 to 14 spirals and tapered ends, measures 6 to 15 μm in total length and 0.2 μm in width. The cytoplasm is surrounded by a trilaminar cytoplasmic membrane, which in turn is surrounded by a delicate peptidoglycan layer providing some structural rigidity. This layer is surrounded by a lipid-rich outer membrane that contains relatively few integral membrane proteins. Endoflagella wind around the cell body in the periplasmic space and appear to be responsible for motility.

The sequencing of the genome of T. pallidum has yielded information about the organism’s metabolic capabilities. T. pallidum lacks the genes required to synthesize enzyme cofactors, fatty acids, and nucleotides de novo. In addition, it lacks genes encoding the enzymes of the Krebs cycle and oxidative phosphorylation. To compensate, the genome of the Krebs cycle and oxidative phosphorylation. To compensate, the genome of the Spirillum venereum is rich in genes for the synthesis of amino acids, carbohydrates, and cations. In addition, the genome lacks genes encoding the enzymes required for the anabolic synthesis of nucleotides de novo. In addition, it lacks genes encoding the enzymes required for the anabolic synthesis of nucleotides de novo.

Data suggest that sequence variation occurs in TprK during infection and that this variation is a mechanism for immune invasion. Researchers have now identified molecular signatures that can differentiate T. pallidum subspecies pallidum from the other pathogenic T. pallidum subspecies by culture-independent, polymerase chain reaction (PCR)—based methods. Other Treponema species found in the human mouth, genital mucosa, and gastrointestinal tract have no proven pathogenic role in human disease. These spirochetes can be confused with T. pallidum on dark-field examination.

The total number of cases of syphilis reported annually in the United States declined from 575,593 in 1943 to a low of 31,575 in 2000—a 95% decrease. This downward trend was interrupted by an epidemic peaking in 1990. Surveillance of the number of new cases of infectious syphilis—a better indicator of disease activity—has revealed four cycles of 7 to 10 years, each with a rapid rise and fall in incidence (with peaks in 1965, 1975, 1982, and 1990). From 1990 to 2000, the number of reported cases of infectious syphilis declined by >88%. In 1997, however, the number of cases of early syphilis began to rise in Seattle, Washington, marking the beginning of a trend that, by 2000, included Los Angeles and San Francisco. Infectious syphilis rates have also begun to rise in the southern region of the United States.

The populations at highest risk for acquiring syphilis have changed. Between 1977 and 1982, approximately half of all patients with early syphilis in the United States were homosexual or bisexual men. The epidemic of syphilis that peaked in 1990 predominantly involved African-American heterosexual men and women and occurred largely in urban areas, where infectious syphilis has been correlated significantly with the exchange of sex for crack cocaine. Since 1990, syphilis rates have declined steadily among African Americans but remain higher than those for other racial/ethnic groups. Foci of syphilis still exist in a small number of counties in the southern United States, and rates are still increasing there. The current outbreak of syphilis in large cities on the West Coast of the United States is focused in men who have sex with men; a high proportion of the individuals in this group who have syphilis are also infected with HIV.

The incidence of congenital syphilis roughly parallels that of infectious syphilis in females. The number of reported cases of congenital syphilis in infants ≤1 year of age was lowest (107 cases) in 1978, when infectious syphilis was most prevalent among homosexual and bisexual men. The dramatic increase in the incidence of primary and secondary syphilis among women from 1986 to 1990 resulted in a proportionate increase in the number of infants born with congenital syphilis—to 4424 infants in 1991. The incidence of early syphilis among women has declined since 1991, as has the number of reported cases of congenital syphilis in infants (with 529 cases in 2000). It is important to note that the case definition for congenital syphilis was broadened in 1989 and now includes all live or stillborn infants delivered to women with untreated or inadequately treated syphilis at delivery.

Approximately one of every two individuals named as sexual contacts of persons with infectious syphilis becomes infected. Many sexual contacts will already have developed manifestations of syphilis when they are first seen, and ~30% of apparently uninfected contacts who are examined within 30 days of exposure actually have incubating infection and will later develop infectious syphilis if not treated. Thus, the identification and “epidemiologic” treatment of all recently exposed sexual contacts constitute an important aspect of syphilis control. Also important is the identification of infected persons by serologic testing of pregnant women, persons admitted to hospitals, military inductees, and persons undergoing examination in physicians’ offices. Still controversial are laws and regulations requiring routine premartial serologic testing for syphilis, where—though national data are not available—the yield is undoubtedly lower.

NATURAL COURSE AND PATHOGENESIS OF UNTREATED SYPHILIS
T. pallidum rapidly penetrates intact mucous membranes or microscopic abrasions in skin and within a few hours enters the lymphatics and blood to produce systemic infection and metastatic foci long before the appearance of a primary lesion. Blood from a patient with incubating or early syphilis is infectious. The generation time of T. pallidum during
early active disease in vivo is estimated to be 30 to 33 h, and the incubation period of syphilis is inversely proportional to the number of organisms inoculated. The concentration of treponemes generally reaches at least 10^7/g of tissue before the appearance of a clinical lesion. On the basis of intradermal injection of graded doses of *T. pallidum* into eight volunteers, the 50% infectious dose was calculated to be 57 organisms. The median incubation period in humans (~21 days) suggests an average inoculum of 500 to 1000 infectious organisms for naturally acquired disease. The incubation period (from inoculation until the primary lesion becomes discernible) rarely exceeds 6 weeks. Subcutaneous therapy during the incubation period may delay the onset of the primary lesion, but it is not certain that such treatment reduces the probability that symptomatic disease will ultimately develop.

The primary lesion appears at the site of inoculation, usually persists for 4 to 6 weeks, and then heals spontaneously. Histopathologic examination of primary lesions shows perivascular infiltration, chiefly by lymphocytes (including CD8+ and CD4+ cells), plasma cells, and macrophages, with capillary endothelial proliferation and subsequent obliteration of small blood vessels. The cellular infiltration displays a T_4,1-type cytokine profile consistent with the activation of macrophages. At this time *T. pallidum* is demonstrable in the chancre in spaces between epithelial cells; within invaginations or phagosomes of epithelial cells, fibroblasts, plasma cells, and the endothelial cells of small capillaries; within lymphatic channels; and in the regional lymph nodes. Phagocytosis of organisms by activated macrophages ultimately causes their destruction, which results in spontaneous resolution of the chancre.

The generalized parenchymal, constitutional, and mucocutaneous manifestations of secondary syphilis usually appear about 6 to 8 weeks after healing of the chancre, although 15% of patients with secondary syphilis still have persisting or healing chancres. In other patients, secondary lesions may appear several months after the chancre has healed, and some patients may enter the latent stage without ever recognizing secondary lesions. The histopathologic features of secondary maculopapular skin lesions are hyperkeratosis of the epidermis; capillary proliferation with endothelial swelling in the superficial corium; and dermal papillae with transmigration of polymorphonuclear leukocytes and, in the deeper corium, perivascular infiltration by CD8+ lymphocytes, CD4+ lymphocytes and macrophages, and plasma cells. Treponemes are found in many tissues, including the atherosclerotic plaques of the eye and the cerebrospinal fluid (CSF). Invasion of the CNS by *T. pallidum* occurs during the first weeks or months of infection, and CSF abnormalities are detected in as many as 40% of patients during the secondary stage. Clinical hepatitis and immune complex–induced membranous glomerulonephritis are relatively rare but recognized manifestations of secondary syphilis; liver function tests may yield abnormal results in up to a quarter of patients with early syphilis. Generalized nontender lymphadenopathy is noted in 85% of patients with secondary syphilis. The paradoxical appearance of secondary manifestations despite high titers of antibody (including immobilizing antibody) to *T. pallidum* is unexplained but may result from changes in expression of surface antigens. Secondary lesions subside within 2 to 6 weeks, and the infection enters the latent stage, which is detectable only by serologic testing. In the preantibiotic era, up to 25% of untreated patients experienced at least one generalized or localized mucocutaneous relapse, usually during the first year; therefore, identification and examination of sexual contacts are most important for patients with syphilis of <1 year’s duration. Recurrent generalized rash is now rare.

In the preantibiotic era, about one-third of patients with untreated latent syphilis developed clinically apparent tertiary disease; today, in industrialized countries, specific treatment and coincidental therapy for early and late syphilis have all but eliminated the continental relapse. For sporadic cases of neurosyphilis in persons infected with HIV. In the past, the most common type of tertiary disease was the gumma, a usually benign granulomatous lesion. Today, gummas are very uncommon. Cardiovascular syphilis, now also rare, is caused by obliterative small-vessel endarteritis, usually involving the vasa vasorum of the ascending aorta and resulting in aneurysm. Asymptomatic CNS involvement is demonstrable in up to 25% of patients with late latent syphilis. The factors that contribute to the development and progression of tertiary disease are unknown.

The course of untreated syphilis was studied retrospectively in a group of nearly 2000 patients with primary or secondary disease diagnosed clinically (the Oslo Study, 1891–1951) and was assessed prospectively in 431 African-American men with seropositive latent syphilis of ≥3 years’ duration (the notorious Tuskegee Study, 1932–1972). In the Oslo Study, 24% of patients developed relapsing secondary lesions within 4 years, and 28% eventually developed one or more manifestations of tertiary syphilis. Cardiovascular syphilis, including aortitis, was detected in 10% of patients, none of whom had been infected before age 15; 7% of patients developed symptomatic neurosyphilis, and 16% developed benign tertiary syphilis (gummas of the skin, mucous membranes, and skeleton). Syphilis was the primary cause of death in 15% of men and 8% of women. Cardiovascular syphilis was documented in 35% of men and 22% of women who eventually came to autopsy. In general, serious late complications were nearly twice as common among men as among women.

The Tuskegee Study showed that the death rate among untreated African-American men with syphilis (25 to 50 years old) was 17% higher than that among uninfected subjects and that 30% of all deaths were attributable to cardiovascular or CNS syphilis. By far the most important factor in increased mortality was cardiovascular syphilis. Anatomic evidence of aortitis was found in 40 to 60% of autopsied subjects with syphilis (vs. 15% of control subjects), whereas CNS syphilis was found in only 4%. Rates of hypertension were also higher among the infected subjects. The ethical issues eventually raised by this study, begun in the preantibiotic era but continuing into the early 1970s, had a major influence on the development of current guidelines for human medical experimentation, and the history of the study may still contribute to a reluctance of some African Americans to participate as subjects in clinical research.

These two studies both showed that about one-third of patients with untreated syphilis develop clinical or pathologic evidence of tertiary syphilis, that about one-fourth die as a direct result of tertiary syphilis, and that there is additional excess mortality not directly attributable to tertiary syphilis.

**MANIFESTATIONS ■ Primary Syphilis** The typical primary chancre usually begins as a single painless papule that rapidly becomes indurated and usually becomes indurated, with a characteristic cartilaginous consistency on palpation of the edge and base of the ulcer. In heterosexual men the chancre is usually located on the penis (Fig. 153-1), whereas in homosexual men it is often found in the anal canal or rectum, in the mouth, or on the external genitalia. In women, common primary
Atypical primary lesions are common. The clinical appearance depends on the number of treponemes inoculated and on the immunologic status of the patient. A large inoculum produces a dark-field-positive ulcerative lesion in nonimmune volunteers but may produce a small dark-field-negative papule, an asymptomatic but seropositive latent infection, or no response at all in individuals with a history of syphilis. A small inoculum may produce only a papular lesion, even in nonimmune individuals. Therefore, syphilis should be considered even in the evaluation of trivial or atypical dark-field-negative genital lesions. The genital lesions that most commonly must be differentiated from those of primary syphilis include those caused by herpes simplex virus infection (Chap. 163), chancroid (Chap. 130), traumatic injury, and donovanosis (Chap. 145). Primary genital herpes may produce inguinal adenopathy, but the nodes are tender and the lesions consist of multiple painful vesicles, which later ulcerate and are often accompanied by systemic symptoms, including fever. Recurrent genital herpes typically begins with a unilateral cluster of painful vesicles, usually without associated adenopathy. Chancroid produces painful, superficial, exudative, nonindurated ulcers, more often multiple than in syphilis (see Fig. 130-2); adenopathy is common, can be either unilateral or bilateral, is tender, and may be suppurative. Donovanosis, which is rare in the United States and Europe, is usually seen as a granulomatous ulcer that, although painless, is friable.

Regional lymphadenopathy usually accompanies the primary syphilitic lesion, appearing within 1 week of the onset of the lesion. The nodes are firm, nonsuppurative, and painless. Inguinal lymphadenopathy is bilateral and may occur with anal as well as with external genital chancre. The chancre generally heals within 4 to 6 weeks (range, 2 to 12 weeks), but lymphadenopathy may persist for months.

Secondary Syphilis The protean manifestations of the secondary stage usually include localized or diffuse symmetric mucocutaneous lesions and generalized nontender lymphadenopathy. The healing primary chancre is still present in 15% of cases, and the stages may overlap more frequently in persons with concurrent HIV infection than in those without this co-infection. The skin rash consists of macular, papular, papulosquamous, and occasionally pustular syphilides; often more than one form is present simultaneously. The eruption may be very subtle. Approximately 25% of patients with a discernible rash of secondary syphilis may be unaware that they have dermatologic manifestations. Initial lesions are bilaterally symmetric, pale red or pink, nonpruritic, discrete, round macules that measure 5 to 10 mm in diameter and are distributed on the trunk and proximal extremities. After several days or weeks, red papular lesions 3 to 10 mm in diameter also appear (Fig. 153-2). These lesions, which may progress to necrotic lesions (resembling pustules) in association with increasing endarteritis and perivascular mononuclear infiltration, are distributed widely, frequently involve the palms and soles (Fig. 153-3), and may occur on the face and scalp. Tiny papular follicular syphilides involving hair follicles may result in patchy alopecia, with loss of scalp hair, eyebrows, or beard in up to 5% of cases.

In warm, moist, intertriginous body areas, including the perianal area, vulva, scrotum, inner thighs, axillae, and skin under pendulous breasts, papules can enlarge and become eroded to produce broad, moist, pink or gray-white, highly infectious lesions called condylomata lata (Fig. 153-4); these lesions develop in 10% of patients with secondary syphilis. Superficial mucosal erosions, called mucous patches, occur in 10 to 15% of patients and may involve the lips, oral mucosa, tongue (Fig. 153-5), palate, pharynx, vulva and vagina, glans penis, or inner prepuce. The typical mucous patch is a painless silver-gray erosion surrounded by a red periphery. During relapses of secondary syphilis, condylomata lata are particularly common, and skin lesions tend to be asymmetrically distributed and more infiltrated, resembling skin lesions of late syphilis. These characteristics may reflect increasing cellular immunity.

Constitutional symptoms that may accompany or precede secondary syphilis include sore throat (15 to 30%), fever (5 to 8%), weight loss (2 to 20%), malaise (25%), anorexia (2 to 10%), headache (10%), and meningismus (5%). Acute meningitis occurs in only 1 to 2% of cases, but numbers of cells and levels of protein in CSF are increased.
Mucous patches on the tongue of a patient with secondary syphilis.

FIGURE 153-5

(Courtesy of Ron Roddy.)

in 30% of cases. *T. pallidum* has been recovered from CSF during primary and secondary syphilis in 30% of cases; this finding is often but not always associated with other CSF abnormalities.

Less common complications of secondary syphilis include hepatitis, nephropathy, gastrointestinal involvement (hypertrophic gastritis, patchy proctitis, ulcerative colitis, or a rectosigmoid mass), arthritis, and periostitis. Ocular findings that suggest secondary syphilis include otherwise-unexplained pupillary abnormalities, optic neuritis, and a retinitis pigmentosa syndrome as well as the classic iritis (especially granulomatous iritis) or uveitis. The diagnosis of secondary syphilis is often considered in such patients only after they fail to respond to steroid therapy. Anterior uveitis has been reported in 5 to 10% of patients with secondary syphilis, and *T. pallidum* has been demonstrated in the aqueous humor from such patients. Hepatic involvement is common in syphilis; although it is usually asymptomatic, at least 25% of patients may have abnormal liver function tests. Frank *syphilitic hepatitis* is distinguished by an unusually high serum level of alkaline phosphatase and by a nonspecific histologic appearance that is unlike that of viral hepatitis and includes moderate inflammation with polymorphonuclear leukocytes and lymphocytes, some hepatocellular damage, and no cholestasis. *Renal involvement* produces proteinuria associated with an acute nephritic syndrome (or rarely with hemorrhagic glomerulonephritis) and is characterized by subepithelial electron-dense deposits and glomerular immune complexes—findings suggesting immune-complex glomerulonephritis. Like those of primary syphilis, the manifestations of the secondary stage resolve spontaneously, usually within 1 to 6 months.

**Latent Syphilis** Positive serologic tests for syphilis, together with a normal CSF examination and the absence of clinical manifestations of syphilis, indicate a diagnosis of latent syphilis. The diagnosis is often suspected on the basis of a history of primary or secondary lesions, a history of exposure to syphilis, or the delivery of an infant with congenital syphilis. A previous negative serologic test or a history of lesions or exposure may help establish the duration of latent infection, which is an important factor in the selection of appropriate therapy. Early latent syphilis encompasses the first year after infection, whereas late latent syphilis (beginning ≥1 year after infection in the untreated patient) is associated with relative immunity to infectious relapse. *T. pallidum* may still seed the bloodstream intermittently during the latent stage, and pregnant women with latent syphilis may infect the fetus in utero. Moreover, syphilis has been transmitted through the transfusion of blood from patients with latent syphilis of many years’ duration. It was previously thought that untreated late latent syphilis had three possible outcomes: (1) it could persist throughout the lifetime of the infected individual; (2) it could end in the development of late syphilis; or (3) it could end with the spontaneous cure of infection, with reversion of serologic tests to negative. It is now apparent, however, that the more sensitive treponemal antibody tests rarely, if ever, become negative without treatment. About 70% of untreated patients with latent syphilis never develop clinically evident late syphilis, but the occurrence of spontaneous cure is in doubt.

**Involvement of the Central Nervous System** Traditionally, neurosyphilis has been considered to be a late manifestation of syphilis, but this view is inaccurate. CNS syphilis represents a continuum encompassing early invasion (usually within the first weeks or months of infection), months to years of asymptomatic involvement, and, in some cases, development of early or late neurologic manifestations.

**ASYMPTOMATIC NEUROSYPHILIS** The diagnosis of asymptomatic neurosyphilis is made in patients who lack neurologic symptoms and signs but who have CSF abnormalities including mononuclear pleocytosis, increased protein concentrations, or a reactive Venereal Disease Research Laboratory (VDRL) slide test. Such abnormalities are found in up to one-quarter of patients with untreated late syphilis, and these are the patients who are known to be at risk for neurologic complications. In primary and secondary syphilis, such abnormalities may be found in up to 40% of untreated patients, and *T. pallidum* can be isolated from CSF of 30% of patients even in the absence of other CSF abnormalities. Although the therapeutic implications of these findings in early syphilis are uncertain, it seems appropriate to conclude that even patients with early syphilis who have such findings do indeed have asymptomatic neurosyphilis and should be treated for neurosyphilis. In patients with untreated asymptomatic neurosyphilis, the overall cumulative probability of progression to clinical neurosyphilis is about 20% in the first 10 years but increases with time; the likelihood is highest among patients with the greatest degree of pleocytosis or protein elevation. Patients with untreated latent syphilis and normal CSF probably run no risk of subsequent neurosyphilis. In one study, neurosyphilis was associated with a rapid plasma reagin (RPR) titer of ≥1:32, regardless of clinical stage or HIV infection status.

**SYMPTOMATIC NEUROSYPHILIS** Although mixed features are common, the major clinical categories of symptomatic neurosyphilis include meningovascular, and parenchymatous syphilis. The last category includes general paresis and tabes dorsalis. The onset of symptoms usually comes <1 year after infection for meningeal syphilis, at 5 to 10 years for meningoocclusive syphilis, at 20 years for general paresis, and at 25 to 30 years for tabes dorsalis. However, symptomatic neurosyphilis, particularly in the antibiotic era, often presents not as a classic picture but rather as mixed and subtle or incomplete syndromes.

**Meningeal syphilis** may involve either the brain or the spinal cord, and patients may present with headache, nausea, vomiting, neck stiffness, cranial nerve involvement, seizures, and changes in mental status. This condition may be concurrent with or may follow the secondary stage. Patients presenting with uveitis or iritis frequently have meningeal syphilis. **Meningovascular syphilis** reflects diffuse inflammation of the pia and arachnoid together with evidence of focal or widespread arterial involvement of small, medium, or large vessels. The most common presentation is a stroke syndrome involving the middle cerebral artery of a relatively young adult; however, unlike the usual thrombotic or embolic stroke syndrome of sudden onset, meningoocclusive syphilis often becomes manifest after a subacute encephalitic prodrome (with headaches, vertigo, insomnia, and psychological abnormalities), which is followed by a gradually progressive vascular syndrome.

The manifestations of general paresis reflect widespread late parenchymal damage and include abnormalities corresponding to the mnemonic paresis: personality, affect, reflexes (hyperactive), eye (e.g., Argyll Robertson pupils), sensorium (illusorys delusions, hallucinations), intellect (a decrease in recent memory and in the capacity for orientation, calculations, judgment, and insight), and speech.
**Syphilis**

*Syphilis* is a chronic, worldwide, systemic infection caused by *Treponema pallidum*, an aerobic spirochete. The disease is transmitted primarily through sexual contact, but it can also be transmitted from mother to child during pregnancy, childbirth, or breastfeeding. Syphilis is classified into three stages: primary, secondary, and tertiary, with late congenital syphilis also recognized. Each stage is characterized by distinct clinical manifestations.

### Primary Syphilis

Primary syphilis typically presents as a painless, skin lesion called achanthral, or chancre, which occurs at the site of inoculation. The chancre is usually solitary, but multiple lesions may occur in immunocompromised individuals. The chancre is typically found on the genitalia, but it can also appear on the mouth, conjunctiva, or anogenital area.

### Secondary Syphilis

Secondary syphilis occurs anywhere from 2 to 10 weeks after the chancre heals. This stage is characterized by a widespread rash, mucous patches, and a variety of systemic manifestations. The rash is often described as a *papulosquamous* eruption, which can resemble other skin conditions such as psoriasis. Other symptoms may include Koplik spots (painless, red macules on the buccal mucosa), lymphadenopathy, hepatosplenomegaly, and mucous patches in the mouth.

### Tertiary Syphilis

Tertiary syphilis, also known as late syphilis, can manifest in various systems of the body, including the cardiovascular, nervous, and skeletal systems.

#### Cardiovascular Manifestations

Cardiovascular manifestations include syphilitic aortitis, which can lead to aortic regurgitation, saccular aneurysms, or coronary ostial stenosis. These abnormalities can be detected on physical examination or through imaging studies.

#### Nervous System Manifestations

Nervous system manifestations of tertiary syphilis can include changes in mental status, seizures, and peripheral neuropathy. These can lead to a variety of clinical presentations, including tabes dorsalis, paresis, neurosyphilis, meningovascular syphilis, and meningitis.

#### Skeletal Manifestations

Skeletal manifestations of tertiary syphilis can include osteochondritis, osteitis, periostitis, and destructive or sclerosing osteitis. These may lead to characteristic changes in the skeletal system, such as Hutchinson’s teeth, saber shins, and clubfoot.

### Late Congenital Syphilis

Late congenital syphilis occurs when the infection is acquired in utero and remains untreated after 2 years of age. The manifestations of late congenital syphilis can include cranial nerve palsy, deafness, blindness, and growth and dental abnormalities.

### Laboratory Diagnosis

Diagnosis of syphilis is typically based on clinical presentation and confirmed by laboratory testing. The venereal disease research laboratory (VDRL) test and the rapid plasma reagin (RPR) test are commonly used serologic tests for syphilis. The fluorescent treponemal antibody absorption (FTA- Abs) test is a more specific alternative. Dark-field microscopy of fresh clinical specimens can also be used, although it is less sensitive than serologic testing.

### Treatment

Treatment of syphilis is essential to prevent progression to late complications. Penicillin G is the drug of choice for almost all forms of syphilis. First-line regimens include benzathine penicillin G administered intramuscularly as a single dose. Alternative regimens may be necessary in penicillin-allergic patients.

---

Dorsalis is also a late manifestation of syphilis that presents as symptoms and signs of demyelination of the posterior columns, dorsal roots, and dorsal root ganglia. Symptoms include ataxic wide-based gait and footslap; paresthesia; bladder disturbances; impotence; areflexia; and loss of position, deep pain, and temperature sensations. Trophic joint degeneration (Charcot’s joints) and perforating ulceration of the feet can result from loss of pain sensation. The small, irregular Argyll Robertson pupil, a feature of both tabes dorsalis and paresis, reacts to accommodation but not to light. Optic atrophy also occurs frequently in association with tabes.

**Other Manifestations of Late Syphilis**

The slowly progressive inflammatory disease leading to tertiary manifestations begins early during the pathogenesis of syphilis, although these manifestations may not become clinically apparent for years. Early syphilitic aortitis becomes evident soon after secondary lesions subside, and treponemes that trigger the development of gummas may have seeded the tissue years earlier.

#### Cardiovascular Syphilis

Cardiovascular manifestations are attributable to endarteritis obliterans of the vasa vasorum, which provide the blood supply to large vessels. This condition results in uncomplicated aortitis, aortic regurgitation, saccular aneurysm, or coronary ostial stenosis, with symptoms usually appearing 10 to 40 years after infection. In the preantibiotic era, symptomatic cardiovascular complications developed in ~10% of persons with late untreated syphilis, although syphilitic aortitis was demonstrated at autopsy in about one-half of African-American men with untreated syphilis.

Linear calcification of the ascending aorta on chest x-ray films suggests asymptomatic syphilitic aortitis, as arteriosclerosis seldom produces this sign. Syphilitic aneurysms—usually saccular, occasionally fusiform—do not lead to dissection. Only 1 in 10 aortic aneurysms of syphilitic origin involves the abdominal aorta.

#### Late Benign Syphilis (Gumma)

Gummas may be multiple or diffuse but are usually solitary lesions that range from microscopic in size to several centimeters in diameter. Histologic examination shows a granulomatous inflammation with a central area of necrosis. Although rarely demonstrated microscopically, *T. pallidum* has reportedly been recovered from these lesions. The most commonly involved sites include the skin and skeletal system, the mouth and upper respiratory tract, the larynx, the liver, and the stomach; however, any organ may be involved. Gummas of the skin produce painless and indurated nodular, papulosquamous, or ulcerative lesions that are usually indolent. These lesions may resemble those of many other chronic granulomatous conditions, including tuberculosis and sarcoidosis, leprosy, and deep fungal infections. Skeletal gummas most frequently involve the long bones of the legs, although any bone may be affected. Radiographic abnormalities with advanced gummas of bone include periostitis or destructive or sclerosing osteitis. Upper respiratory gummas can lead to perforation of the nasal septum or palate.

Because the histologic changes may be suggestive but are nonspecific, the diagnosis of late benign syphilis is confirmed by serologic testing and by therapeutic trial. Treatment with penicillin results in rapid healing of active gummatous lesions.

**Congenital Syphilis**

Transmission of *T. pallidum* from a syphilitic woman to her fetus across the placenta may occur at any stage of pregnancy, but the lesions of congenital syphilis generally have their onset after the fourth month of gestation, when fetal immunologic competence begins to develop. This timing suggests that the pathogenesis of congenital syphilis depends on the immune response of the host rather than on a direct toxic effect of *T. pallidum*. The risk of infection of the fetus during untreated early maternal syphilis is estimated to be 75 to 95%, decreasing to about 35% for maternal syphilis of ≥2 years’ duration. Adequate treatment of the mother before the 16th week of pregnancy should prevent fetal damage. Untreated maternal infection may result in a rate of fetal loss of up to 40% (with stillbirth more common than abortion because of the late onset of fetal pathology), prematurity, neonatal death, or nonfatal congenital syphilis. Among infants born alive, only fulminating congenital syphilis is clinically apparent at birth, and these babies have a very poor prognosis. The most common clinical problem is the healthy-appearing baby born to a mother with a positive serologic test. Routine serologic testing in early pregnancy is considered cost-effective in virtually all populations, even in areas with a low prenatally prevalent syphilis. Where the prevalence of syphilis is high or when the patient is at high risk, serologic testing should be repeated in the third trimester and at delivery.

The manifestations of congenital syphilis can be divided into three types according to their timing: (1) early manifestations, which appear within the first 2 years of life (often between 2 and 10 weeks of age), are infectious and resemble the manifestations of severe secondary syphilis in the adult; (2) late manifestations, which appear after 2 years and are noninfectious; and (3) residual stigmata. The earliest sign of congenital syphilis is usually rhinitis, or “snuffles” (23%), which is soon followed by other mucocutaneous lesions (35 to 41%). These may include bullae (syphilitic pemphigus), vesicles, superficial desquamation, petechiae, and (later) papulosquamous lesions, mucous patches, and condylomata lata. The most common early manifestations are bone changes (61%), including osteochondritis, osteitis, and periostitis. Hepatosplenomegaly (50%), lymphadenopathy (32%), anemia (34%), jaundice (30%), thrombocytopenia, and leukocytosis are common. *T. pallidum* can be isolated, by rabbit inoculation, from the CSF of 22% of infected neonates without prior antibiotic exposure.

Neonatal congenital syphilis must be differentiated from other generalized congenital infections, including rubella, cytomegalovirus or herpes simplex virus infection, and toxoplasmosis, as well as from erythroblastosis fetalis. Neonatal death is usually due to pulmonary hemorrhage, secondary bacterial infection, or severe hepatitis.

Late congenital syphilis is that which remains untreated after 2 years of age. In 60% of cases, the infection remains subclinical; the clinical spectrum in the remainder of cases differs in certain respects from that of acquired late syphilis in the adult. For example, cardiovascular syphilis rarely develops in late congenital syphilis, whereas interstitial keratitis is much more common and occurs between the ages of 5 and 25. Other manifestations include eighth-nerve deafness and recurrent arthropathy. Bilateral knee effusions are known as Clutton’s joints. Asymptomatic neurosyphilis is present in about one-third of untreated patients, and clinical neurosyphilis occurs in one-quarter of untreated individuals >6 years old. Gummatous periostitis occurs between the ages of 5 and 20 and, as in nonneueral endemic syphilis, tends to cause destructive lesions of the palate and nasal septum.

Characteristic stigmata include Hutchinson’s teeth—centrally notched, widely spaced, peg-shaped upper central incisors—and “mulberry” molars—sixth-year molars with multiple, poorly developed cusps. The abnormal facies of patients with congenital syphilis include frontal bossing, saddle nose, and poorly developed maxillae. Saber shins, characterized by anterior tibial bowing, are rare. Rhagades are linear scars at the angles of the mouth and nose that are caused by secondary bacterial infection of the early facial eruption.

**Laboratory Examinations**

- **Demonstration of the Organism**: *T. pallidum* cannot be detected by culture; therefore, other tests are necessary. Dark-field microscopic examination of lesion exudate is useful in evaluating moist cutaneous lesions, such as the chancre of primary syphilis or the condylomata lata of secondary syphilis. The identification of a single characteristic motile organism by a trained observer is sufficient for diagnosis. Examination of oral lesions and anal ulcers by this method is not recommended, as it is difficult to differentiate *T. pallidum* from other spirochetes that may be present.

Most syphilis is diagnosed in settings where dark-field microscopy is not available. The direct fluorescent antibody test (DFTA) test, in which a centrifugal latex suspension of fluorescein-conjugated polyclonal antitreponemal antibody for the detection of *T. pallidum* in fixed smears prepared from suspect lesions. More
sensitive PCR tests have been developed but are available only in research laboratories. *T. pallidum* can be found in tissue with appropriate silver stains, although these results should be interpreted with caution because artifacts resembling *T. pallidum* are often seen. Treponemes can be demonstrated more reliably in tissue by immunofluorescence or immuno-histochemical methods using specific monoclonal or polyclonal antibodies to *T. pallidum*.

**Serologic Tests for Syphilis**  There are two types of serologic test for syphilis: nontreponemal and treponemal. Both types of test are reactive in persons with any treponemal infection, including yaws, pinta, and endemic syphilis.

The nontreponemal tests measure IgG and IgM directed against a cardiolipin-lecithin-cholesterol antigen complex. The most widely used nontreponemal antibody tests for syphilis are the RPR test, which can be automated (ART), and the VDRL slide test. The RPR test is easier to perform and uses unheated serum; it is the test of choice for rapid serologic diagnosis in a clinic or office setting. The VDRL test, however, remains the standard for use with CSF.

The RPR and VDRL tests are equally sensitive and may be used for initial screening or for quantitation of serum antibody. The titer reflects the activity of the disease. Titers rise during the evolution of early syphilis; VDRL titers usually reach 1:32 or higher in secondary syphilis. A persistent fall by two dilutions (fourfold) or more after treatment of early syphilis provides essential evidence of an adequate response to therapy. VDRL titers do not correspond directly to RPR titers, and sequential quantitative testing (as for response to therapy) must employ a single test.

Two standard treponemal tests are used for confirmation of reactive nontreponemal results: the fluorescent treponemal antibody–absorbed (FTA-ABS) test and the agglutination assays for antibodies to *T. pallidum*. The microhemagglutination assay for *T. pallidum* (MHA-TP) has been replaced by the Serodia TP-PA test (Fujirebio, Tokyo), which is more sensitive for primary syphilis. The *T. pallidum* hemagglutination test (TPHA) is widely used in Europe but is not available in the United States. Both the agglutination assays and the FTA-ABS test are very specific and, when used for confirmation of positive nontreponemal tests, have a very high positive predictive value for the diagnosis of syphilis. However, even these tests give false-positive results at rates as high as 1 to 2% when used for the screening of normal populations. New enzyme-linked immunosorbent assays have also been approved as confirmatory tests.

The relative sensitivities of the VDRL and RPR tests, the FTA-ABS test, and the TP-PA test in the various stages of untreated syphilis are shown in Table 153-1. The nontreponemal tests may be nonreactive in very early primary syphilis, and the detection of antibody can be maximized by the performance of a treponemal test. All treponemal and nontreponemal tests are reactive during secondary syphilis, and a nonreactive result virtually excludes syphilis in a patient with otherwise-compatible mucocutaneous lesions. (Fewer than 1% of patients with secondary syphilis have a VDRL test that is nonreactive or weakly reactive with undiluted serum but is positive at higher serum dilutions—the *prozone phenomenon*.) Although the nontreponemal tests will become nonreactive or will be reactive at lower titers after therapy for early syphilis, the treponemal tests often remain reactive after therapy and therefore are not helpful in determining the infection status of persons with past syphilis. Treatment of early primary syphilis may result in seroreversion in treponemal tests.

For practical purposes, most clinicians need to be familiar with the three uses of serologic tests for syphilis: (1) testing of large numbers of sera for screening or diagnostic purposes (e.g., the RPR or VDRL test), (2) quantitative measurement of antibody titer to assess the clinical activity of the infection or to monitor the response to therapy (e.g., the RPR or VDRL test), and (3) confirmation of the diagnosis of syphilis in a patient with a positive nontreponemal antibody test or with a suspected clinical diagnosis of syphilis (e.g., the FTA-ABS test or the Serodia TP-PA test).

For measurement of IgM in neonates in whom congenital syphilis is suspected, the syphilis Capita-M test (Trinity Biotech, Jamestown, NY) and the 19S IgM FTA-ABS test are available.

**False-Positive Serologic Tests for Syphilis**  Because the antigen used in nontreponemal tests is found in other tissues, the tests may be reactive in persons without treponemal infection, although rarely do titers exceed 1:8 in such patients. In a population selected for screening because of clinical suspicion, history of exposure, or increased risk for sexually transmitted infections, fewer than 1% of reactive tests are falsely positive. The modern VDRL and RPR tests are 97 to 99% specific, and false-positive reactions are now limited largely to those conditions listed in Table 153-2. False positivity is common among persons with autoimmune disorders. The prevalence of false-positive nontreponemal tests increases with advancing age; 10% of people >70 years of age have false-positive reactions. In the patient with a false-positive nontreponemal test, syphilis is excluded by a nonreactive treponemal test.

**Evaluation for Neurosyphilis**  Involvement of the CNS is detected by examination of CSF for pleocytosis (>5 white blood cells/mm³), increased protein concentration (>45 mg/dL), or VDRL reactivity. CSF abnormalities can be demonstrated in up to 40% of cases of primary or secondary syphilis and in 25% of cases of latent syphilis. In older asymptomatic seropositive individuals, the yield of lumbar puncture is relatively low. *T. pallidum* has been recovered by CSF inoculation into rabbits from up to 30% of patients with primary or secondary syphilis but rarely from those with latent syphilis. The demonstration of *T. pallidum* in CSF is often associated with other CSF abnormalities; however, organisms can be recovered from patients with otherwise-normal CSF. Before the advent of penicillin, the risk of developing clinical neurosyphilis was roughly proportional to the intensity of CSF changes. CSF examination is recommended by the Centers for Disease Control and Prevention (CDC) in the evaluation of any sero-
positive patient with neurologic signs and symptoms, patients with other late syphilis, cases of suspected treatment failure, and HIV-infected patients with untreated syphilis of unknown duration or of >1 year’s duration. The possibility of asymptomatic neurosyphilis in some patients with early disease is not addressed by these recommendations. Because standard therapy with penicillin G benzathine (benzathine benzylpenicillin) for early syphilis fails to result in treponemical drug levels in the CSF, some experts also advise lumbar puncture in early syphilis, particularly in patients with HIV infection or with non-treponemal test titers of ≥1:32.

The CSF VDRL test is highly specific but is insensitive and may be non-reactive even in cases of progressive symptomatic neurosyphilis. The degree of sensitivity is highest in meningovascular syphilis and paresis and is lower in asymptomatic neurosyphilis and tabes dorsalis. The unabsorbed FTA test on CSF is reactive far more often than the CSF VDRL test in all stages of syphilis, but FTA reactivity may reflect passive transfer of serum antibody into the CSF. A nonreactive CSF FTA test, however, may be used to rule out neurosyphilis.

**Evaluation for Syphilis in Patients Infected with HIV** Because persons at highest risk for syphilis (inner-city populations, homosexually active men, and people in many developing countries) are also at increased risk for HIV infection, these two infections frequently coexist. There is evidence that syphilis and other genital-uterine diseases may be important risk factors for the acquisition and transmission of HIV infection.

The manifestations of syphilis may be altered in patients with concurrent HIV infection, and multiple cases of neurologic relapse after standard therapy have been reported in HIV-infected patients. *T. pallidum* has been isolated from the CSF of several patients after therapy for early syphilis with penicillin G benzathine. A multicenter U.S. study of early syphilis found similar clinical responses to therapy in persons with and without concurrent HIV infection, although the study lacked sufficient statistical power to exclude an effect of HIV and 41% of subjects were lost to follow-up. Serologically defined treatment failure was more common among HIV-infected patients than among those without this co-infection. This investigation confirmed the high rate of CNS invasion in early syphilis and the persistence of *T. pallidum* after standard therapy: 11 of 43 HIV-infected patients and 21 of 88 HIV-uninfected patients had *T. pallidum* detectable in CSF before therapy; 7 of the 35 patients who underwent lumbar puncture after therapy (some HIV-infected and others uninfected) still had *T. pallidum* detectable in CSF.

There is no clear evidence that the sensitivity of serologic tests for syphilis differs in HIV-infected versus HIV-uninfected patients. Rates of decline of serologic titers appear to be slower in HIV-infected individuals. The clinical significance of this observation is unclear.

Persons with newly diagnosed HIV infection should be tested for syphilis; conversely, all patients with newly diagnosed syphilis should be tested for HIV infection. Some authorities, persuaded by reports of the persistence of *T. pallidum* in the CSF of HIV-infected persons after standard penicillin benzathine therapy for early syphilis, recommend examination of CSF for evidence of neurosyphilis for all co-infected patients, regardless of the clinical stage of syphilis, with treatment for neurosyphilis if CSF abnormalities are found or if CSF examination is not performed. Others do not recommend routine CSF examination for HIV-co-infected patients with early syphilis and believe that standard therapy is sufficient. Serologic testing after treatment is important for all patients with syphilis, particularly those also infected with HIV.

### TREATMENT

#### Treatment of Acquired Syphilis

The CDC’s 2002 guidelines for the treatment of syphilis are summarized in Table 153-3 and are discussed below. Penicillin G is the drug of choice for all stages of syphilis. *T. pallidum* is killed by very low concentrations of penicillin G, although a long period of exposure to penicillin is required because of the unusually slow rate of multiplication of the organism. The efficacy of penicillin against syphilis remains undiminished after 50 years of use. Other antibiotics effective in syphilis include the tetracyclines, erythromycin, and the cephalosporins. Aminoglycosides and spectinomycin inhibit *T. pallidum* only in very large doses, and the sulfonamides and the quinolones are inactive. Azithromycin shows significant promise as an effective oral agent against *T. pallidum*.

Serum levels of penicillin G of ≥0.03 μg/mL for at least 7 days are considered necessary for the cure of early syphilis. Recurrence rates for a given regimen increase as infection progresses from incubating to seronegative primary to seropositive primary to secondary to late syphilis. Therefore, it is probable, but unproven, that a longer duration of therapy is required to effect cure as the infection progresses.

#### PATIENTS WITH EARLY SYPHILIS AND THEIR CONTACTS

Preventive (abortive, “epidemiologic”) treatment is recommended for seronegative individuals without signs of syphilis who have been exposed to infectious syphilis within the previous 3 months. Before treatment is given, every effort should be made to establish a diagnosis by examination and serologic testing. The regimen recommended for prevention are the same as those recommended for early syphilis.

Penicillin G benzathine is the most widely used agent for the treat-
ment of early syphilis, although it is more painful on injection than penicillin G procaine. A single dose of 2.4 million units cures more than 95% of cases of primary syphilis. Because the drug’s efficacy in secondary syphilis may be slightly lower, some physicians administer a second dose of 2.4 million units 1 week after the initial dose at this stage of disease. Clinical relapse can follow treatment with penicillin G benzathine in patients with both HIV infection and early syphilis. Because the risk of neurorelapse may be higher in HIV-infected patients, examination of CSF from HIV-seropositive individuals with syphilis of any stage is recommended by some experts; therapy appropriate for neurosyphilis should be given if there is any evidence of CNS syphilis.

For penicillin-allergic patients with early syphilis, a 2-week course of therapy with doxycycline or tetracycline is recommended. These regimens appear to be effective, although no well-controlled studies have been performed and poor compliance may be problematic. Limited studies suggest that ceftriaxone (1 g/d, given intramuscularly or intravenously, for 8 to 10 days) and azithromycin (a single oral dose of 2 g) may be effective against early syphilis. These nonpenicillin regimens have not been evaluated in HIV-infected individuals and should be used with caution.

**Late Latent and Late Syphilis** If CSF abnormalities are found, the patient should be treated for neurosyphilis. The recommended treatment for late latent syphilis with normal CSF, for cardiovascular syphilis, and for late benign syphilis (gumma) is penicillin G benzathine, 2.4 million units intramuscularly once a week for 3 successive weeks (7.2 million units total). Doxycycline or tetracycline (given for 4 weeks) offers an untested alternative for penicillin-allergic patients with latent or late syphilis and normal CSF. Penicillin-allergic HIV-infected persons with late latent or late syphilis should be desensitized and treated with penicillin if compliance and follow-up cannot be ensured. The clinical response to treatment for benign tertiary syphilis is usually impressive; however, responses to therapy for cardiovascular syphilis are not dramatic because aortic aneurysm and aortic regurgitation cannot be reversed by antibiotic treatment.

**Neurosyphilis** Penicillin G benzathine, given in total doses of up to 7.2 million units to adults, or 50,000 units/kg to infants, does not produce detectable concentrations of penicillin G in CSF, and asymptomatic neurosyphilis may relapse in patients treated with 2.4 million units; the risk may be higher in HIV-infected patients. Therefore, the use of penicillin G benzathine alone for the treatment of neurosyphilis is not recommended. On the other hand, administration of intravenous penicillin G in recommended doses is thought to ensure treponemical concentrations of penicillin G in CSF. The clinical response to penicillin therapy for meningeval syphilis is dramatic, but the response to treatment for parenchymal neurosyphilis is variable. In general, treatment of neurosyphilis with existing damage may produce no clinical change but may arrest disease progression.

Several recent publications have reported neurologic relapse after high-dose intravenous penicillin therapy for neurosyphilis in HIV-infected patients. No alternative therapies have been explored, but careful follow-up is essential, and re-treatment is warranted in such patients.

No data support the use of antibiotics other than penicillin G for the treatment of neurosyphilis; however, some of the third-generation cephalosporins and azithromycin may deserve further evaluation. In patients with penicillin allergy demonstrated by skin testing, desensitization and treatment with penicillin is the recommended course.

**Management of Syphilis in Pregnancy** Every pregnant woman should undergo a nontreponemal test at her first prenatal visit, and women at high risk of exposure should have a repeat test in the third trimester and at delivery. In the untreated pregnant patient with presumed syphilis, expedient evaluation and initiation of treatment appropriate to the stage of the disease are essential. Patients should be warned of the risk of a Jarisch-Herxheimer reaction, which may be associated with mild premature contractions but rarely results in premature delivery.

Penicillin is the only recommended therapy for syphilis in pregnancy. If the patient has a well-documented penicillin allergy, desensitization and penicillin therapy should be undertaken according to the CDC’s 2002 treatment guidelines. After treatment, a quantitative nontreponemal test should be repeated monthly throughout pregnancy. Treated women whose titers rise by fourfold or who do not show a fourfold decrease in titer over a 3-month period should be re-treated.

**Evaluation and Management of Congenital Syphilis** Newborn infants of mothers with reactive serologic tests may themselves have reactive tests, whether or not they have become infected, because of transplacental transfer of maternal IgG antibody. Rising or persistent titers indicate infection, and the infant should be treated. Neonatal IgM antibody can be detected in cord or neonatal serum with the syphilis Capita-M or 19S IgM FTA-ABS test; its detection indicates active infection. For asymptomatic infants born to women treated adequately with penicillin during pregnancy, monthly quantitative nontreponemal tests may be performed to monitor for appropriate declines in titer.

An infant should be treated at birth if the seropositive mother has received penicillin therapy in the third trimester, inadequate penicillin treatment, or therapy with a drug other than penicillin; if her treatment status is unknown; or if the infant may be difficult to follow. It is unwise to require proof of diagnosis before treatment in such cases. The CSF should be examined to obtain baseline values before treatment. Penicillin is the only recommended drug for syphilis in infants. The penicillin dosage used for the treatment of the patient with late congenital syphilis is calculated in the same way as for the infant, until dosage based on weight reaches that used for adult neurosyphilis. Specific recommendations for the treatment of infants are included in the CDC’s 2002 guidelines.

**Jarisch-Herxheimer Reaction** A dramatic though usually mild reaction consisting of fever (average temperature elevation, 1.5°C), chills, myalgias, headache, tachycardia, increased respiratory rate, increased circulating neutrophil count, and vasodilation with mild hypotension may follow the initiation of treatment for syphilis. This reaction occurs in ~50% of patients with primary syphilis, 90% of those with secondary syphilis, and 25% of those with early latent syphilis, and defervescence takes place within 12 to 24 h. The reaction is more delayed in neurosyphilis, with fever peaking after 12 to 14 h. In patients with secondary syphilis, erythema and edema of the mucocutaneous lesions may increase. Patients should be warned to expect such symptoms, which can be managed with symptom-based treatment. Steroid and other anti-inflammatory therapy is not required for this mild transient reaction.

**Follow-Up Evaluation of Responses to Therapy** The response of syphilis to treatment should be determined by monitoring the quantitative VDRL or RPR titer (Table 153-4). More frequent serologic examination is recommended for patients concurrently infected with HIV. Because the FTA-ABS and agglutination tests remain positive in most patients treated for seropositive syphilis, these tests are not useful in following the response to therapy. After successful treatment of seropositive first-episode primary or secondary syphilis, the VDRL titer progressively declines, becoming negative by 12 months in 75% of seropositive primary cases and in 20 to 40% of secondary cases. Patients with a history of syphilis have less rapid declines in titer, and are less likely to become VDRL- or RPR-negative. Re-treatment should be considered if serologic responses are not adequate or if clinical signs persist or recur. Every effort should be made to differentiate treatment failure from reinfection, and the CSF should be examined. Patients in whom treatment failure is suspected, especially those with abnormal CSF, should be treated for neurosyphilis. If the patient remains seropositive but asymptomatic after such re-treatment, no further therapy is necessary. Patients treated for late latent syphilis frequently have low initial VDRL or RPR titers and may not have a fourfold drop after therapy with penicillin; about half of these patients remain seropositive (with low titers) for years after therapy. Re-treat-
The endemic, or nonvenereal, treponematoses are bacterial infections that are caused by close relatives of Treponema pallidum subspecies pallidum, the etiologic agent of venereal syphilis (Chap. 153). Yaws, pinta, and endemic syphilis are distinguished from venereal syphilis by mode of transmission, age of acquisition, geographic distribution, and clinical features. These infections are limited primarily to rural areas of developing nations and are seen in the United States and Europe only in recent immigrants from endemic regions. Much of our “knowledge” about the endemic treponematoses is based upon impressions and observations of health care workers who have visited endemic areas; virtually no well-designed studies of the natural history, diagnosis, or treatment of these infections have been conducted. The treponemal infections are compared and contrasted in Table 154-1.

**Epidemiology** The endemic treponematoses are chronic diseases acquired during childhood and, like syphilis, can cause severe late manifestations years after initial infection. These infections were very common in Africa, Asia, and South America when the World Health Organization (WHO) and UNICEF embarked on a highly successful mass eradication campaign. From 1952 to 1969, it is estimated that over 160 million people were examined for treponemal infections and over 50 million cases, contacts, and latent infections were treated. This categorical program is one of WHO’s outstanding successes in that the prevalence of active yaws was reduced from >20% to <1% in many rural areas and endemic syphilis was eradicated in Bosnia. In the decades since the eradication programs, lack of focused surveillance and diversion of resources to other pressing needs have resulted in a resurgence of these infections in some regions, particularly in Africa. The estimated geographic distribution of the endemic treponematoses in the 1990s is shown in Fig. 154-1. In the early 1980s, WHO sponsored a series of regional meetings on the endemic treponematoses, and areas of resurgent yaws morbidity were identified in West Africa (Ivory Coast, Ghana, Togo, Benin) and extending into the Central African Republic and rural Democratic Republic of Congo (formerly Zaire). The prevalence of endemic syphilis is estimated to be >10% in some regions of Mali, Niger, Burkina Faso, and Senegal. In Asia and the western Pacific, yaws is still prevalent in Indonesia.

<sup>a</sup> Try to distinguish between reinfection and treatment failure. If evidence of treatment failure exists, perform CSF examination. If CSF is normal, treat as for late latent syphilis (Table 153-3). If CSF is abnormal, treat as for neurosyphilis (Table 153-3).
Transmission defined by the climate of the region and the culture of or by the same organism, with clinical manifestations and routes of about whether the treponematoses are caused by different organisms. Treponemes have been identified to date. A controversy has existed species T. pallidum studied organisms are morphologically identical to species T. pallidum because of their genetic similarity; the fourth (T. carateum) remains a separate species simply because no organisms have been available for genetic studies. However, a molecular signature has been defined that can be used to differentiate T. pallidum subspecies pallidum from the nonvenereal subspecies of T. pallidum, and unpublished studies have identified a number of distinct differences in the tpr gene family between venereal and nonvenereal treponemes. Whether these differences are related to the different clinical courses has not yet been determined.

**CLINICAL FEATURES** All of the treponemal infections are characterized by defined disease stages, with a localized primary lesion, disseminated secondary lesions, periods of latency, and possible late lesions. Primary and secondary stages are more frequently overlapping in yaws and endemic syphilis, and the late manifestations of pinta are very mild relative to the destructive lesions of the other treponematoses. The current preference is to divide the clinical course of the endemic treponematoses into “early” and “late” stages. The major clinical features differing between venereal syphilis and the nonvenereal infections are the apparent lack of congenital transmission and the lack of central nervous system (CNS) involvement in the nonvenereal infections. It is not known whether these distinctions are accurate. Because of the high degree of genetic relatedness among the organisms, there is little biologic reason to think that T. pallidum subspecies endemicum and T. pallidum subspecies pertenue would be unable to cross the blood-brain barrier or to invade the placenta. These organisms obviously can disseminate from the site of primary infection to other tissues, and they can persist for decades. In this respect, they are like T. pallidum subspecies pallidum. The lack of recognized congenital infection may be due to the fact that the nonvenereal treponematoses are usually acquired during childhood. By the time an infected girl becomes sexually mature, she would be at low risk for

* CNS involvement in the endemic treponematoses has been postulated by some investigators (see text).
transplacental transmission. Neurologic involvement may not have been recognized in nonvenereal treponemal infection because of the lack of trained medical personnel in endemic regions, the lag of years to decades between acquisition of infection and possible CNS manifestations, or a low rate of symptomatic CNS disease.

Some published evidence supports congenital transmission as well as cardiovascular, ophthalmologic, and CNS involvement in yaws. Although the case is strong, particularly for CNS involvement, most studies that have shown a relatively high incidence (average, 24.9%) of cerebrospinal fluid (CSF) abnormalities in patients with yaws were not controlled for other possible causes of CSF abnormalities, did not include treponeme-specific tests, or did not follow patients for resolution of abnormalities after antitreponemal therapy. Thus, while no firm conclusions can be drawn about the invasion of the CNS and placenta by the non-pallidum treponemes, it may be erroneous to accept unquestioningly the frequently repeated belief that these organisms fail to cause such manifestations.

Yaws Also known as pian, framboesia, or bouba, yaws is a chronic infection that is usually acquired in childhood and is caused by T. pallidum subspecies pertenue. The disease is characterized by the development of one or several primary lesions (called the “mother yaw”), followed by the appearance of multiple disseminated skin lesions. The early lesions may persist for many months, are infectious, and usually recur several times within the early years of infection. Late manifestations are destructive and can involve skin, bone, and joints.

The infection is transmitted by direct contact with infectious lesions, and transmission may be enhanced by disruption of the skin by insect bites or abrasions. Children with open lesions and without covering clothing are most likely to transmit infection during play or group sleeping. After an average incubation period estimated at 3 to 4 weeks, the first lesion begins as a papule, usually on an extremity, and then enlarges (particularly during moist warm weather) to become papillomatous or “raspberry-like” (thus the name “framboesia”) (Fig. 154-2). Regional lymphadenopathy develops, and the lesion usually heals within 6 months; dissemination is thought to occur during the early weeks and months of infection. A generalized secondary eruption, accompanied by generalized lymphadenopathy, appears either concurrent with or following the primary lesion, may take several forms (macular, papular, or papillomatous), and may become secondarily infected with other bacteria. Painful papillomatous lesions on the soles of the feet result in a painful crablike gait (“crab yaws”), and periostitis may result in nocturnal bone pain and polydactylitis. All early skin lesions are infectious, and cutaneous relapses are common during the first 5 years. Late yaws is recognized in ~10% of untreated patients and is manifested by gummas of the skin and long bone, hyperkeratosis of the palms and soles, osteitis and periostitis, and hydrarthrosis. The late gummatous lesions are characteristically very destructive and extensive. Destruction of the nose, maxilla, palate, and pharynx is termed gangosa and is similar to the destructive lesions seen in leprosy and leishmaniasis.

Endemic Syphilis Endemic syphilis, also called bejel, siti, dichuchwa, njovera, or skerljevo, is a chronic infection caused by T. pallidum subspecies endemicum. Like other endemic treponematoses, endemic syphilis is chronic and is acquired in childhood. The early lesions are primarily localized to the mucocutaneous and mucosal surfaces, and the infection may be transmitted by direct contact, by kissing, or by sharing drinking and eating utensils. A role for insects in transmission has been suggested but is unproved. The initial lesion, usually an introral papule (Fig. 154-2), often goes unrecognized and is followed by mucous patches on the oral mucosa and mucocutaneous lesions resembling the condylomata lata of secondary syphilis. This eruption may last for months or even years, and treponemes can readily be demonstrated in early lesions. Periostitis and regional lymphadenopathy are common. After a variable period of latency, late manifestations may appear, including osseous and cutaneous gummas. Destructive gummas, osteitis, and gangosa are more common in endemic syphilis than in late yaws. Gummas of the nipples develop in women who have previously had endemic syphilis and who breast-feed infants with oral lesions. Thus, it appears that the late lesion may result from repeated exposure of a sensitized host.

Pinta Pinta (also called mal del pinto, carate, azul, or puripuru) is the most benign of the treponemal infections and is caused by T. carateum. This disease has three stages that are characterized by marked changes in skin color (Fig. 154-2), but it does not appear to cause destructive lesions or to involve other tissues. Transmission occurs by direct contact, usually during late childhood. The initial papule is most often located on the extremities or face and is pruritic. After one to many months of infection, numerous disseminated secondary lesions (pintides) appear. These lesions are initially red but become deeply pigmented, ultimately turning a dark slate blue. The secondary lesions are infectious and highly pruritic and may persist for years. Late pigmented lesions are called dyschromic macules and contain treponemes. Over time, most pigmented lesions show varying degrees of depigmentation, becoming brown and eventually white and giving the skin a mottled appearance. White achromic lesions are characteristic of the late stage.

DIAGNOSIS Diagnosis of the endemic treponematoses is based upon clinical manifestations and, when available, dark-field microscopy and serologic testing. The same tests that are used for venereal syphilis (Chap. 153) become reactive during all treponemal infections, and there is no serologic test that can discriminate among the different infections. The nonvenereal treponemal infections should be considered in the evaluation of a reactive syphilis serology in any person who has emigrated from an endemic area.
**TREATMENT**

The recommended therapy for patients and their contacts is benzathine penicillin at a dose of 1.2 million units intramuscularly; the dose for children <10 years of age is 600,000 units. There have been no controlled studies to show that the recommended lower dose (which is half the dose recommended for patients and contacts in early venereal syphilis) is effective in stopping relapse or progression to late disease. Definitive evidence of resistance to penicillin is lacking. However, because failure to heal existing lesions and frequent relapse following treatment for yaws have been described in Papua New Guinea, some health workers have suggested doubling the recommended dose of benzathine penicillin. Limited data suggest the efficacy of tetracycline for the treatment of yaws, but no such data exist for other endemic treponematoses. Solely on the basis of experience with venereal syphilis, it is thought that doxycycline, tetracycline, and erythromycin (at doses appropriate for syphilis; Chap. 153) are therapeutic alternatives for patients allergic to penicillin. A Jarisch-Herxheimer reaction (Chap. 153) may follow treatment of endemic treponematoses. Nontreponemal serologic titers [in the Venereal Disease Research Laboratory (VDRL) slide test or the rapid plasma reagin (RPR) test] usually decline after effective therapy, but patients may not become seronegative.

---

**LEPTOSPIROSIS Peter Speelman**

Leptospirosis is an emerging infectious disease, as illustrated by recent large outbreaks in Asia, Central and South America, and the United States. The disease is caused by pathogenic leptospires and characterized by a broad spectrum of clinical manifestations, varying from inapparent infection to fulminant, fatal disease. In its mild form, leptospirosis may present as an influenza-like illness with headache and myalgias. Severe leptospirosis, characterized by jaundice, renal dysfunction, and hemorrhagic diathesis, is referred to as *Weil’s syndrome*.

**ETIOLOGIC AGENTS**

Leptospires are spirochetes belonging to the order Spirochaetales and the family Leptospiraceae. Traditionally, the genus *Leptospira* comprised two species: the pathogenic *L. interrogans* and the free-living *L. biflexa*. Although 16 genomospecies of pathogenic leptospires are now recognized on the basis of their DNA relatedness, it is more practical clinically and epidemiologically to use a classification based on serologic differences. The pathogenic leptospires are divided into serovars according to their antigenic composition. More than 200 serovars make up the 25 serogroups.

Leptospires are coiled, thin, highly motile organisms with hooked ends and two periplasmic flagella that permit burrowing into tissue (Fig. 155-1). These organisms are 6-20 μm long and ~0.1 μm wide; they stain poorly but can be seen microscopically by dark-field examination and after silver impregnation staining. Leptospires require special media and conditions for growth; it may take weeks for cultures to become positive.

**EPIDEMIOLOGY**

Leptospirosis is an important zoonosis with a worldwide distribution that affects at least 160 mammalian species. Rodents, especially rats, are the most important reservoir, although other wild mammals as well as domestic and farm animals may also harbor these microorganisms. Leptospires establish a symbiotic relationship with their host and can persist in the renal tubules for years. Some serovars are generally associated with particular animals—e.g., icterohaemorrhagiae/copenhageni with rats, grippotyphosa with voles, hardjo with cattle, canicola with dogs, and pomona with pigs—but may occur in other animals as well.

Transmission of leptospires may follow direct contact with urine, blood, or tissue from an infected animal or exposure to a contaminated environment; human-to-human transmission is rare. Since leptospires are excreted in the urine and can survive in water for many months, water is an important vehicle in their transmission. Epidemics of leptospirosis may result from exposure to flood waters contaminated by urine from infected animals, as has been reported from Nicaragua. Leptospirosis occurs most commonly in the tropics because the climate as well as the sometimes poor hygienic conditions favor the pathogen's survival. In many developing countries, leptospirosis is an underestimated problem. Reliable data on morbidity and mortality from leptospirosis have gradually started to appear. In 1999, more than 500,000 cases were reported from China, with case-fatality rates ranging from 0.9 to 7.9%. In Brazil, more than 28,000 cases were reported in the same year.

Humans are not commonly infected with leptospires. However, in the United States, the 40 to 120 cases reported annually to the Centers for Disease Control and Prevention (CDC) surely represent a significant underestimate of the total number. Certain occupational groups...
are at especially high risk; included are veterinarians, agricultural workers, sewage workers, slaughterhouse employees, and workers in the fishing industry. Such individuals may acquire leptospirosis through direct exposure to or contact with contaminated water and soil. Leptospirosis has also been recognized in deteriorating inner cities where rat populations are expanding. One report described leptospirosis in urban residents of Baltimore who were sporadically exposed to rat urine.

Recreational exposure and domestic-animal contact are also prominent sources of leptospirosis. Recreational water activities, such as canoeing, windsurfing, swimming, and waterskiing, place persons at risk for leptospirosis. In 1998, a large outbreak occurred among athletes and community residents after a triathlon in Illinois. Among athletes, the ingestion of one or more swallows of lake water was a prominent risk factor for illness. Heavy rains that preceded the triathlon, with consequent agricultural runoff, are likely to have increased the level of leptospiral contamination in the lake water.

Sometimes leptospirosis is acquired during travel abroad. In a study in the Netherlands, 14% of patients with confirmed leptospirosis had acquired the infection while traveling in tropical countries, mostly in Southeast Asia. Transmission via laboratory accidents has been reported but is rare. Leptospirosis develops occasionally after unanticipated immersion in contaminated water (e.g., in an automobile accident) and rarely after an animal bite. Most cases occur in men, with a peak incidence during the summer and fall in Western countries and during the rainy season in the tropics.

**PATHOGENESIS** The pathogenesis of leptospirosis is incompletely understood. Leptospires may enter the host through abrasions in the skin or through intact mucous membranes, especially the conjunctiva and the lining of the oro- and nasopharynx. Drinking of contaminated water may introduce leptospires through the mouth, throat, or esophagus. After entry of the organisms, leptospiremia develops, with subsequent spread to all organs. Multiplication takes place in blood and in tissues, and leptospires can be isolated from blood and cerebrospinal fluid (CSF) during the first 4 to 10 days of illness. CSF examination during this period documents pleocytosis in the majority of instances, but only a minority of patients develop symptoms and signs of meningitis at this point. All forms of leptospires can damage the wall of small blood vessels; this damage leads to vasculitis with leakage and extravasation of cells, including hemorrhages. The most important known pathogenic properties of leptospires are adhesion to cell surfaces and cellular toxicity.

Vasculitis is responsible for the most important manifestations of the disease. Although leptospires mainly infect the kidneys and liver, any organ may be affected. In the kidney, leptospires migrate to the interstitium, renal tubules, and tubular lumen, causing interstitial nephritis and tubular necrosis. Hypovolemia due to dehydration or altered capillary permeability may contribute to the development of renal failure. In the liver, centrilobular necrosis with proliferation of Kupffer cells may be found. However, severe hepatocellular necrosis is not a feature of leptospirosis. Pulmonary involvement is the result of hemorrhage and not of inflammation. Invasion of skeletal muscle by leptospires results in swelling, vacuolation of the myofibrils, and focal necrosis. In severe leptospirosis, vasculitis may ultimately impair the microcirculation and increase capillary permeability, resulting in fluid leakage and hypovolemia.

When antibodies are formed, leptospires are eliminated from all sites in the host except the eye, the proximal renal tubules, and perhaps the brain, where they may persist for weeks or months. The persistence of leptospires in the aqueous humor occasionally causes chronic or recurrent uveitis. The systemic immune response is effective in eliminating the organism but may also produce symptomatic inflammatory reactions. A rise in antibody titer coincides with the development of meningitis; this association suggests that an immunologic mechanism is responsible.

After the start of antimicrobial treatment for leptospirosis, a Jarisch-Herschheimer reaction similar to that seen in other spirochetal diseases may develop. Although frequently described in older publications, this reaction seems to be a rare event in leptospirosis and is certainly less frequent in this infection than in other spirochetal diseases.

**CLINICAL MANIFESTATIONS** (Fig. 155-2) It is important to try to obtain a history of exposure to contaminated materials. Serologic evidence of past inapparent infection is found in 15 to 40% of persons who have been exposed but have not become ill. In symptomatic cases of leptospirosis, clinical manifestations vary from mild to serious or even fatal. More than 90% of symptomatic persons have the relatively mild and usually anicteric form of leptospirosis, with or without meningitis. Severe leptospirosis with profound jaundice (Weil’s syndrome) develops in 5 to 10% of infected individuals. The idea that distinct clinical syndromes are associated with specific serogroups has been refuted.

The incubation period is usually 1 to 2 weeks but ranges from 2 to 20 days (Fig. 155-2). Typically, an acute leptospiremic phase is followed by an immune leptospiruric phase. The distinction between the first and second phases is not always clear, and milder cases do not always include the second phase.

**Anicteric Leptospirosis** Leptospirosis may present as an acute influenza-like illness, with fever, chills, severe headache, nausea, vomiting, and myalgias. Muscle pain, which especially affects the calves, back, and abdomen, is an important feature of leptospiral infection. Less common features include sore throat and rash. The patient usually has an intense headache (frontal or retroorbital) and sometimes develops photophobia. Mental confusion may be evident. Pulmonary involvement, manifested in most cases by cough and chest pain and in a few cases by pleurisy, is not uncommon.

The most common finding on physical examination is fever with conjunctival suffusion. Less common findings include muscle tender-
ness, lymphadenopathy, pharyngeal injection, rash, hepatomegaly, and splenomegaly. The rash may be macular, maculopapular, erythematous, urticarial, or hemorrhagic. Mild jaundice may be present.

Most patients become asymptomatic within 1 week. After an interval of 1 to 3 days, the illness recurs in a number of cases. The start of this second (immune) phase coincides with the development of antibodies. Symptoms are more variable than during the first (leptospiremic) phase. Usually the symptoms last for only a few days, but occasionally they persist for weeks. Often the fever is less pronounced and the myalgias are less severe than in the leptospiremic phase. An important event during the immune phase is the development of aseptic meningitis. Although no more than 15% of all patients have symptoms and signs of meningitis, many patients have CSF pleocytosis. Meningeal symptoms usually disappear within a few days but may persist for weeks. Similarly, pleocytosis generally disappears within 2 weeks but occasionally persists for months. Aseptic meningitis is more common among children than among adults. Iritis, iridocyclitis, and chorioretinitis—late complications that may persist for years—can become apparent as early as the third week but often present several months after the initial illness. One epidemic of uveitis among patients with leptospirosis has been reported. Mortality in anicteric leptospirosis is almost nil, although death as a result of pulmonary hemorrhage occurred in 2.4% of cases in a Chinese outbreak.

Severe Leptospirosis (Weil’s Syndrome) Weil’s syndrome, the most severe form of leptospirosis, is characterized by jaundice, renal dysfunction, hemorrhagic diathesis, and a mortality rate ranging from 5 to 15%. In Europe, this syndrome is frequently but not exclusively associated with infection due to serovar icterohaemorrhagiae/copenhagenii. The onset of illness is no different from that of less severe leptospirosis; however, after 4 to 9 days, jaundice as well as renal and vascular dysfunction generally develop. Although some degree of defervescence may be noted after the first week, a biphasic disease pattern like that seen in anicteric leptospirosis is lacking. The jaundice of Weil’s syndrome, which can be profound and give an orange cast to the skin, is usually not associated with severe hepatic necrosis.

Death is rarely due to liver failure. Hepatomegaly and tenderness in the right upper quadrant are usually detected. Splenomegaly is found in 20% of cases.

Renal failure may develop, often during the second week of illness. Hypovolemia and decreased renal perfusion contribute to the development of acute tubular necrosis with oliguria or anuria. Dialysis is sometimes required, although a fair number of cases can be managed without dialysis. Renal function may be completely regained.

Pulmonary involvement occurs frequently; in some clusters of cases, it is a major manifestation, resulting in cough, dyspnea, chest pain, and blood-stained sputum and sometimes in hemoptysis or even respiratory failure. Hemorrhagic manifestations are seen in Weil’s syndrome: epistaxis, petechiae, purpura, and ecchymoses are found commonly, while severe gastrointestinal bleeding and adrenal or subarachnoid hemorrhage are detected rarely.

Rhabdomyolysis, hemolysis, myocarditis, pericarditis, congestive heart failure, cardiogenic shock, adult respiratory distress syndrome, necrotizing pancreatitis, and multiorgan failure have all been described during severe leptospirosis.

Laboratory and Radiologic Findings (Fig. 155-2) The kidneys are invariably involved in leptospirosis. Related findings range from urinary sediment changes (leukocytes, erythrocytes, and hyaline or granular casts) and mild proteinuria in anicteric leptospirosis to renal failure and azotemia in severe disease.

The erythrocyte sedimentation rate is usually elevated. In anicteric leptospirosis, peripheral leukocyte counts range from 3000 to 26,000/μL, with a left shift; in Weil’s syndrome, leukocytosis is often marked. Mild thrombocytopenia occurs in up to 50% of patients and is associated with renal failure.

In contrast to patients with acute viral hepatitis, those with leptospirosis typically have elevated serum levels of bilirubin and alkaline phosphatase as well as mild increases (up to 200 U/L) in serum levels of aminotransferases. In Weil’s syndrome, the prothrombin time may be prolonged but can be corrected with vitamin K. Levels of creatine phosphokinase, which are elevated in up to 50% of patients with leptospirosis during the first week of illness, may help to differentiate this infection from viral hepatitis.

When a meningeal reaction develops, polymorphonuclear leukocytes predominate initially and the number of mononuclear cells increases later. The protein concentration in the CSF may be elevated; CSF glucose levels are normal.

In severe leptospirosis, pulmonary radiographic abnormalities are most common than would be expected on the basis of physical examination. These abnormalities most frequently develop 3 to 9 days after the onset of illness. The most common radiographic finding is a patchy alveolar pattern that corresponds to scattered alveolar hemorrhage. Radiographic abnormalities most often affect the lower lobes in the periphery of the lung fields.

Diagnosis (Fig. 155-2) A definite diagnosis of leptospirosis is based either on isolation of the organism from the patient or on seroconversion or a rise in antibody titer in the microscopic agglutination test (MAT). In the United States, the MAT is performed only at the CDC. In cases with strong clinical evidence of infection, a single antibody titer of 1:400 to 1:800 (depending on whether the case occurs in a low- or high-endemic area) in the MAT is required. Preferably, a fourfold or greater rise in titer is detected between acute- and convalescent-phase serum specimens. Antibodies generally do not reach detectable levels until the second week of illness. The antibody response can be affected by early treatment.

The MAT, which uses a battery of live leptospiiral strains, and the enzyme-linked immunosorbent assay (ELISA), which uses a broadly reacting antigen, are the standard serologic procedures. These tests usually are available only in specialized laboratories and are used for determination of the antibody titer and for tentative identification of the serogroup—and in some cases the serovar—involved (thus the importance of using antigens representative of the serovars prevalent in the particular geographic area). Since cross-reactions occur frequently, however, it is often impossible to identify the infecting serogroup or serovar. Serologic testing cannot be used as the basis for a decision about whether to start treatment.

In addition to the MAT and the ELISA, various other tests with diagnostic value have been developed. Some tests, such as an indirect hemagglutination test and a microcapsule agglutination test, are commercially available. A recent advance is the development of rapid serologic assays that apply lateral flow, latex agglutination, or ELISA methodology with reasonable sensitivity and specificity. These methods do not require culture or MAT facilities. However, in endemic areas, pooled serum samples from the local population are required as positive and negative controls. Polymerase chain reaction (PCR) techniques have been developed but so far have not found widespread use outside research and reference laboratories.

Leptospires can be isolated from blood and/or CSF during the first 10 days of illness and from urine for several weeks beginning at around 1 week. Cultures most often become positive after 2 to 4 weeks, with a range of 1 week to 4 months. Sometimes urine cultures remain positive for months or years after the start of illness. For isolation of leptospires from body fluids or tissues, Ellinghausen-McCullough-Johnson-Harris (EMJH) medium is useful; other possibilities are Fletcher medium and Korthof medium. Specimens can be mailed to a reference laboratory for culture, since leptospires remain viable in anticoagulated blood (heparin, EDTA, or citrate) for up to 11 days. Isolation of leptospires is important since it is the only way the infecting serovar can be correctly identified. Dark-field examination of blood or urine frequently results in misdiagnosis and should not be used.

Differential Diagnosis Leptospirosis should be differentiated from other febrile illnesses associated with headache and muscle pain, such
as dengue, malaria, enteric fever, viral hepatitis, Hantavirus infections, and rickettsial diseases. In light of the strong similarity in epidemiology and clinical presentation between leptospirosis and Hantavirus infections and given the reported occurrence of dual infections, it is advisable to conduct serologic testing for Hantavirus in cases of suspected leptospirosis. When patients have a flulike disease with disproportionately severe myalgia or aseptic meningitis, a diagnosis of leptospirosis should be considered.

**Treatment**

The effectiveness of antimicrobial therapy for the mild febrile form of leptospirosis is controversial, but such treatment is indicated for more severe forms. Treatment should be initiated as early as possible; nevertheless, contrary to previous reports, treatment started after the first 4 days of illness is effective.

For severe cases of leptospirosis, intravenous administration of penicillin G, amoxicillin, ampicillin, or erythromycin is recommended (Table 155-1). In milder cases, oral treatment with tetracycline, doxycycline, ampicillin, or amoxicillin should be considered. Although several other antibiotics, including newer cephalosporins, are highly active against leptospires in vitro, no clinical experience has yet been gained with these drugs.

In rare cases, a Jarisch-Herxheimer reaction develops within hours after the start of antimicrobial therapy (see “Pathogenesis” above). Although so far the only effective mode of management is supportive, the role of antibodies to tumor necrosis factor in the treatment of this reaction deserves further study. A beneficial effect of the use of such antibodies for the modulation of the reaction has been demonstrated in patients with louse-borne relapsing fever. Patients with severe leptospirosis and renal failure may require dialysis. Those with Weil’s syndrome may need transfusions of whole blood and/or platelets. Intensive care may be necessary.

**Prognosis**

Most patients with leptospirosis recover. Mortality is highest among patients who are elderly and those who have Weil’s syndrome. Leptospirosis during pregnancy is associated with high fetal mortality. Long-term follow-up of patients with renal failure and hepatic dysfunction has documented good recovery of renal and hepatic function.

**Prevention**

Individuals who may be exposed to leptospires through their occupations or their involvement in recreational water activities should be informed about the risks. Measures for controlling leptospirosis include avoidance of exposure to urine and tissues from infected animals, vaccination of animals, and rodent control. The animal vaccine used in a given area should contain the serovars known to be present in that area. Unfortunately, some vaccinated animals still excrete leptospires in their urine. Vaccination of humans against a specific serovar prevalent in an area has been undertaken in some European and Asian countries and has proved effective. Although a large-scale trial of vaccine in humans has been reported from Cuba, no conclusions can be drawn about efficacy and adverse reactions because of insufficient details on study design. Chemoprophylaxis with doxycycline (200 mg once a week) has appeared to be efficacious to some extent but is indicated only in rare instances of sustained short-term exposure (Table 155-1).

**Further Reading**

The disease typically occurs sporadically or in small—often familial—clusters. Infected soft ticks may cause repeated infections among persons living or sleeping in the same dwelling. In sub-Saharan Africa, *O. moubata*, the vector of *B. duttoni*, infests native huts and rest houses, hiding in crevices of floors and walls during the day and emerging at night to feed on sleeping inhabitants.

In the United States, TBRF disease occurs west of the Mississippi River, especially in forested mountainous areas of far western states, where *B. hermsii* is the causative agent. Less commonly, persons are infected with *B. turicatae* following exposures in tick-infested caves in semidesert areas of the Southwest. On average, ~35 cases of TBRF are reported annually in the United States. *B. hermsii* infections most often occur during spring and summer months among persons sleeping in rustic mountain cabins and vacation homes and occasionally in permanent residences and in outdoor settings. Infections of humans are sometimes precipitated by the disappearance of rodents (e.g., as a result of epizootic plague) that nest in foundations, wall spaces, and attics and that serve as the usual maintenance hosts for *O. hermsii* ticks. Outbreaks caused by *B. hermsii* have taken place among persons staying in cabins along the north rim of the Grand Canyon and in the mountains of California, Idaho, and Colorado. In North America, most recent cases have been reported from Washington, California, Colorado, Idaho, Oregon, and British Columbia.

**PATHOGENESIS AND PATHOLOGY**

In humans, relapsing-fever borreliae pass through the skin or mucous membranes, multiply in the blood, and circulate in great numbers during febrile periods. The organisms have also been found in the liver, spleen, bone marrow, and central nervous system and may be sequestered at these sites during periods of remission. The disease tends to be more severe when spirochete density in the blood is high. Even though the pathophysiologic manifestations of the disease resemble responses to endotoxin, and although plasma from some patients with relapsing fever coagulates on exposure to a high concentration of *B. recurrentis* (such as abrasions caused by scratching of pruritic louse bites). Spirochetes are not transmitted directly by the bite of a louse (anterior station transmission) or by inoculation of louse feces (posterior station transmission). Lice have a life span of only a few weeks, feed at frequent intervals, and survive only a few days off the human host. Head lice do not appear to be vectors of LBRF.

LBRF has severely affected military and civilian populations disrupted by war and other disasters. In the nineteenth century, the disease was common among slum dwellers, prisoners, and others living in impoverished, overcrowded, and unhygienic conditions. In the first half of the twentieth century, during periods of war and famine, both LBRF and louse-borne typhus were epidemic in eastern Europe, the Balkans, and the former Soviet Union. The global distribution and incidence of LBRF were substantially reduced following improvements in standards of living, sanitation, and hygiene; LBRF is now an important disease only in northeastern Africa, especially the highlands of Ethiopia, where an estimated 10,000 cases occur annually. In Ethiopia, the disease affects mostly homeless men crowded together in unhygienic circumstances, especially during the cool rainy season, when washing and changing clothing is more difficult. LBRF has repeatedly spilled out of Ethiopia into populations of displaced persons in neighboring Somalia and Sudan. During the Second World War, the spread of LBRF from Ethiopia and the Sudan to western Africa was pandemic.

Short-term visitors to endemic areas (e.g., tourists) are at almost no risk of LBRF, but persons who have close contact with LBRF populations (such as relief workers) can acquire the disease from lice, accidental needle sticks, or other direct contact with contaminated blood.

**Tick-Borne Relapsing Fever**

Argasid ticks of the genus *Ornithodoros* transmit TBRF through their saliva and excreta when they feed on humans. As a rule, the ticks become infected with TBRF borreliae as part of a zoonotic cycle when they feed on spirochete-infected rodents and lagomorphs; the exception to this rule is *O. moubata*, a tick species that acquires *B. duttoni* by feeding on infected humans. Ticks transmit TBRF borreliae vertically from one stage to the next; in some species, infection is transmitted transovarially over several generations. Soft ticks are hardy and can survive for 10 years with only an occasional blood meal. These ticks feed painlessly, relatively quickly (for 20 to 45 min), and usually at night while hosts are sleeping. Thus patients with TBRF are often unaware of tick exposures.

TBRF borreliae are widely distributed throughout the world. Human infection with these organisms is generally underrecognized and underreported. TBRF is most highly endemic in sub-Saharan Africa but is also found in countries of the Mediterranean littoral, Middle Eastern states, southern Russia, the Indian subcontinent, Central Asia, and China and at low frequency in North, Central, and South America. The disease typically occurs sporadically or in small—often familial—clusters. Infected soft ticks may cause repeated infections among persons living or sleeping in the same dwelling. In sub-Saharan Africa, *O. moubata*, the vector of *B. duttoni*, infests native huts and rest houses, hiding in crevices of floors and walls during the day and emerging at night to feed on sleeping inhabitants.

In the United States, TBRF disease occurs west of the Mississippi River, especially in forested mountainous areas of far western states, where *B. hermsii* is the causative agent. Less commonly, persons are
tachycardic and mildly tachypneic and become prostrate as the disease progresses. Some patients have meningismus. The conjunctivae are often injected, and photophobia is common. The sclerae may become icteric, particularly in the later stages of illness. The mucous membranes may be dry, and patients are often dehydrated. Scattered petechiae develop on the trunk, extremities, and mucous membranes in one-third or more of patients with TBRF but in a smaller proportion of patients with TBRF. A nonproductive cough is common, but chest sounds are usually normal; pleuritic pain and an accompanying pleuritic rub are sometimes noted. Cardiac findings are compatible with a high-output state; tachycardia and summation gallop are common. Tender enlargement of the spleen and liver frequently occurs in the acute phase of illness.

Epistaxis and blood-tinged sputum are common complications, and gastrointestinal and central nervous system hemorrhage can occur. Because of this coagulopathy, one LBRF outbreak in southern Sudan was thought to be viral hemorrhagic fever. Other complications of variable incidence include iridocyclitis, optic neuritis, lymphocytic meningitis, coma, isolated cranial-nerve palsy, pneumonitis, myocarditis, and rupture of the spleen. Life-threatening complications are unusual in otherwise healthy persons given supportive care, especially if the illness is diagnosed and treated early. Children generally have a milder course of illness than adults.

Without treatment, symptoms intensify over a 2- to 7-day period (average, 5 days in LBRF and 3 days in TBRF), ending in a spontaneous crisis that coincides with the disappearance of spirochetes from the circulation. The crisis comprises two phases over several hours: a chill phase, characterized by rigors, rising temperature, and hypermetabolism, and a flush phase of falling temperature, diaphoresis, and a decreased effective circulating blood volume. The pathophysiologic events associated with this crisis are magnified when precipitated by antibiotic treatment and are indistinguishable from the Jarisch-Herxheimer reaction of treated syphilis (see “Treatment,” below). The crisis is followed by a period of exhaustion, sleep, and an uneventful recovery. Orthostatic hypotension is typical in the early recovery phase. Not uncommonly, in the first week of convalescence, the patient experiences 1 or 2 days of mild fever unassociated with detectable spirochetemia. In untreated patients, spirochetemia and symptoms may recur after a period of several days or weeks (average interval to first relapse, 9 days in LBRF and 7 days in TBRF). Only one or two relapses characteristically occur in untreated patients with LBRF, whereas as many as 10 (average, three) can occur in untreated patients with TBRF. In most cases, the illness becomes shorter and milder and the afebrile intervals longer with each relapse. Because of the great antigenic variation among Borrelia strains, infection confers only partial immunity, and repeated infections of the same individual have been recorded.

Diseases that should be considered in the differential diagnosis of relapsing fever or that may complicate relapsing fever include typhus, typhoid fever, nontyphoid salmonellosis, malaria, dengue and other arboviral illnesses, tuberculosis, leptospirosis, and viral hemorrhagic fevers. In the United States, the geographic distribution of Colorado tick fever (Chap. 180) overlaps that of TBRF, and the two diseases have similar manifestations early in their courses.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis of relapsing fever is confirmed most easily by the detection of spirochetes in blood, bone marrow aspirates, or cerebrospinal fluid. Motile spirochetes can be seen when specimens are examined by dark-field microscopy. Fixed organisms are clearly visible in Wright-, Giemsa-, or acridine orange–stained preparations of thin or dehemoglobinized thick smears of peripheral blood or buffy-coat preparations (Fig. 156-1). Organisms are most numerous in specimens taken during periods of high temperature preceding the crisis; smears of peripheral blood are positive in ≥70% of patients with LBRF and in a lower percentage of patients with TBRF. In reference laboratories, relapsing-fever spirochetes are cultured from blood by the inoculation of BSK II medium or by the intraperitoneal inoculation of immature laboratory mice. Serum antibodies to Borrelia can be detected by enzyme immunoassays, indirect fluorescent antibody (IFA) assay, and western immunoblotting using whole-cell sonicates as antigen; however, these tests are unstandardized and subject to insensitivity and cross-reactivity with other spirochetal agents, including B. burgdorferi (the agent of Lyme disease) and Treponema pallidum. A recently developed western immunoblot test employing species-specific recombinant glycerophosphodiester phosphodiesterase (GlpQ) as antigen has been shown to be more sensitive and specific than the whole-cell sonicate IFA or enzyme-linked immunosorbent assay (ELISA) tests.

Other laboratory findings in relapsing fever are nonspecific. The leukocyte count is normal or moderately elevated, with an unremarkable cell differential. Serum bilirubin levels are generally only slightly elevated. Thrombocytopenia commonly occurs in relapsing-fever patients during the acute phase of the illness; platelet counts rebound during early convalescence. Prothrombin and partial thromboplastin times are often moderately prolonged during acute illness, as are standardized bleeding times. Fibrinogen concentrations in the blood are normal, and fibrinolysis is mild or absent. Results of the Rumpel-
Leede tourniquet test for capillary fragility are negative, despite the presence of petechiae.

TREATMENT

Relapsing-fever borreliae are exquisitely sensitive to antibiotics. Treatment with doxycycline (or another tetracycline), erythromycin, or chloramphenicol produces rapid clearance of spirochetes and a remission of symptoms (Table 156-2). The response to a single dose of penicillin may be delayed and incomplete. Although a single dose of doxycycline (or another tetracycline), erythromycin, or chloramphenicol is highly effective in the treatment of LBRF, less is known about the efficacy of single-dose treatment of TBRF. Empirical treatment of TBRF for 7 days is therefore recommended to reduce the risk of persisting or relapsing borreliosis. For children <8 years of age and for pregnant women, erythromycin or penicillin may be preferred, given the potential adverse effects of tetracyclines.

Treatment of LBRF with a rapidly acting antibiotic regularly precipitates a Jarisch-Herxheimer-like reaction within 1 to 4 h of the first dose. This reaction, which occurs in more than 50% of treated TBRF patients in North America, tends to be more severe when the patient has LBRF rather than TBRF and when high numbers of spirochetes are circulating in the bloodstream. In the chill phase of the reaction, rigors and rising fever are accompanied by an increasing metabolic rate, alveolar hyperventilation, high cardiac output, increasing peripheral vascular resistance, and decreased pulmonary arterial pressure. The body temperature commonly rises to ≥41°C (≥105.8°F). This high fever is accompanied often by agitation and confusion and sometimes by delirium. Fever can be partially controlled by the use of a cooling blanket and ice packs and by sponging of the patient with tepid water and alcohol. The chill phase terminates after 10 to 30 min, giving way to a flush phase characterized by a fall in body temperature, drenching sweats, and sometimes (more commonly in LBRF) a potentially dangerous fall in systemic arterial pressure and rise in pulmonary arterial pressure. Although cardiac output is maintained at high levels, the effective circulating blood volume decreases as peripheral vascular resistance falls. Vital signs must be monitored carefully during this period of the reaction, which usually lasts ≤8 h. Clinical and electrocardiographic evidence of myocarditis and myocardial dysfunction includes a prolonged QT interval, a third heart sound (S₃), elevated central venous pressure, arterial hypotension, and rare pulmonary congestion. The use of delayed-release intramuscular penicillin may prolong or delay the clearance of spirochetes and thereby attenuate the accompanying Jarisch-Herxheimer reaction, but this response is not predictable; furthermore, single-dose penicillin treatment sometimes results in relapse of spirochtemia and symptoms. Glucocorticoids and nonsteroidal anti-inflammatory agents do not prevent or significantly modify the cardiopulmonary disturbances of the Jarisch-Herxheimer reaction, although hydrocortisone and acetaminophen given at the same time as antibiotics reduce peak body temperature. Although pretreatment with antibody to TNF-α may moderate the Jarisch-Herxheimer reaction in treated patients with LBRF, its use in LBRF is impractical and its use in TBRF (whose treatment is associated with a relatively mild Jarisch-Herxheimer reaction) is not warranted. Close monitoring of fluid balance, arterial and venous pressures, and myocardial function is advised in supportive management of the Jarisch-Herxheimer reaction in patients with LBRF.

The management of patients with relapsing fever–induced myocardial dysfunction requires caution in the administration of intravenous fluids and, in some cases, use of short-term inotropic therapy. The inability of heparin to control bleeding in LBRF suggests that disseminated intravascular coagulation is not important in its causation. Vitamin K and other soluble vitamins are sometimes given to counter dietary deficiencies in patients with LBRF. Because postural hypotension is often pronounced during the acute phase of relapsing fever and in the early stage of recovery, patients should be assisted when arising from bed.

Untreated LBRF has a high case-fatality rate, especially among persons in otherwise poor health, such as those in famine-affected populations. The fatality rate among treated persons is usually <5%. In general, TBRF is a milder disease than LBRF; the spontaneous crisis and the Jarisch-Herxheimer reactions are less pronounced and the case-fatality rates are lower for TBRF than for LBRF.

PREVENTION AND CONTROL

LBRF can be prevented by addressing socioeconomic circumstances that promote louse infestation (crowding, poverty, homelessness), by applying hygienic practices that reduce numbers of body lice (washing clothes, drying clothes in direct sunlight, changing clothes at frequent intervals), and by using acaricides. Spread of infection can be controlled by early case detection and treatment of infected persons and close contacts. Historically, outbreaks of LBRF have been controlled by mass delousing. In situations like those in refugee camps, individuals, their clothes, and their bed-

ting should be deloused with appropriate acaricides, such as 0.5% permethrin dust. Impregnation of clothing with liquid permethrin, a residual acaricide, can provide long-term protection against infestation. In outbreaks of fever that involve louse-infested populations, empirical single-dose treatment with doxycycline will be effective against typhus as well as LBRF. B. recurrens has a fragile life cycle and is eradicable.

TBRF can be prevented by the avoidance of rodent- and tick-infested dwellings and infested natural sites. Limiting rodent access to the foundations and attics of homes and vacation cabins and eliminating harborage for rodents in and around these dwellings reduce the potential for tick exposure. Rodents and rodent nests should be removed from infested buildings and their surroundings. Tick harborage of infested buildings or other circumscribed sites, such as rodent burrows and nests in hollow logs surrounding dwellings and in rodent-infested caves, can be chemically treated by pest-control specialists using various acaricides, such as carbaryl, diazinon, chlorpyrifos, pyrethrins, and malathion. Persons who enter tick-infested sites can protect themselves by wearing clothing that denies ticks access to the skin, by applying repellents to exposed skin and to clothing, and by applying an acaricide containing permethrin to clothing. Reporting of suspected cases of relapsing fever to public health authorities is important so that an epidemiologic investigation and control measures can be initiated promptly. Prompt diagnosis and treatment of relapsing fever in pregnant women is important in avoiding the potentially severe consequences of fetal or neonatal infection acquired in utero.

*a For tick-borne relapsing fever, parenteral therapy is used only until oral treatment is tolerated.*
Lyme Borreliosis

DEFINITION Lyme borreliosis is caused by a spirochete, *Borrelia burgdorferi*, sensu lato, that is transmitted by ticks of the *Ixodes ricinus* complex. The infection usually begins with a characteristic expanding skin lesion, erythema migrans (EM; stage 1, localized infection). After several days or weeks, the spirochete may spread hematogenously to many different sites (stage 2, disseminated infection). Possible manifestations of disseminated infection include secondary anular skin lesions, meningitis, cranial or peripheral neuritis, carditis, atrioventricular nodal block, or migratory musculoskeletal pain. Months to years later (usually after periods of latent infection), intermittent or chronic arthritis, chronic encephalopathy or polyneuropathy, or acrodermatitis may develop (stage 3, persistent infection). Most patients experience early symptoms of the illness during the summer, but the infection may not become symptomatic until it progresses to stage 2 or 3. Despite regional variations, the basic stages of the illness are similar worldwide.

Lyme disease was recognized as a separate entity in 1976 because of geographic clustering of children in Lyme, Connecticut, who were thought to have juvenile rheumatoid arthritis. The rural setting of the case clusters and the identification of EM as a feature of the illness suggested that the disorder was transmitted by an arthropod. It became apparent that Lyme disease was a multisystem illness that affected primarily the skin, nervous system, heart, and joints. Epidemiologic studies of patients with EM implicated certain *Ixodes* ticks as vectors of the disease. Early in the twentieth century, EM had been described in Europe and attributed to *I. ricinus* tick bites. In 1982, a previously unrecognized spirochete, now called *Borrelia burgdorferi*, was recovered from *Ixodes scapularis* ticks and then from patients with Lyme disease. The entity is now called Lyme disease or Lyme borreliosis.

ETIOLOGIC AGENT *B. burgdorferi*, the causative agent of Lyme disease, is a fastidious, microaerophilic bacterium. The spirochete’s genome is quite small (−1.5 Mb) and consists of a highly unusual linear chromosome of 950 kb as well as 9 linear and 12 circular plasmids. *B. burgdorferi* contains many immunogenic proteins, including a number of differentially expressed lipoproteins, most of which are encoded by plasmid DNA. To date, three groups of pathogenic *B. burgdorferi* organisms, together referred to as *B. burgdorferi sensu lato*, have been identified. All North American strains have belonged to the first group, *B. burgdorferi sensu stricto*. Although all three of the identified groups have been found in Europe, most isolates have been strains of group 2 (*B. garinii*) or group 3 (*B. afzelii*), and only the latter two groups have been found in Asia. These differences may well account for the clinical variations in the disease in different geographic regions.

EPIDEMIOLOGY Lyme borreliosis in all locations is transmitted by ticks of the *I. ricinus* complex: *I. scapularis* (also called *I. dammini*), *I. pacificus*, *I. ricinus*, and *I. persulcatus*. *I. scapularis* is the principal vector in the northeastern United States from Maine to Maryland and in the midwestern states of Wisconsin and Minnesota. *I. pacificus* is the vector in the western states of California and Oregon. The disease is acquired throughout Europe (from Great Britain to Scandinavia to European Russia), where *I. ricinus* is the vector, and in Asia, China, and Japan, where *I. persulcatus* is the vector. These ticks may transmit other diseases as well. In the United States, *I. scapularis* also transmits babesiosis and human anaplasmosis; in Europe and Asia, *I. ricinus* and *I. persulcatus* also transmit tick-borne encephalitis.

Ticks of the *I. ricinus* complex have larval, nymphal, and adult stages; they require a blood meal at each stage. The risk of infection in a given area depends largely on the density of these ticks as well as their feeding habits and animal hosts, which have evolved differently in different locations. For *I. scapularis* in the northeast, the white-footed mouse is the preferred host of the immature larval and nymphal ticks. It is critical that both of the tick’s immature stages feed on the same host, because the life cycle of the spirochete depends on horizontal transmission: in early summer from infected nymphs to mice and in late summer from infected mice to larvae, which then molt to become the infected nymphs that will begin the cycle again the following year. It is the tiny nymphal tick that is primarily responsible for transmission of the disease to humans during the early summer months. White-tailed deer, which are not involved in the life cycle of the spirochete, are the preferred host for the adult stage of *I. scapularis* and seem to be critical to the tick’s survival.

Lyme disease is now the most common vector-borne infection in the United States. Since surveillance was begun by the Centers for Disease Control and Prevention (CDC) in 1982, the number of cases has increased dramatically. More than 15,000 new cases are now reported each summer. In Europe, Lyme borreliosis is widely established in forested areas; there, the highest reported frequencies of the disease are in the middle of the continent and in Scandinavia. Cases have occurred in persons who reside in endemic suburban, wooded, or rural areas and in persons who visit, hike, camp, or hunt in these areas.

PATHOGENESIS To maintain its complex enzootic cycle, *B. burgdorferi* must adapt to two markedly different environments: the tick and the mammalian host. The spirochete expresses outer-surface proteins A and B (OspA and OspB) in the midgut of the tick, whereas OspC is upregulated as the organism travels to the tick’s salivary gland and thence to the mammalian host. The tick must usually be attached for at least 24 h for transmission of *B. burgdorferi*.

After injection into the human skin, *B. burgdorferi* may migrate outward, producing EM, and may spread hematogenously to other organs. A number of mechanisms may aid in spirochetal dissemination. For example, the sequences of OspC vary considerably among strains, and only a few groups of sequences are associated with disseminated disease. Spread through the skin and other tissue matrices may be facilitated by the binding of human plasminogen and its activators to the surface of the spirochete. During its dissemination and homing to specific sites, the organism attaches to mammalian cells and becomes associated with specific integrins, matrix glycosaminoglycans, and extracellular matrix proteins. For example, *Borrelia* decorin-binding proteins A and B bind decorin, a glycosaminoglycan on collagen fibrils; this binding may explain why the organism is commonly aligned with collagen fibrils in the extracellular matrix in the heart, nervous system, or joints. The only known virulence factors of *B. burgdorferi* are surface proteins that allow the spirochete to attach to mammalian cells.

Inflammatory innate immune responses are critical in the control of early disseminated infection. Spirochetal lipoproteins, which bind to the CD14 molecule and toll-like receptor 2 on macrophages, are potent activators of the innate immune response, leading to the production of macrophage-derived inflammatory cytokines. After the first several weeks of infection, T cells, which are part of the adaptive immune response, generally exhibit heightened responsiveness to *B.
burgdorferi antigens, and evidence of B-cell hyperactivity is found, including elevated total serum IgM levels, cryoprecipitates, and circulating immune complexes. Titers of specific IgM antibody to B. burgdorferi peak between the third and sixth week after disease onset. The specific IgG response develops gradually over months, with response to an increasing array of at least 12 spirochetal polypeptides and maximal expansion during the period of arthritis. Histologic examination of all affected tissues reveals an infiltration of lymphocytes, macrophages, and plasma cells with some degree of vascular damage (including mild vasculitis or hypertervascular occlusion), suggesting that the spirochete may have been present in or around blood vessels.

Despite the innate and adaptive immune responses, B. burgdorferi may sometimes survive in certain sites. The ability of the spirochete to downregulate the expression of surface-exposed protein antigens is one important mechanism of immune evasion. In addition, during disseminated infection, a surface-exposed lipoprotein called VlsE undergoes extensive antigenic variation. However, the organism does not have mechanisms that help to protect it from antibiotic therapy. For example, B. burgdorferi has only been seen extracellularly in affected tissues; it has not been shown to “hide out” in intracellular locations, thereby evading antibiotic exposure.

CLINICAL MANIFESTATIONS

Early Infection: Stage 1 (Localized Infection)

After a incubation period of 3 to 32 days, EM, which occurs at the site of the tick bite, usually begins as a red macule or papule that expands slowly to form a large annular lesion. As the lesion increases in size, it often develops a bright red outer border and partial central clearing. Because of the small size of ixodid ticks, most patients do not remember the preceding tick bite. The center of the lesion sometimes becomes intensely erythematous and indurated, vesicular, or necrotic. In other instances, the expanding lesion remains an even, intense red; several red rings are found within an outside ring; or the central area turns blue before the lesion clears. Although EM can be located anywhere, the thigh, groin, and axilla are particularly common sites. The lesion is warm but not often painful. Approximately 20% of patients do not exhibit this characteristic skin manifestation. In Europe, EM is often an indolent localized infection of the skin; in contrast, in the United States, this lesion is associated with more intense inflammation and signs that often suggest dissemination of the spirochete.

Early Infection: Stage 2 (Disseminated Infection)

In cases in the United States, B. burgdorferi often spreads hematogenously to many sites within days or weeks after the onset of EM. In these cases, patients may develop secondary annular skin lesions similar in appearance to the initial lesion. Skin involvement is commonly accompanied by severe headache, mild stiffness of the neck, fever, chills, migratory musculoskeletal pain, arthralgias, and profound malaise and fatigue. Less common manifestations include generalized lymphadenopathy or splenomegaly, hepatitis, sore throat, nonproductive cough, conjunctivitis, iritis, or testicular swelling. Except for fatigue and lethargy, which are often constant, the early signs and symptoms of Lyme disease are typically intermittent and changing. Even in untreated patients, the early symptoms usually become less severe or disappear within several weeks. In ~15% of patients, the infection presents with these nonspecific systemic symptoms.

Symptoms suggestive of meningeal irritation may develop early in Lyme disease when EM is present but usually are not associated with cerebrospinal fluid (CSF) pleocytosis or an objective neurologic deficit. After several weeks or months, ~15% of untreated patients develop frank neurologic abnormalities, including meningitis, subtle encephalitic signs, cranial neuritis (including bilateral facial palsy), motor or sensory radiculoneuropathy, mononeuritis multiplex, cerebellar ataxia, or myelitis—alone or in various combinations. In the United States, the usual pattern consists of fluctuating symptoms of meningitis accompanied by facial palsy and peripheral radiculoneuropathy. Lymphocytic pleocytosis (~100 cells per μL) is found in CSF, often along with elevated protein levels and normal or slightly low glucose concentrations. In Europe and Asia, the first neurologic sign is characteristically radicular pain, which is followed by the development of CSF pleocytosis (called meningopolyneuritis or Banwarth’s syndrome), but meningeal or encephalitic signs are frequently absent. In children, the optic nerve may be affected because of inflammation or increased intracranial pressure, which may lead to blindness. These early neurologic abnormalities usually resolve completely within months, but in rare cases, chronic neurologic disease may occur later.

Within several weeks after the onset of illness, ~8% of patients develop cardiac involvement. The most common abnormality is a fluctuating degree of atroventricular block (first-degree, Wenckebach, or complete atrioventricular block). Some patients have more diffuse cardiac involvement, including electrocardiographic changes indicative of acute myopericarditis, left ventricular dysfunction evident on radionuclide scans, or (in rare cases) cardiomegaly or pancarditis. Cardiac involvement usually lasts for only a few weeks but may recur. Chronic cardiomyopathy caused by B. burgdorferi has been reported in Europe.

During this stage, musculoskeletal pain is common. The typical pattern consists of migratory pain in joints, tendons, bursae, muscles, or bones (usually without joint swelling) lasting for hours or days and affecting one or two locations at a time.

Late Infection: Stage 3 ( Persistent Infection)

Months after the onset of infection, ~60% of patients in the United States who have received no antibiotic treatment develop frank arthritis. The typical pattern comprises intermittent attacks of oligoarticular arthritis in large joints (especially the knees), lasting for weeks to months in a given joint. Small joints and periarticular sites also may be affected, primarily during early attacks. The number of patients who continue to have recurrent attacks decreases each year. However, in a small percentage of cases, involvement of large joints—usually one or both knees—becomes chronic and may lead to erosion of cartilage and bone. These patients have a higher frequency of the class II major histocompatibility complex alleles associated with rheumatoid arthritis, particularly HLA-DRBI*0401 or *0101 alleles, than patients with brief Lyme arthritis. Moreover, they may have persistent arthritis for months or even several years after the apparent eradication of spirochetes from the joints with antibiotic therapy. In these genetically susceptible individuals, it has been postulated that autoimmune may develop within the proinflammatory milieu of the joints because of molecular mimicry between a dominant T-cell epitope of OspA and a similar sequence in a human protein.

White cell counts in joint fluid range from 500 to 110,000/μL (average, 25,000/μL); most of these cells are polymorphonuclear leukocytes. Tests for rheumatoid factor or antinuclear antibodies usually give negative results. Examination of synovial biopsy samples reveals fibrin deposits, villous hypertrophy, vascular proliferation, microangiopathic lesions, and a heavy infiltration of lymphocytes and plasma cells.

Although less common, chronic neurologic involvement may also become apparent months or years after the onset of infection, sometimes following long periods of latent infection. The most common form of chronic central nervous system involvement is subtle encephalopathy affecting memory, mood, and sleep and often accompanied by axonal polyneuropathy manifested as either distal paresthesias or spinal radicular pain. Patients with encephalopathy frequently have evidence of memory impairment in neuropsychological tests and abnormal results in CSF analyses. In cases with polyneuropathy, electromyography generally shows extensive abnormalities of proximal and distal nerve segments. Encephalomyelitis or leukoencephalitis, a rare manifestation of Lyme borreliosis associated primarily with B. garinii infection in Europe, is a severe neurologic disorder that may include spastic paraparesis, upper motor-neuron bladder dysfunction, and lesions in the periventricular white matter. The prolonged course of chronic neuroborreliosis following periods of latent infection is reminiscent of tertiary neurosyphilis.
Acrodermatitis chronica atrophicans, the late skin manifestation of the disorder, has been associated primarily with *B. afzelii* infection in Europe and Asia. It has been observed mostly in elderly women. The skin lesions, which are usually found on the acral surface of an arm or leg, begin insidiously with reddish-violaceous discoloration; they become sclerotic or atrophic over a period of years.

**DIAGNOSIS** The culture of *B. burgdorferi* in Barbour-Stoenner-Kelly (BSK) medium permits definitive diagnosis, but this complex method has been used only in research studies. Moreover, with a few exceptions, positive cultures have been obtained only early in the illness—primarily from biopsy samples of EM skin lesions, less often from plasma samples, and occasionally from CSF samples. Later in the infection, polymerase chain reaction (PCR) is greatly superior to culture for the detection of *B. burgdorferi* DNA in joint fluid, and this has been the major use for PCR testing in Lyme disease. In one study, *B. burgdorferi* DNA was detected by PCR in synovial fluid samples from 75 (85%) of 88 patients and in none of 64 control samples. However, the sensitivity of PCR determinations in CSF from patients with neuroborreliosis has been much lower. There seems to be little if any role for PCR in the detection of *B. burgdorferi* DNA in blood or urine samples. Moreover, this procedure, which must be carefully controlled to prevent contamination, is not routinely available.

Because of the problems associated with direct detection of *B. burgdorferi*, Lyme disease is usually diagnosed by the recognition of a characteristic clinical picture with serologic confirmation. Although serologic testing may yield negative results during the first several weeks of infection, most patients have a positive antibody response to *B. burgdorferi* after that time. The limitation of serologic tests is that they do not clearly distinguish between active and inactive infection. Patients with previous Lyme disease—particularly in cases progressing to late stages—often remain seropositive for years, even after adequate antibiotic treatment. In addition, about 10% of patients are seropositive because of asymptomatic infection. If these individuals subsequently develop another illness, the positive serologic test for Lyme disease may cause diagnostic confusion. Conversely, in rare instances, patients who receive inadequate antibiotic therapy during the first several weeks of infection may subsequently develop subtle joint or neurologic symptoms but are seronegative. The important point is that seronegative Lyme disease is usually a mild, attenuated illness that responds well to standard courses of antibiotic therapy. According to an algorithm published by the American College of Physicians (Table 157-1), serologic testing for Lyme disease is recommended only for patients with at least an intermediate pretest probability of Lyme disease, such as those with oligoarthritis. It should not be used as a screening procedure in patients with pain or fatigue syndromes. In such patients, the probability of a false-positive serologic result is higher than that of a true-positive result.

For serologic analysis of Lyme disease in the United States, the CDC recommends a two-step approach in which samples are first tested by enzyme-linked immunosorbent assay (ELISA) and equivocal or positive results are then tested by western blotting. During the first month of infection, both IgM and IgG responses to the spirochete should be determined, preferably in both acute- and convalescent-phase serum samples. Approximately 20 to 30% of patients have a positive response detectable in acute-phase samples, whereas about 70 to 80% have a positive response during convalescence (2 to 4 weeks later). After 1 month of infection, by which time most patients with active Lyme disease have disseminated infection, the specificity and sensitivity of the IgG response to the spirochete are both very high—in the range of 95% to 99%—as determined by the two-test approach of ELISA and western blot. At this point and thereafter, a single test (that for IgG) is usually sufficient. In persons with illness of >1 month’s duration, a positive IgM test result alone is likely to be false-positive and therefore should not be used to support the diagnosis. According to current criteria adopted by the CDC, an IgM western blot is considered positive if two of the following three bands are present: 23, 39, and 41 kDa. However, the combination of the 23- and 41-kDa bands may still represent a false-positive result. An IgG blot is considered positive if 5 of the following 10 bands are present: 18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kDa. In European cases, there is less expansion of the antibody response, and no single set of criteria for the interpretation of immunoblots results in high levels of sensitivity and specificity in all countries.

Several second-generation tests that use recombinant spirochetal proteins or synthetic peptides have shown promising results. For example, an IgG ELISA employing a 26-mer peptide from invariant region 6 (IR6) of the ViSE lipoprotein has a sensitivity and a specificity similar to those achieved with the IgM and IgG two-test approach using sonicated whole spirochetes. However, the IR6 ELISA has a limitation similar to that affecting standard serology, in that a positive test result does not distinguish clearly between active and past infection. The IR6 ELISA may be of value with regard to European as well as American strains of the spirochete.

**DIFFERENTIAL DIAGNOSIS** Classic EM is a slowly expanding erythema, often with partial central clearing. If the lesion expands little, it may represent the red papule of an uninfected tick bite. If the lesion expands rapidly, it may represent cellulitis (e.g., streptococcal cellulitis) or an allergic reaction, perhaps to tick saliva. Patients with secondary anular lesions may be thought to have erythema multiforme, but neither the development of blistering mucosal lesions nor the involvement of the palms or soles is a feature of *B. burgdorferi* infection. In the southeastern United States, an EM-like skin lesion, sometimes with mild systemic symptoms, may be associated with *Amblyomma americanum* tick bites, but the cause of this illness has not yet been identified.

In the United States, *I. scapularis* ticks may transmit not only *B. burgdorferi* but also *Babesia microti*, a red blood cell parasite (Chap. 195), or *Anaplasma phagocytophila*, the agent of human anaplasmosis (formerly called the agent of human granulocytotropic ehrlichiosis; Chap. 158). Although babesiosis and anaplasmosis are most often asymptomatic, infection with any of these three agents may cause nonspecific systemic symptoms, and coinfected patients may have more severe or persistent symptoms than patients infected with a single agent. Standard blood counts may yield clues regarding the presence of coinfection. Anaplasmosis may cause leukopenia or thrombocytopenia, and babesiosis may cause thrombocytopenia or (in severe cases) hemolytic anemia. However, IgM serologic responses may confuse the diagnosis. For example, *A. phagocytophila* may elicit a positive IgM response to *B. burgdorferi*. The frequency of coinfection in different studies has been variable. In one prospective study, 4% of patients with EM had evidence of coinfection.

Facial palsy caused by *B. burgdorferi*, which occurs in the early disseminated phase of the infection (often in July, August, or September), is usually recognized by its association with EM. However, facial palsy without EM may be the presenting manifestation of Lyme disease. In such cases, both the IgM and IgG responses to the spirochete are usually positive. The most common infectious agents that cause

facial palsy are herpes simplex virus type 1 (Bell’s palsy; Chap. 163) and varicella-zoster virus (Ramsay-Hunt syndrome; Chap. 164).

Later in the infection, oligoarticular Lyme arthritis most resembles reactive arthritis in an adult or the pauciarticular form of juvenile rheumatoid arthritis in a child. Patients with Lyme arthritis usually have the highest IgG antibody responses seen in the infection, with reactivity to many spirochetal proteins.

The most common problem in diagnosis is to mistake Lyme disease for chronic fatigue syndrome (Chap. 370) or fibromyalgia (Chap. 315). This difficulty is compounded by the fact that a small percentage of patients do in fact develop these chronic pain or fatigue syndromes in association with or soon after Lyme disease. Compared with Lyme disease, chronic fatigue syndrome or fibromyalgia tends to produce more generalized and disabling symptoms, including marked fatigue, severe headache, diffuse musculoskeletal pain, multiple symmetric tender points in characteristic locations, pain and stiffness in many joints, diffuse dysesthesia, difficulty with concentration, and sleep disturbances. Patients with chronic fatigue syndrome or fibromyalgia lack evidence of joint inflammation; they have normal results in neurologic tests; and they usually have a greater degree of anxiety and depression than patients with chronic neuroborreliosis.

**TREATMENT**

As outlined in the algorithm in Fig. 157-1, the various manifestations of Lyme disease can usually be treated successfully with orally administered antibiotics; the exceptions are objective neurologic abnormalities and third-degree atrioventricular heart block, which seem to require intravenous therapy. For early Lyme disease, doxycycline is effective in men and in nonpregnant women. An advantage of this regimen is that it is also effective against *A. phagocytophila*, which is transmitted by the same tick that transmits the Lyme disease agent. Amoxicillin, cefuroxime axetil, and erythromycin or its congeners are second-, third-, and fourth-choice alternatives, respectively. In children, amoxicillin is effective (not more than 2 g/d); in cases of penicillin allergy, cefuroxime axetil or erythromycin may be used. In contrast to second- or third-generation cephalosporin antibiotics, first-generation cephalosporins, such as cephalexin, are not effective. For patients with infection localized to the skin, a 14-day course of therapy is generally sufficient; in contrast, for patients with disseminated infection, a 21-day course is recommended. Approximately 15% of patients experience a Jarisch-Herxheimer-like reaction during the first 24 h of therapy. In multicenter studies, more than 90% of patients whose early Lyme disease was treated with these regimens had satisfactory outcomes, although some patients reported symptoms after treatment. Objective evidence of persistent infection or relapse was rare, and retreatment was usually unnecessary.

One of these oral antibiotic regimens, when given for 30 to 60 days, or intravenous ceftriaxone, given for 14 to 28 days, is effective for the treatment of Lyme arthritis. Oral therapy is easier to administer, is associated with fewer side effects, and is considerably less expensive. However, the response to oral therapy may be slower than to intravenous therapy, and some patients given oral therapy have subsequently developed overt neuroborreliosis, which may require intravenous therapy for a successful outcome. In the small percentage of patients with arthritis in whom arthritic symptoms persist for months or even years after the apparent eradication of spirochetes from the joints with antimicrobial therapy, treatment with anti-inflammatory agents or synovectomy may be successful.

For objective neurologic abnormalities (with the possible exception of facial palsy alone), parenteral antibiotic therapy seems to be necessary. Intravenous ceftriaxone, given for 14 to 28 days, is most commonly used for this purpose, but intravenous cefotaxime or intravenous penicillin G for the same duration may also be effective. In patients with high-degree atrioventricular block or a PR interval of $>0.3$ s, intravenous therapy for at least part of the course and cardiac monitoring are recommended, but the insertion of a permanent pacemaker is not necessary.

It is unclear how and whether asymptomatic infection should be treated, but patients with such infection are often given a course of oral antibiotics. Because maternal-fetal transmission of *B. burgdorferi* seems to occur rarely, if at all, standard therapy for the manifestations of the illness is recommended for pregnant women. Long-term persistence of *B. burgdorferi* has not been documented in any large series of patients after treatment with currently recommended regimens. Therefore, there is no indication for multiple, repeated antibiotic courses in the treatment of Lyme disease.

After appropriately treated Lyme disease, a small percentage of patients continue to have subjective symptoms, primarily musculoskeletal pain, neurocognitive difficulties, or fatigue. This so-called chronic Lyme disease or post–Lyme disease syndrome is a disabling condition that is similar to chronic fatigue syndrome or fibromyalgia. In a large study, one group of patients with post–Lyme disease syndrome received intravenous ceftriaxone for 30 days followed by oral doxycycline for 60 days, while another group received intravenous and oral placebo preparations for the same durations. No significant differences were found between groups in the numbers of patients reporting that their symptoms had improved, become worse, or stayed the same. Such patients are best treated for the relief of symptoms rather than with prolonged courses of antibiotics.

The risk of infection with *B. burgdorferi* after a recognized tick bite is so low that antibiotic prophylaxis is not routinely indicated. However, if an attached, engorged *I. scapularis* nymph is found or if follow-up is anticipated to be difficult, a single 200-mg dose of doxycycline, which effectively prevents Lyme disease when given within 72 h after the tick bite, may be administered.

**PROGNOSIS** The response to treatment is best early in the disease. Later treatment of Lyme borreliosis is still effective, but the period of con-
valescence may be longer. Eventually, most patients recover with minimal or no residual deficits.

**REINFECTION** Reinfeciton may occur after EM when patients are treated with antimicrobial agents. In such cases, the immune response is not adequate to provide protection from subsequent infection. However, patients who develop an expanded immune response to the spirochete over a period of months (such as those with Lyme arthritis) have protective immunity for a period of years and do not acquire the infection again.

**PREVENTION** Protective measures for the prevention of Lyme disease may include the avoidance of tick-infested areas, the use of repellents and acaricides, tick checks, and modification of landscapes in or near residential areas. Although a vaccine for Lyme disease used to be available, the manufacturer has discontinued its production. Therefore, no vaccine is now commercially available for the prevention of this infection.

---

### Rickettsial Diseases

The rickettsiae make up a family of gram-negative cocccobacilli and short bacilli that grow strictly in eukaryotic cells. Characteristics of these organisms include their obligately intracellular location and persistence. The pathogenic rickettsiae move through mammalian reservoirs; they are transmitted by insect or tick vectors. Except for louse-borne typhus, humans are incidental hosts. Among rickettsiae, *Coxiella burnetii* (the agent of Q fever) is notorious for its ability to survive for an extended period outside of the reservoir or vector and for its extreme infectiousness: inhalation of a single microorganism can cause pneumonia. Clinical infections with rickettsiae can be classified into five general groups: (1) tick-, louse-, flea-, and gamasid mite–borne, spotted fever group (SFG) and typhus group rickettsial diseases; (2) chigger-borne scrub typhus; (3) tick-borne ehrlichioses and anaplasmosis; (4) neorickettsiosis (sennetsu fever); and (5) Q fever. The rickettsiae that cause spotted fevers, typhus, and scrub typhus are listed along with their vectors, geographic ranges, and associated diseases in Table 158-1.

### Tick-, Mite-, and Flea-Borne Spotted Fevers

**ROCKY MOUNTAIN SPOTTED FEVER** Rocky Mountain spotted fever (RMSF), the most severe of the rickettsial diseases, is caused by *Rickettsia rickettsii*. This organism possesses two major immunodominant surface-exposed proteins, OmpA and OmpB, which have species-specific conformational epitopes. OmpA functions as an adhesin for the host cell; OmpB, the most abundant outer-membrane protein, shares genetic sequences and limited antigens with typhus group rickettsiae. This small (0.3 μm by 1.0 μm) bacillus has a gram-negative cell wall.

structure; its lipopolysaccharide shares antigens mainly within the SFG and is not endotoxic in the quantities found in human infections.

Discovered in the American West in the late nineteenth century, RMSF is at present documented in 48 states (with the highest prevalences in the south-central and southeastern states) as well as in Canada, Mexico, Costa Rica, Panama, Colombia, Argentina, and Brazil. It is transmitted by *Dermacentor variabilis*, the American dog tick, in the eastern two-thirds of the United States and in California; by *D. andersoni*, the Rocky Mountain wood tick, in the western United States; by *Rhipicephalus sanguineus* in Mexico; and by *Amblyomma cajennense* in Central and South America. Maintained principally by transovarian transmission from one generation of ticks to the next, *R. rickettsii* can be acquired by uninfected ticks through the ingestion of a blood meal from rickettsemic small mammals.

Humans become infected during the active season of the vector tick species. In northern areas, cases occur mainly in the spring; in warmer southern states, most cases occur from May to September, although some cases are reported in the winter. Although 4% of *D. variabilis* ticks contain rickettsiae, the vast majority of these are non-pathogenic species such as *R. montanensis* and *R. bellii*. The likelihood of an individual tick’s containing *R. rickettsii* is remote. From 1971 to 2001, the reported incidence of RMSF was in the range of 0.16 to 0.50 cases per 100,000 population in the United States. In 2001, 0.20 persons per 100,000 in the United States developed RMSF. This rate is probably an underestimate, since the diagnosis is difficult and reporting incomplete. The 5- to 9-year-old age group has the highest incidence. The mortality rate was 20 to 25% in the preantibiotic era porting incomplete. The 5- to 9-year-old age group has the highest incidence. The mortality rate was 20 to 25% in the preantibiotic era and now remains at ~3 to 5% because of delayed diagnosis and treatment. The case-fatality ratio increases with each decade of life above age 20.

**Pathogenesis**  *R. rickettsii* organisms are inoculated into the dermis along with secretions of the tick’s salivary glands after ≥6 h of feeding. Rickettsiae spread lymphohematogenously throughout the body, attach via OmpA to the endothelial cell membrane, and induce their own engulfment. Once intracellularly located, they escape rapidly from the phagosome, replicate in the cytosol by binary fission, and spread from cell to cell, propelled by polar polymerization of the host cell’s actin. The result is numerous foci of contiguous infected endothelial cells that are extensive enough to manifest clinically after a dose-dependent incubation period of ~1 week (range, 2 to 14 days). *R. rickettsii* is more invasive than other rickettsiae, routinely spreading to infect vascular smooth-muscle cells. Despite frequent statements to the contrary, occlusive thrombosis and ischemic necrosis are not the fundamental pathologic basis for tissue and organ injury in RMSF. Instead, increased vascular permeability, with resulting edema, hypovolemia, and ischemia, is responsible. Indeed, immunohistologic studies of severely infected humans and animals have demonstrated numerous zones of infected endothelium, only a small proportion of which contain thrombi. The thrombi are usually located to one side of the lumen, which is not occluded. These hemostatic plugs appear to be an appropriate host response rather than a pathogenic process. Consumption of platelets results in thrombocytopenia in 32 to 52% of patients, but disseminated intravascular coagulation with hypofibrinogenemia is rare. Activation of platelets, generation of thrombin, and activation of the fibrinolytic system all appear to be homeostatic physiologic responses to endothelial injury.

**Clinical Manifestations**  The incubation period averages 7 days. Early in the illness, when medical attention usually is first sought, RMSF is difficult to distinguish from many self-limiting viral illnesses. Fever, headache, malaise, myalgia, nausea, vomiting, and anorexia are the most frequent symptoms during the first 3 days. The patient becomes progressively more ill as vascular injury and infection advance. In one large series, only one-third of patients were diagnosed with presumptive RMSF early in the clinical course and treated appropriately as outpatients. In the tertiary care setting, RMSF is all too often recog-nized only when its late severe manifestations, developing at the end of the first week or during the second week of illness in patients without appropriate treatment, prompt admission to the intensive care unit.

The progressive nature of the infection is clearly manifested in the skin. Rash is evident in only 14% of patients on the first day of illness and in only 49% during the first 3 days. Macules (1 to 5 mm) appear first on the wrists and ankles and then on the remainder of the extremities and the trunk. Later, more severe vascular damage results in frank hemorrhage at the center of the maculopapule, a petechia that does not disappear upon compression (Fig. 158-1). This sequence of events is sometimes delayed or aborted by effective treatment. In fact, rash appears on day 6 or later in 20% of cases and does not appear at all in 9 to 16% of cases, including some with severe visceral lesions that result in death. Petechiae occur in 41 to 59% of cases, appearing on or after day 6 in 74% of cases that include a rash. Involvement of the palms and soles, often considered diagnostically important, usually occurs relatively late in the course (after day 5 in 43% of cases) and does not occur at all in 18 to 64% of cases.

The microcirculation, both systemic and pulmonary, is the target of intracellular rickettsial infection, and the clinical manifestations reflect the ensuing vascular changes. Widespread increased vascular permeability results in edema, decreased plasma volume, hypoalbuminemia, reduced serum oncotic pressure, and prerenal azotemia. Hypotension occurs in 17% of cases. Extensive infection of the pulmonary microcirculation is associated with noncardiogenic pulmonary edema. Cardiac involvement is most frequently manifested as dysrhythmia, which is detected in 7 to 16% of cases. Pulmonary involvement, often a major factor in fatal cases, is observed in 17% of cases, of which 12% are considered to represent severe respiratory disease and 8% require mechanical ventilation.

Central nervous system (CNS) involvement is the other important
determinant of the outcome of RMSF. Encephalitis, presenting as confusion or lethargy, is apparent in 26 to 28% of cases. Progressively severe encephalitis manifests as stupor or delirium in 21 to 26% of cases, as ataxia in 18%, as coma in 9 to 10%, and as seizures in 8%. Cranial nerve palsy, hearing loss, severe vertigo, nystagmus, dysarthria, aphasia, unilateral corticospinal signs, ankle clonus, extensor toe signs, hyperreflexia, spasticity, fasciculations, ataxosis, neurogenic bladder, hemiplegia, paraplegia, and complete paralysis have been reported. Meningoencephalitis results in cerebrospinal fluid (CSF) pleocytosis in 34 to 38% of cases; usually there are 10 to 100 cells per microliter with a mononuclear predominance, but occasionally there are more than 100 cells per microliter and a polymorphonuclear predominance. The CSF protein concentration is increased in 30 to 35% of cases, but the CSF glucose concentration is usually normal.

Renal failure, which occurs in more severely ill patients, is often reversible with rehydration. However, in the most severe cases, shock results in acute tubular necrosis–induced renal failure, which often requires hemodialysis.

Hepatic injury is manifested in 38% of cases as mildly or moderately increased serum aminotransferase concentrations and is due to focal death of individual hepatocytes, but hepatic failure does not occur. Jaundice is recognized in 8 to 9% of cases and an elevated serum bilirubin concentration in 18 to 30%. Marked hyperbilirubinemia occasionally occurs, probably as a consequence of both hemolysis and hepatocytic injury.

Bleeding is a potentially life-threatening effect of severe vascular damage. Anemia develops in 30% of cases and is severe enough to require red blood cell transfusions in 11%. Blood is detected in the stools or vomitus of 10% of patients, and death has followed massive upper gastrointestinal hemorrhage.

Other characteristic clinical laboratory findings include a normal white blood cell count with increased numbers of immature myeloid cells, increased plasma levels of proteins of the acute-phase response (C-reactive protein, fibrinogen, ferritin, and others), and hyponatremia (in 56% of cases) due to the appropriate secretion of antidiuretic hormone in response to the hypovolemic state. Skeletal muscle injury, clinically manifested as myositis, has been documented in several individual cases by the detection of marked elevations in serum creatine kinase or of histopathologic evidence of vascular injury in skeletal muscle and multifocal rhabdomyonecrosis. Ocular involvement includes conjunctivitis in 30% of cases and retinal vein engorgement, flame hemorrhages, arterial occlusion, and papilledema with normal CSF pressure in some instances.

In untreated cases, death usually occurs 8 to 15 days after the onset of illness. A rare presentation, fulminant RMSF, is fatal within 5 days after onset. This fulminant presentation has been associated with RMSF in black males who have a glucose-6-phosphate dehydrogenase (G6PD) deficiency and is thought to be related to an undefined effect of hemolysis on the rickettsial infection. Although survivors of RMSF usually appear to return to their previous state of health, permanent sequelae, including neurologic deficits and amputation of gangrenous extremities, may follow severe illness.

**Differential Diagnosis**

The diagnosis of RMSF during the acute stage is more difficult than is generally appreciated. Clinical and epidemiologic considerations are more important than laboratory features early in the illness. The most important epidemiologic factor is a history of exposure within the 12 days preceding disease onset to a potentially tick-infested environment during a season of possible tick activity. However, only 60% of patients actually recall being bitten by a tick during the incubation period.

The differential diagnosis for early clinical manifestations of RMSF (fever, headache, and myalgia without a rash) includes influenza, enteroviral infection, infectious mononucleosis, viral hepatitis, leptospirosis, typhoid fever, gram-negative or gram-positive bacterial sepsis, burns, meningococcemia, disseminated gonococcal infection, secondary amebiasis, murine typhus, sylvatic flying-squirrel typhus, and rickettsialpox. Enterocolitis may be suggested by nausea, vomiting, and abdominal pain; prominence of abdominal tenderness has resulted in exploratory laparotomy. CNS involvement may masquerade as bacterial and viral meningoencephalitis, with seizures, coma, neurologic signs, and CSF abnormalities. Cough, pulmonary signs, and chest roentgenographic opacities may lead to a diagnostic consideration of bronchitis or pneumonia.

At presentation during the first 3 days of illness, only 3% of patients exhibit the classic triad of fever, rash, and history of tick exposure. When a rash appears, a diagnosis of RMSF should certainly be considered. However, many illnesses considered in the differential diagnosis may also be associated with a rash, including rubella, rubella, meningococcemia, disseminated gonococcal infection, secondary syphilis, toxic shock syndrome, drug hypersensitivity, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, Kawasaki syndrome, and immune complex vasculitis. Conversely, any person in an endemic area with a provisional diagnosis of one of the above illnesses may have RMSF.

The most common serologic test for confirmation of the diagnosis is the indirect immunofluorescence assay. Between 7 and 10 days after onset, a diagnostic titer of ≥1:64 is usually detectable. Latex agglutination and a solid-state enzyme immunoassay are also available commercially. Latex agglutination usually yields a diagnostic titer of ≥1:128 at 7 to 9 days after onset. The sensitivity and specificity of the indirect immunofluorescence assay are 94 to 100% and 100%, respectively, and the latex agglutination test has a sensitivity of 71 to 94% and a specificity of 96 to 99%. The performance of the solid-state immunoassay has not been reported. It is important to understand that serologic tests for RMSF are usually negative at the time of presentation for medical care and that treatment should not be delayed while a positive serologic result is awaited.

The only diagnostic test that is useful during the acute illness is immunohistologic examination (immunofluorescence or immunoenzyme staining) of a cutaneous biopsy of a rash lesion for *R. rickettsii*. Examination of a 3-mm punch biopsy of such a lesion is 70% sensitive and 100% specific. Polymerase chain reaction (PCR) amplification and detection of *R. rickettsii* DNA in peripheral blood is a relatively insensitive approach except in the preterminal state; rickettsiae are present in large quantities in heavily infected foci of endothelial cells but in relatively low quantities in the circulation. Cultivation of rickettsiae in cell culture is technically feasible but is seldom undertaken because of biohazard and technologic concerns.

**TREATMENT**

The drug of choice for the treatment of both children and adults with RMSF is doxycycline, except when the patient is pregnant or allergic to the drug. Because of the severity of RMSF, immediate empirical administration of doxycycline should be strongly considered in any patient with a consistent clinical presentation in the appropriate epidemiologic setting. Doxycycline is administered orally (or, in the presence of coma or vomiting, intravenously) at 200 mg/d in two divided doses. Patients who are allergic to doxycycline or in whom this drug is contraindicated should receive chloramphenicol (50 to 75 mg/kg daily in four divided oral doses, for 7 days); the complete blood count should be monitored during chloramphenicol treatment. For children with suspected RMSF infection, up to five courses of doxycycline may be administered with minimal risk of dental staining. Other regimens include oral tetracycline (25 to 50 mg/kg per day) in four divided doses. The antirickettsial drug should be administered until the patient has been afebrile and improving clinically for 2 or 3 days. β-Lactam antibiotics, erythromycin, and aminoglycosides have no role in the treatment of RMSF, and sulfadContaining drugs are likely to exacerbate this infection. There is not enough clinical experience to comment on the use of such drugs in this setting. The most seriously ill patients are managed in intensive care units, with careful administration of fluids to achieve optimal tissue perfusion without precipitating non-

\(^a\) Not approved by the U.S. Food and Drug Administration.
\(^b\) Azithromycin is more effective than doxycycline in vitro against both doxycycline-susceptible and doxycycline-resistant strains of *O. tsutsugamushi*.

Prevention  Avoidance of tick bites is the only available preventive approach. Protective clothing and tick repellents, which could reduce the risk, are seldom actually used. After possible tick exposure, it is wise to inspect the body once or twice a day and remove ticks before they can inoculate rickettsiae.

**Mediterranean Spotted Fever (Boutonneuse Fever) and Other Tick-Borne Spotted Fevers**  The etiologic agent of Mediterranean spotted fever, *R. conorii*, is prevalent in southern Europe (below the 45th parallel), all of Africa, and southwestern and south-central Asia. The tick vector and reservoir is *R. sanguineus*, the brown dog tick. The name of this disease varies with the region in which it occurs; examples include Kenya tick typhus, Indian tick typhus, Israeli spotted fever, and Astrakhan spotted fever. Whatever the designation, the disease is characterized by a high fever, rash, and—in most geographic locales—an inoculation eschar (*tauche noire*) at the site of the tick bite. A severe form of the disease, associated with a 50% mortality rate, has been observed in patients with diabetes, alcoholism, or heart failure. African tick-bite fever, which is caused by *R. africae* and has been recognized since the beginning of the twentieth century, was first documented in the modern era in Zimbabwe in 1992. The disease occurs in rural areas and follows bites by ticks of cattle and wild animals. *R. africae* is prevalent in *Amblyomma hebraeum* and *A. variegatum* ticks, which readily feed on humans. Cases occur throughout sub-Saharan Africa and in the Caribbean islands. The average incubation period is 7 days (range, 4 to 10 days). The illness is mild and consists of headache, fever, eschar at the tick bite site, and regional lymphadenopathy. *Amblyomma* ticks often feed in groups, and several ticks may be found on one patient, with the subsequent development of multiple eschars. Rash is typically transient and may be vesicular. African tick-bite fever is the most prevalent rickettsiosis worldwide, and—because of tourism in sub-Saharan Africa—is the most frequently occurring imported rickettsiosis in Europe and North America.

**Rickettsia japonica** causes Japanese spotted fever. Patients present with fever, cutaneous eruption, and an inoculation eschar. A similar disease in northern Asia is caused by *R. sibirica*. In Australia, two spotted fevers have been described. *Queensland tick typhus* is due to *R. australis* and is transmitted by *Ixodes holocyclus*. The skin rash in this disease is usually maculopapular but is sometimes vesicular, and there is an inoculation eschar. *Flinders Island spotted fever*, observed also on nearby Tasmania, is due to *R. honei*. In Europe, patients infected with *R. slovaca* after a Dermacentor tick bite manifest an eschar and regional lymphadenopathy.

**Diagnosis**  The diagnosis of these tick-borne spotted fevers is based on clinical and epidemiologic findings and is confirmed by cell-culture isolation of rickettsiae, by PCR of skin biopsies (a method not available in most laboratories), or by serology. The serologic identification of infection with a specific species requires cross-absorption (Table 158-2). In an endemic area, patients presenting with fever, rash, and/or a skin lesion consisting of a black necrotic area or a crust surrounded by erythema should be considered to have one of these rickettsial spotted fevers.

**TREATMENT**  See Table 158-2.

**Rickettsialpox**  Rickettsialpox was first described in 1946 by a general practitioner in New York City and soon afterwards was shown to be caused by a distinct species, *R. akari*. This organism was isolated from mice and their mites (*Liponyssoides sanguineus*), which maintain the organisms by transovarian transmission. *R. akari* shares lipopolysaccharide antigens with other members of the SFG.
Clinical Manifestations  A papule forms at the site of the mite bite. This lesion develops a central vesicle that becomes a 1- to 2.5-cm painless black crusted eschar surrounded by an erythematous halo (Fig. 158-2). Enlargement of the lymph nodes draining the region of the eschar suggests initial lymphogenous spread. After an incubation period of 10 to 17 days, during which the eschar and regional lymphadenopathy frequently go unnoticed, the onset of illness is marked by malaise, chills, fever, headache, and myalgia. A macular rash appears 2 to 6 days after onset and evolves sequentially into papules, vesicles, and crusts that heal without scarring (Fig. 158-3). In some cases the rash remains macular or maculopapular. Some patients suffer nausea, vomiting, abdominal pain, cough, conjunctivitis, or photophobia. Untreated rickettsialpox is not fatal, with fever lasting 6 to 10 days.

Diagnosis and Treatment  See Table 158-2.

CAT FLEA-ASSOCIATED RICKETTSIOSIS  An emerging rickettsiosis caused by *R. felis* has been documented in North and South America and Europe. Transmitted and maintained transovarially in the geographically widespread cat flea *Ctenocephalides felis*, the infection has been described as moderately severe, with fever, rash, headache, and CNS and gastrointestinal signs. However, the clinical spectrum and frequency of the various clinical manifestations have yet to be determined.

FLEA- AND LOUSE-BORNE TYPHUS GROUP RICKETTSIOSES

ENDEMIC MURINE TYPHUS (FLEA-BORNE)  Murine typhus was postulated to be a distinct disease, with rats as the reservoir and fleas as the vector, by Maxcy in 1926. Dyer isolated the etiologic agent, *R. typhi*, from rats and fleas in 1931. By the end of World War II, murine typhus was known to be a global disease.

Epidemiology  *R. typhi* is maintained in mammalian host/flea cycles, with rats (*Rattus rattus* and *R. norvegicus*) and the Oriental rat flea (*Xenopsylla cheopis*) as the classic zoonotic niche. Fleas acquire *R. typhi* from rickettsemic rats and carry the organism throughout the rest of their life span. Nonimmune rats and humans are infected when rickettsia-laden flea feces are “scratched” into pruritic bite lesions; less frequently, the flea bite itself transmits the organisms. Yet another possible route of transmission is the inhalation of aerosolized flea feces. Infected rats appear healthy, although they are rickettsemic for 2 weeks.

Currently, <100 cases of endemic typhus are reported annually in the United States. These cases occur mainly in southern Texas and southern California, where the classic rat/flea cycle is absent and an opossum/cat flea (*C. felis*) cycle is prominent. Cases of endemic typhus occur year-round, mainly in warm (often coastal) areas. This infection has also been reported from Greece, Spain, and Indonesia. The prevalence peaks from April through June in southern Texas and during the warm months of summer and early fall in other geographic locations. Patients seldom recall a flea bite or exposure to fleas, although exposure to animals such as cats, opossums, raccoons, skunks, and rats is reported by nearly 40% of those who are questioned.

Clinical Manifestations  The incubation period of experimental murine typhus in volunteers averages 11 days, with a range of 8 to 16 days. Close observation during this period reveals prodromal symptoms of headache, myalgia, arthralgia, nausea, and malaise developing 1 to 3 days before the abrupt onset of chills and fever. Nearly all patients experience nausea and vomiting early in the illness.

The duration of untreated illness averages 12 days, with a range of 9 to 18 days. Rash is present in only 13% of patients at the time of presentation for medical care (usually ~4 days after onset of symptoms), appearing an average of 2 days later in half of the remaining patients and never appearing in the other half. The initial macular rash is often detected by careful inspection of the axilla or the inner surface of the arm. Subsequently, the rash becomes maculopapular, involving the trunk more often than the extremities; it is seldom petechial and rarely involves the face, palms, or soles. A rash is detected in only 20% of patients with dark brown or black skin.

Pulmonary involvement is frequently prominent in murine typhus; 35% of patients have a hacking, nonproductive cough, and 23% of patients who undergo chest radiography have pulmonary densities due to interstitial pneumonia, pulmonary edema, and pleural effusions. Biharial rales are the most common pulmonary sign. Less common clinical symptoms and signs include abdominal pain, confusion, stupor, seizures, ataxia, coma, and jaundice. Clinical laboratory studies fre-
Epidemic typhus due to infection with *R. prowazekii* is transmitted by the human body louse (*Pediculus humanus corporis*), which lives on clothes and is found in poor hygienic conditions (especially in jails, where the disease causes is called *jail fever*) and usually in cold areas. Lice acquire *R. prowazekii* when they ingest a blood meal from a rickettsemic patient. The rickettsiae multiply in the midgut epithelial cells of the louse and spill over into the louse feces. The infected louse defecates during its blood meal, and the patient autoinoculates the organisms by scratching. The fact that the louse abandons dead hosts and patients with high fever (>40°C) improves its efficiency as a vector. Since the louse does not pass *R. prowazekii* to its offspring, the disease is usually spread from person to person by the louse-borne route. Lice die within 1 to 2 weeks after infection, turning red because of intestinal perforation just prior to death—hence the name *red louse disease*. This epidemic form of typhus is related to poverty, cold weather, war, and disasters and is currently prevalent in mountainous areas of Africa, South America, and Asia. A large outbreak involving 100,000 people in refugee camps in Burundi occurred in 1997, a small focus was reported in Russia in 1998, sporadic cases have been reported from Algeria, and annual outbreaks have occurred in Peru. The global reemergence of the disease is due to proliferation of body lice. In the United States, sporadic cases of epidemic typhus are transmitted by flying-squirrel fleas. Eastern flying-squirrel (*Glaucomys volans*) lice and fleas have been found to be infected with *R. prowazekii*. The flying-squirrel fleas occasionally bite humans.

Brill-Zinsser disease is a recrudescent, mild form of epidemic typhus occurring years after the acute disease, probably as a result of immunosuppression or old age. Nathan Brill first identified recrudescent typhus in New York in 1898. In 1933 Hans Zinsser noted that >90% of patients with recrudescent typhus had emigrated from typhus-endemic areas of Europe. Strains of *R. prowazekii* indistinguishable from classic strains were isolated from patients with recrudescent typhus. Furthermore, *R. prowazekii* was isolated from the lymph nodes of patients undergoing elective surgery who had had typhus years earlier. Thus the typhus rickettsiae can remain dormant for years and can reactivate with waning immunity.

Rickettsiae, particularly *R. prowazekii*, are potential agents of bioterrorism (Chap. 205). *R. prowazekii* and *R. rickettsii* have a high case-fatality ratio, cause diseases that are difficult to diagnose, and can be engineered to display complete antimicrobial resistance. A strain of tetracycline-resistant *R. prowazekii* was developed in the former Soviet Union. *R. prowazekii* and *R. typhi* have dormant forms that survive extracellularly for long periods, and all rickettsiae are highly infectious when inhaled as aerosols.

**Clinical Manifestations** After an incubation period of ~1 week (range, 7 to 14 days), the onset of illness is abrupt, with prostration, severe headache, and fever rising rapidly to 38.8°C to 40.0°C (102°F to 104°F). Cough is frequently prominent, occurring in 70% of patients. Myalgias are usually severe. In the outbreak in Burundi, the disease was referred to as *sutama* (“crouching”), the myalgias being so severe that patients crouched in an attempt to alleviate the pain. A rash begins on the upper trunk, usually on the fifth day, and then becomes generalized, involving all of the body except the face, palms, and soles. Initially, this rash is macular; without treatment, it becomes maculopapular, petechial, and confluent. The rash is frequently absent or not detected on black skin in Africa, where 60% of patients have *spotted epidemic typhus*. Photophobia, with considerable conjunctival injection and eye pain, is frequent. The tongue may be dry, brown, and furred. Confusion and coma are common. Skin necrosis and gangrene of the digits as well as interstitial pneumonia have been noted in severe cases. Untreated disease is fatal in 7 to 40% of cases, with outcome depending primarily on the condition of the host. Patients with untreated infections develop renal insufficiency and multiorgan involvement in which neurologic manifestations are frequently prominent. Overall, 12% of patients with *epidemic typhus* have neurologic involvement. Nonetheless, *vaccinal typhus* infection transmitted by flying-squirrel ectoparasites is a milder illness; whether this milder disease is due to host factors (e.g., better health status) or organism factors (e.g., attenuated virulence) is unknown.

**Diagnosis and Treatment** See Table 158-2. Epidemic typhus is sometimes misdiagnosed as typhoid fever in tropical countries (Chap. 137).

**Prevention** Prevention of epidemic typhus involves control of body lice. Clothes should be changed regularly, and insecticides should be used every 6 weeks to control the louse population.

**Scrub typhus**

The etiologic agent of scrub typhus is a small, obligately intracellular bacterium of the family Rickettsiaceae that differs substantially from other family members in its genetic makeup and in the composition of its cell wall (which, for example, lacks lipopolysaccharide and peptidoglycan). Consequently, this organism has been classified as a species in a separate genus, *Orientia tsutsugamushi*. *O. tsutsugamushi* is maintained in nature by transovarian transmission in trombiculid mites, mainly of the genus *Leptotrombidium*. After hatching, infected larval mites (chiggers, the only stage that feeds on an animal host) inoculate organisms into the skin while feeding. Scrub typhus is found in environments that harbor the infected chiggers, particularly areas of heavy scrub vegetation—e.g., where the forest is regrowing after being cleared and along riverbanks. Infections occur during the wet season, when the mites lay their eggs. The disease is endemic in eastern and southern Asia, northern Australia, and islands of the western Pacific Ocean. Scrub typhus is also found in tropical areas of India, Sri Lanka, Bangladesh, Myanmar, Thailand, Malaysia, Laos, Vietnam, Kampuchea, China, Taiwan, the Philippines, Indonesia, Papua New Guinea, northern Australia, and islands of the South Pacific Ocean; in temperate areas of Japan, Korea, far-eastern Russia, Tadzhikistan, the mountains of northern India, Pakistan, and Nepal; and in nontropical areas of China, such as Tibet and Shangdong Province. Those infected include indigenous rural workers, residents of suburban areas, and westerners visiting endemic areas for professional or recreational purposes. Infections are more prevalent than the number of clinical diagnoses would suggest; in some areas >3% of the population is infected or reinfected each month. Immunity wanes over 1 to 3 years, and there is remarkable antigenic diversity.

**Clinical Manifestations** The illness varies in severity from mild and self-limiting to fatal. After an incubation period of 6 to 21 days (usually 8 to 10 days), the onset of disease is characterized by fever, headache, myalgia, cough, and gastrointestinal symptoms. Some patients develop no further signs or symptoms and recover spontaneously after a few days. The classic case description includes an eschar at the site of chigger feeding, regional lymphadenopathy, and a maculopapular rash—signs that are seldom observed in indigenous patients. Fewer than 50% of Westerners develop an eschar, and <40% develop a rash (on day 4 to 6 of illness). Severe cases typically include prominent meningeal and interstitial pneumonia as key features of vascular injury. Severe illness in persons with G6PD deficiency has been accompanied by hemolysis. The case-fatality rate for untreated classic cases
Ehrlichiae and Anaplasmosis

Ehrlichiae are small, obligately intracellular bacteria with a gram-negative-type cell wall that grow in cytoplasmic vacuoles to form clusters called morulae (Fig. 158-4). Two distinct Ehrlichia species and one Anaplasma species cause human infections that can be severe and frequent (Table 158-3). E. chaffeensis, the agent of human monocytotropic ehrlichiosis (HME), infects predominantly mononuclear phagocytic cells in tissues and blood monocytes. E. ewingii and A. phagocytophila infect cells of myeloid lineage, particularly neutrophils. Confusion may arise from the fact that Anaplasma phagocytophila is the agent of the disease originally designated human granulocytotropic ehrlichiosis (HGE) and Ehrlichia ewingii is a human granulocytotropic pathogen. Such confusion can be avoided through use of the terms human anaplasmosis and ehrlichiosis ewingii, with avoidance of the ambiguous HGE. Both E. chaffeensis and E. ewingii are transmitted mainly by the Lone Star tick Amblyomma americanum and cause persistent infections in the same reservoir, the white-tailed deer. A. phagocytophila is transmitted, with little geographic overlap, by Ixodes scapularis in the northeastern and upper midwestern states and by I. ricinus in Europe. In California, both HME and A. phagocytophila infection have been documented, with apparent partial overlap of their vectors. In Eurasia, reports of human infection caused by an I. persulcatus—transmitted E. muris—like agent and of A. phagocytophila associated with I. persulcatus are beginning to appear. The worldwide prevalence of ehrlichioses and anaplasmoses is an important issue in the field of emerging infectious diseases.

Ehrlichiae were discovered by veterinarians during the investigation of hemolytic anemia of cattle before 1910. Researchers thereafter discerned that “marginal points” visible within erythrocytes were infectious and named the agent Anaplasma marginale. Subsequently, several other species generally considered to be ehrlichiae were detected as veterinary infectious agents, including E. ruminantium, E. canis, E. ewingii, A. phagocytophila, and Neorickettsia risticii.

The current taxonomic positions are determined by nucleic acid sequences of conserved and unique genes among these species. By analysis of 16S ribosomal RNA and other sequences, the family Anaplasmataceae can be divided into four genera: Ehrlichia, Anaplasma, Wolbachia, and Neorickettsia. Given the lack of transovarian transmission in ticks, the natural maintenance of the tick-borne ehrlichiae and anaplasmas clearly depends in part on prolonged or persistent infections in wild and feral mammalian reservoirs. Thus, Ehrlichia and Anaplasma are propagated by horizontal transmission that relies on a tick-mammal-tick cycle; humans are inadvertently infected when they impinge on the natural habitats occupied by the ticks and the reservoir hosts. Wolbachia are associated with human diseases caused by filariae, with symbiosis in some instances. The wolbachiae are important for filarial viability and pathogenicity. Treatment of wolbachia is now a strategy in the control of filariasis. Neorickettsiae parasitize flukes that in turn are parasites of aquatic snails, fish, and insects. Although only one single human neorickettsiosis, sennets fever, has been described, others may be discovered. Probably in association with the ingestion of raw fish containing N. senettii—infected flukes, patients develop an infectious mononucleosis–like illness that was first identified in 1953.

HUMAN MONOCYTOTROPIC EHRLICHIOSIS | Epidemiology

More than 1363 cases of infections caused by E. chaffeensis had been reported to the Centers for Disease Control and Prevention (CDC) as of September 2002. However, since HME is not a reportable disease in most states, this figure is a gross underestimate. Most E. chaffeensis infections have been identified in the south-central, southeastern, and mid-Atlantic states, but cases have also been recognized in California. The vector is the Lone Star tick (A. americanum), which in all its life stages feeds on white-tailed deer—a major reservoir host. Dogs and coyotes have been discovered to be subclinically infected and may also be an important reservoir. Tick bites and exposures are reported by patients, frequently in rural areas and especially in the months May through July. The median age of HME patients is 44 years, and 75% of the affected individuals are male; however, severe and fatal infections in children are also well recognized. Active prospective surveillance has revealed that in rural areas inhabited by abundant deer and Lone Star ticks, HME is a common disease, with an incidence as high as 1000 cases per 1 million population.

Note: IFA, indirect immunofluorescence assay.
Clinical Manifestations  
*E. chaffeensis* is inoculated into the dermal blood pool created by the feeding tick and subsequently disseminates via the blood to tissues. After a median incubation period of 8 days, illness develops. The classic clinical manifestations are not specific and include fever (97% of cases), headache (81%), myalgia (68%), and malaise (84%); less frequently observed are gastrointestinal involvement (nausea, vomiting, diarrhea; 25 to 68%), cough (25%), rash (36% overall, 6% at presentation), and confusion (20%). HME may be severe: 62% of patients with documented cases are hospitalized, and ~3% die. Severe complications include a toxic shock–like or septic shock–like syndrome, respiratory insufficiency and adult respiratory distress, meningoencephalitis, fulminant infection (in immunocompromised patients), severe opportunistic and nosocomial infections, and hemorrhage. Laboratory findings may be of value in the differential diagnosis: 60 to 74% of patients with HME have leukopenia (initially lymphopenia, later neutropenia), 72% have thrombocytopenia, and nearly 90% have elevations in serum levels of hepatic aminotransferases. With effective therapy, rebound lymphocytosis (mainly γ/δ T cells) is common. In spite of abnormal blood counts, examinations reveal hypercellular bone marrow, and noncaseating granulomas may be present. Vasculitis is not a component of HME.

Diagnosis  
Because HME can be fatal, empirical antibiotic therapy should be instituted on the basis of a clinical diagnosis. This diagnosis may be suggested by fever in the setting of known tick exposure during the preceding 3 weeks, leukopenia and/or thrombocytopenia, and in-creased aminotransferase concentrations in serum. Morulae may be suggested by fever in the setting of known tick exposure during

E. ewingii  
*Ehrlichia ewingii* is a neutrophil pathogen that causes febrile lameness in dogs, resembles HME in many respects, including its tick vector (*A. americanum*) and its vertebrate hosts (white-tailed deer and dogs). The illness caused by *E. ewingii* is similar to HME but is somewhat less severe. The majority of cases have been diagnosed in immunocompromised patients.

**TREATMENT**

Tetracycline is effective therapy for HME or *ehrlichiosis ewingii*. Either tetracycline (250 to 500 mg given orally every 6 h) or doxycycline (100 mg given orally or intravenously twice daily) is associated with a lower rate of hospitalization and a shortened duration of fever. The use of chloramphenicol is controversial, and *E. chaffeensis* is not susceptible to this drug in vitro. While a few reports document the persistence of *E. chaffeensis* in patients after the acute phase of illness, such persistence is very infrequent; most infections are cured by relatively short courses of tetracycline therapy (continuing for 3 to 5 days after defervescence).

Prevention  
HME and *ehrlichiosis ewingii* are prevented by the avoidance of ticks in endemic areas. The use of protective clothing and tick repellents, careful tick searches after exposures, and prompt removal of attached ticks are practices that markedly diminish risk.

HUMAN ANAPLASMOSIS  
**Epidemiology**  
As of 2002, 1278 cases of HGE had been reported to the CDC, most of them from upper midwestern and northeastern states; the distribution of cases was similar to that for Lyme disease. Most cases were identified within the range of various *I. persulcatus*—complex ticks, particularly *I. scapularis*. White-footed deer mice and white-tailed deer in the United States as well as red deer in Europe appear to play a role in maintaining HGE in nature. The incidence of HGE peaks in May, June, and July, but the disease may occur throughout the year in conjunction with human exposure to *Ixodes* ticks. HGE affects predominantly males (79%) and older persons (median age, 58 years).

Clinical Manifestations  
Because of high seroprevalence rates in endemic regions, it seems likely that only a minority of infected individuals develop clinical manifestations. The incubation period for HGE varies between 4 and 8 days, and the disease manifests as fever (94 to 100% of cases), myalgia (78 to 98%), headache (61 to 85%), and malaise (98%)—findings suggestive of an influenza-like illness. A minority of patients develop gastrointestinal involvement, including nausea, vomiting, or diarrhea (22 to 39%); rash (2 to 11%); cough (27%); and confusion (17%). Severe complications occur most often in the elderly, but even children may be severely affected. Respiratory insufficiency, with adult respiratory distress syndrome, a toxic shock–like syndrome, and life-threatening opportunistic infections, are the most worrisome complications. Meningoencephalitis has not yet been conclusively recognized with HGE. The case-fatality rate is probably <1%, but nearly 7% of ill patients may require intensive care. As in HME, laboratory findings are of great assistance; most patients develop leukopenia and/or thrombocytopenia with increased serum levels of hepatic aminotransferases. The pancytopenia observed in HGE presumably relates to sequestration or destruction of platelets and leukocytes, since the bone marrow is ordinarily normo- or hypercellular. Vasculitis is not a component of HGE. Unlike HME, HGE is not associated with granulomas. While clear evidence exists for co-infections with *Borrelia burgdorferi* and *Babesia microti*, which are transmitted by the same tick vector(s), there is little evidence of comorbidity or of a persistent or chronic phase for HGE.

Diagnosis  
HGE should be included in the differential diagnosis for patients who have been exposed to ticks and who develop an influenza-like illness during the season of *Ixodes* tick activity (May through December). The concurrent detection of thrombocytopenia, leukopenia, and/or elevations in serum aminotransferase activities further increases the likelihood of HGE. A substantial proportion of patients with HGE develop serologic reactions considered diagnostic of Lyme disease in the absence of clear clinical findings consistent with that diagnosis. Thus, HGE should be considered in the differential diagnosis of atypical severe presentations of Lyme disease. Although not highly sensitive, a thorough peripheral blood film examination for morulae in neutrophils may identify 20 to 75% of infections. PCR testing of EDTA-anticoagulated blood collected before the initiation of tetracycline therapy from patients with active disease is a sensitive and specific method for early confirmation. Serodiagnosis is based mostly upon the retrospective demonstration of a fourfold increase in *A. phagocytophilum* group antibody titer to a minimum of 1:80 in paired serum samples obtained ~1 month apart. IgM antibodies may be detected in many patients within the first 1.5 months after illness. Approximately 15 to 40% of infected persons have a detectable antibody titer at presentation, but, in regions where seroprevalence is high, a single acute-phase polyvalent titer may be misleading.

**TREATMENT**

Doxycycline (100 mg by mouth twice daily) is an effective therapeutic agent, while rifampin has been associated with clinical improvement in pregnant patients with HGE. No prospective studies of any therapy for HGE have been conducted. Most treated patients defervesce within 24 to 48 h.

Prevention  
Prevention of HGE requires tick avoidance. The Lyme disease vaccine offers no protection against HGE, and no other vaccine is available.
Q Fever

Q fever results from infection with C. burnetii. This small gram-negative microorganism (0.2 μm by 0.7 μm) exists in two antigenic forms: phase I and phase II. When C. burnetii is passaged in cell cultures or embryonated eggs, its lipopolysaccharide undergoes truncation that results in an antigenic change called phase variation. The phase I form is extremely infectious and exists in humans and other animals. Passage in cell culture or embryonated eggs results in a shift to the phase II form, which is avirulent. The ability of C. burnetii to form spores allows the organism to survive in harsh environments. Indeed, it can survive for >40 months in skim milk at room temperature and is readily recovered from soil up to 1 month after contamination. Three different plasminoids have been described in various isolates of C. burnetii. Q fever encompasses two broad clinical syndromes: acute and chronic infection. It is likely that the host’s immune response (rather than characteristics of the infecting strain) determines whether or not chronic Q fever develops. Attachment of the virulent form (phase I) of C. burnetii to monocytes requires α, β, integrin only, whereas attachment of the avirulent form (phase II) requires both α, β, and CR3 integrins. The transendothelial migration of monocytes infected by virulent C. burnetii is impaired, while that of monocytes infected by the avirulent form is not. Production of tumor necrosis factor (TNF) by monocytes is initiated by virulent C. burnetii through a mechanism involving both α, β, integrin and interaction with bacterial lipopolysaccharide. C. burnetii survives in monocytes from patients with chronic Q fever but not in monocytes from patients with acute Q fever or from seronegative control subjects. Impairment of the bactericidal activity of the C. burnetii–infected monocyte seems to be due to dysregulation of the cytokine network, as TNF in monocyte supernatants from these patients depresses the microbicidal activity of monocytes. The soluble TNF receptor TNFR75 is upregulated in monocytes from patients with chronic Q fever. This upregulation is due to overproduction of interleukin 10, antibodies to which restore the microbicidal activity of these monocytes in vitro. The CD4+/CD8+ ratio is decreased in patients with Q fever endocarditis. All of the above findings translate into the observations that very few organisms and a strong cellular response are seen in patients with acute Q fever, while many organisms and a moderate cellular response are seen in patients with chronic Q fever.

Epidemiology

Q fever is a zoonosis. The primary sources of human infection are infected cattle, sheep, and goats. However, infected cats, rabbits, pigeons, and dogs have also been shown to transmit C. burnetii to humans. The extensive wildlife reservoir for C. burnetii includes mammals, birds, and ticks. In the infected female mammal, C. burnetii localizes to the uterus and the mammary glands. Infection is reactivated during pregnancy, and high concentrations of C. burnetii are found in the placenta. At parturition, C. burnetii is dispersed as an aerosol, and infection follows inhalation of aerosolized organisms by a susceptible host. Soil is contaminated during parturition, and C. burnetii aerosols can be generated weeks to months later during wind storms. Individuals up to 18 km from the source may be infected. Infected female animals shed the organism in milk for weeks to months after parturition. In rare instances, human-to-human transmission has followed delivery of an infant to an infected woman or autopsy on an infected individual. C. burnetii has been transmitted via blood transfusion. Persons who are at risk for Q fever include abattoir workers, veterinarians, and other individuals who have occupational or avocational contact with infected animals. Exposure to infected newborn animals or to infected products of conception poses the highest risk. Sexual transmission has been demonstrated experimentally in mice, as has transmission during artificial insemination in cattle. Some evidence suggests that C. burnetii can be sexually transmitted among humans. The ingestion of contaminated milk in some areas probably represents a major route of transmission to humans, although the experimental evidence on this point is contradictory. In any event, the vast majority of Q fever cases result from inhalation of contaminated aerosols. Q fever in children is uncommon, accounting for only 1 to 2% of cases.

Infections due to C. burnetii occur in most countries. Indeed, the only areas known to be free of C. burnetii are New Zealand and Antarctica. The primary manifestation of acute Q fever differs from place to place. For example, the primary manifestation is pneumonia in Nova Scotia (Canada), granulomatous hepatitis in Marseille (France), and both of these conditions in the Basque region of Spain. These differences may reflect the route of infection; i.e., the ingestion of contaminated milk may result in hepatitis and the inhalation of contaminated aerosols in pneumonia.

In New South Wales, Australia, 2351 cases of Q fever were reported in 1991 to 2000, and the number of cases per 100,000 persons varied from 6.7 in 1996 to 1.8 in 2000. Males accounted for 84% of the cases and children for 1.5%. In Australia each year, Q fever costs the meat industry almost $1 million and >1700 weeks of time lost from work.

Clinical Manifestations

ACUTE Q FEVER

The incubation period for acute Q fever ranges from 3 to 30 days. The clinical presentations include flulike syndromes, prolonged fever, pneumonia, hepatitis, pericarditis, myocarditis, meningocerebralitis, and infection during pregnancy. A study of 1383 cases of Q fever from southern France gives an indication of the spectrum of the clinical manifestations of Q fever. Among the 1070 patients with acute Q fever, 40% had hepatitis, 20% had both pneumonia and hepatitis, 17% had pneumonia, 14% had isolated fever, 2% had central nervous system involvement, 1% had pericarditis, and 1% had myocarditis; in 3% of patients, the clinical presentation was not defined.

The symptoms of acute Q fever are nonspecific; common among them are fever, extreme fatigue, and severe headache. Other symptoms include chills, sweats, nausea, vomiting, and diarrhea, which occur in 5 to 20% of patients. Cough develops in about half of patients with Q fever pneumonia. Neurologic manifestations of acute Q fever are uncommon; however, in one outbreak in the West Midlands, United Kingdom, 23% of 102 patients had neurologic signs and symptoms as the major manifestation. A nonspecific rash may be evident in 4 to 18% of patients. The white blood cell count is usually normal. Thrombocytopenia is detected in ~25% of patients, and reactive thrombocytosis [with platelet counts of up to 1 million/μL (1 × 10^12/L)] frequently develops during recovery. This thrombocytosis may account for cases of deep vein thrombophlebitis complicating acute Q fever in some series. Uncommon manifestations of acute Q fever include optic neuritis, extrapyramidal neurologic disease, Guillain-Barré syndrome, inappropriate secretion of antidiuretic hormone, epididymitis, orchitis, priapism, hemolytic anemia, hemolytic-uremic syndrome, mediastinal lymphadenopathy mimicking lymphoma, spontaneous rupture of the spleen, pancreatitis, erythema nodosum, and mesenteric panniculitis. Chest radiography may show an opacity that is indistinguishable from that seen in pneumonia of other etiologies. Multiple rounded opacities are commonly observed, and right-sided endocarditis resulting in septic pulmonary embolism can produce the same radiographic appearance.

Up to 70% of the uncommon cases of Q fever in children are asymptomatic. Symptomatic cases in children result in a spectrum of disease similar to that in adults, although only a few cases of Q fever endocarditis in children have been reported.

In Australia and the United Kingdom, a prolonged fatigue state (lasting 5 to 10 years) has followed Q fever in some cases. Low levels of C. burnetii DNA have been noted in the affected patients 0.75 to 5 years after infection.

CHRONIC Q FEVER

Chronic Q fever, which is uncommon, almost always implies endocarditis. This infection usually occurs in patients with previous valvular heart disease, immunosuppression, or chronic renal
insufficiency. Fever is usually absent or low grade. Patients may have nonspecific symptoms for up to 1 year before diagnosis. Valvular vegetations have been seen in only 12% of patients with transthoracic echocardiograms, but the rate of detection may be higher with the use of transesophageal echocardiography. The vegetations in chronic Q fever endocarditis are different from those in bacterial endocarditis, manifesting as nodules on the valve. A high index of suspicion is necessary for a correct diagnosis. The disease should be suspected in all patients with culture-negative endocarditis. In addition, all patients with valvular heart disease and an unexplained purpuric eruption, renal insufficiency, stroke, and/or progressive heart failure should be tested for C. burnetii infection. Patients with chronic Q fever have hepatomegaly and/or splenomegaly. These two findings, especially in combination with positive rheumatoid factor, high erythrocyte sedimentation rate, high C-reactive protein level, and/or increased γ-globulin concentrations (up to 60 to 70 g/L), suggest this diagnosis. Other manifestations of chronic Q fever include infection of vascular prostheses, aneurysms, and bone and as well as chronic sternal wound infection.

**Diagnosis**

C. burnetii can be isolated from buffy-coat blood samples or tissue specimens by a shell-vial technique; however, most laboratories considered highly infectious. PCR can be used to amplify C. burnetii.

**FURTHER READING**

**MECHANISMS OF PATHOGENICITY**

Adherence of mycoplasmas to the surface of the host cell is necessary for colonization and infection. Some pathogenic mycoplasmas are flask-shaped, with specialized tips that enhance adherence. M. pneumoniae adheres via a network of interactive adhesins and accessory proteins and produces hydrogen peroxide, which may cause injury to host cells. M. hominis metabolizes arginine, with the production of potentially cytotoxic amounts of ammonia. Ureaplasmas have been placed in a separate genus because of their unique urease activity; the metabolism of urea also produces ammonia. M. pneumoniae may evoke IgM autoantibodies that agglutinate human erythrocytes at 4°C. These cold agglutinins can cause anemia and other complications.

**INFECTIONS DUE TO MYCOPLASMAS**

William M. McCormack

Mycoplasmas, the smallest free-living organisms known, are prokaryotes that are bounded only by a plasma membrane. Their lack of a cell wall is associated with cellular pleomorphism and resistance to cell wall–active antimicrobial agents, such as penicillins and cephalosporins. The organisms’ small genome limits biosynthesis and explains the difficulties encountered with in vitro cultivation. Mycoplasmas typically colonize mucosal surfaces of the respiratory and urogenital tracts of many animal species. Sixteen species of mycoplasmas have been recovered from humans. Most are commensals. Mycoplasma pneumoniae causes upper and lower respiratory tract infections. M. genitalium and Ureaplasma urealyticum are established causes of urethritis and have been implicated in other genital conditions. M. hominis and U. urealyticum are part of the complex microbial flora of bacterial vaginosis (Chap. 115).

**Prevention**

A vaccine has been shown to be effective in preventing Q fever in abattoir workers in Australia.
pneumonic infection is considerably more common. In very young children, most infections result only in upper respiratory symptoms, whereas children >5 years of age and adults may have bronchitis and pneumonia.

**CLINICAL PRESENTATION** After a prolonged incubation period, fever and constitutional symptoms develop along with headache and cough, both of which can be prominent and distressing. Symptoms typically progress less rapidly than those of viral respiratory tract infections. In the minority (perhaps 5 to 10%) of infected individuals who develop tracheobronchitis or pneumonia, cough becomes more prominent. Sputum, if produced at all, is usually white and may be tinged with blood. The temperature seldom rises above 38.9° to 39.4°C (102° to 103°F). Shaking chills, myalgias, and gastrointestinal symptoms (e.g., nausea, vomiting, and diarrhea) are unusual. Chest muscle soreness may result from frequent and prolonged coughing, but true pleuritic pain is uncommon.

Pharyngeal injection is often noted. Cervical lymph node enlargement is unusual. Ear pain due to bulloous myringitis (blisters on the tympanic membrane) is a unique but uncommon manifestation. As in other “atypical” pneumonias, findings on auscultation of the lung may be normal or nearly normal despite striking radiographic abnormalities. Pleural effusions develop in fewer than 20% of patients. M. pneumoniae infection may be particularly severe in patients who have sickle cell disease and other hemoglobin S-related hemoglobinopathies. The functional asplenia seen in sickle cell disease may contribute to severe mycoplasmal disease as it does in pneumococcal infection. Severe respiratory distress and large pleural effusions may occur.

**EXTRAPULMONARY MANIFESTATIONS** A broad array of extrapulmonary abnormalities have been associated with M. pneumoniae infection. Although these events are unusual, they complicate other respiratory diseases even more rarely and often provide the only clue that an otherwise-unremarkable respiratory infection may be mycoplasmal.

Erythema multiforme (Stevens-Johnson syndrome; see Fig. 46-9) typically occurs in young male patients with M. pneumoniae infection. Other dermatologic manifestations, such as maculopapular and vesicular exanthesms, erythema nodosum, and urticaria, have been reported, but none is as clearly linked to M. pneumoniae as is erythema multiforme. Digital necrosis has been seen in patients with sickle cell disease who develop very high titers of cold agglutinins.

Cardiac abnormalities reported in conjunction with M. pneumoniae infection include myocarditis and pericarditis, which may result in abnormalities of conduction. Of the wide variety of neurologic conditions associated with M. pneumoniae, most have been documented in case reports, where establishment of a cause-and-effect relationship is problematic. Central nervous system abnormalities that have been associated with M. pneumoniae include encephalitis, cerebellar ataxia, Guillain-Barré syndrome, transverse myelitis, and peripheral neuropathies. Arthralgias are not unusual in patients who have mycoplasmal pneumonia; mycoplasmal arthritis is rare except in patients who have hypogammaglobulinemia. Hematologic abnormalities associated with M. pneumoniae include hemolytic anemia and coagulopathies.

The pathogenesis of the extrapulmonary manifestations of M. pneumoniae infection is controversial. Occasional reports have described the identification of M. pneumoniae or its nucleic acids in involved tissues. The fact that most attempts at detection have yielded negative results, however, suggests that these extrapulmonary complications have an immunologic basis. Mycoplasmas, including M. pneumoniae, can nonspecifically stimulate B lymphocytes. M. pneumoniae–infected individuals can develop autoantibodies, including those reactive with brain, heart, and muscle.

**DIAGNOSIS** Most infections with M. pneumoniae are not diagnosed, as they are indistinguishable from upper and lower respiratory tract infections caused by myriad other viral and bacterial pathogens. When the diagnosis is suspected, it is usually because illness is prolonged or extrapulmonary manifestations develop. The white blood cell count is generally somewhat elevated, with few immature cells. Gram’s stain of sputum shows leukocytes without a predominance of any bacterial morphologic type. Since M. pneumoniae lacks a cell wall, it cannot be detected on Gram’s stain. In patients who have pneumonia, the chest radiograph may show reticulonodular or interstitial infiltration, primarily in the lower lobes. As in other “atypical” pneumonias, radiographic abnormalities may be more prominent than would be predicted by auscultation of the chest.

M. pneumoniae can be grown on artificial media, but the process is exacting, requires special media, and takes upwards of 2 weeks. Thus, mycoplasmal cultures do not provide timely information to aid in patient management. The same, unfortunately, is true of serologic diagnosis. Specific antibodies can be detected by enzyme-linked immunosassays, indirect immunofluorescence, or complement fixation but do not develop early enough to guide decisions regarding treatment.

As with most serologic tests, examination of paired acute- and convalescent-phase serum specimens is required for good sensitivity and specificity.

Cold agglutinins are nonspecific but develop within the first 7 to 10 days in more than half of patients with M. pneumoniae pneumonia and may be detectable when the patient presents to a health care provider. In a patient with a compatible clinical picture, a cold agglutinin titer of ≥1:32 supports the diagnosis of mycoplasmal pneumonia. Cold agglutinin determinations are readily available from diagnostic laboratories. The test can also be performed at the bedside by the addition of 1 mL of the patient’s blood to a tube containing anticoagulant (e.g., a tube used to collect blood for determination of prothrombin activity). Before cooling, the nonaggregated red blood cells coat the sides of the inverted tube. The blood is cooled to 4°C when the tube is placed in an ice bath for 3 to 5 min or in a standard refrigerator. In a positive test, clumps of red blood cells can be observed when the tube is inverted. Rewarming of the sample to 37°C in an incubator or by exposure to body heat should reverse the agglutination. A positive “bedside” cold agglutinin test is equivalent to a laboratory titer of ≥1:64.

The lack of sensitive, specific, and timely diagnostic tests has prompted the development of a variety of antigen detection tests that do not involve serology or the cultivation of live organisms. Such tests include antigen capture, indirect enzyme immunoassays, DNA probing, and nucleic acid amplification. Since many viral and bacterial infections result in clinical presentations similar to that caused by M. pneumoniae, examination of specimens for single antigens is unlikely to be useful. Rather, tests that examine an individual specimen for multiple antigens are needed. Multiplex nucleic acid amplification tests that examine a single throat swab or sputum sample for all of the most likely causative microorganisms are feasible with current technology. Prototype multiplex polymerase chain reaction (PCR) assays have already been developed. If such tests become available clinically, more precise etiologic diagnosis of upper and lower respiratory tract infections will be possible.

**TREATMENT**

Pneumonia due to M. pneumoniae is usually self-limited and is seldom life-threatening. Effective antimicrobial agents do shorten the duration of illness and, by reducing coughing, may conceivably render the patient less infectious. Although symptoms are alleviated by antimicrobial treatment, the organism usually is not eradicated. Cultures positive for M. pneumoniae may persist for months despite clinically effective antimicrobial therapy. The beneficial effects, if any, of such treatment on extrapulmonary manifestations of M. pneumoniae infection are unknown.

Because most mycoplasmal infections are not specifically diagnosed, management is directed at one of two syndromes: upper respiratory tract infection or community-acquired pneumonia. Upper respiratory infections, whether caused by viruses or by M. pneumoniae, do not require antimicrobial treatment. Community-acquired
pneumonia (Chap. 239) may be caused by bacteria such as Streptococcus pneumoniae and Haemophilus influenzae or by “atypical” agents such as Chlamydia pneumoniae, Legionella pneumophila, and M. pneumonietae. Recommended treatment regimens are detailed in Tables 159-1 and 159-2. Treatment of documented M. pneumonietae pneumonia is usually continued for 14 to 21 days.

GENITAL MYCOPLASMAS (See also Chap. 115)

EPIDEMIOLOGY M. hominis and U. urealyticum are the most prevalent genital mycoplasmas. Infants may become colonized with one or both of these organisms during passage through a colonized birth canal. Neonatal colonization tends not to persist. Only ~10% of prepubertal girls and even fewer prepubertal boys are colonized with ureaplasmas. After puberty, colonization occurs mainly as a result of sexual activity. Among adults, disadvantaged populations have higher colonization rates. Ureaplasmas can be cultured from the vaginas of ~80% of women cared for in public clinics and about half of women cared for by private obstetricians and gynecologists. Similarly, vaginal M. hominis is found in ~50% of women attending public clinics and in ~20% of private patients. Men have somewhat lower rates of genital colonization than women. In short, both U. urealyticum and M. hominis are frequently detected in genital specimens from healthy, sexually experienced adults. Evaluation of the role of these organisms in human disease must take into account their high prevalence among healthy people.

M. fermentans colonizes both the respiratory and genital tracts in more than 20% of adults. There is no convincing evidence that M. fermentans causes human disease; although it had been implicated as a possible determinant of HIV-1 disease progression, more recent data do not support such a role. M. genitalium is a fastidious organism that is difficult to cultivate. PCR studies have identified the organism more successfully. Little is known about the epidemiology of M. genitalium.

ASSOCIATION WITH HUMAN DISEASE Nongonococcal Urethritis (NGU) Chlamydia trachomatis is the organism most firmly implicated in the etiology of NGU. There is no doubt that sexually transmitted U. urealyticum and M. genitalium also cause some cases of NGU. The ubiquity of ureaplasmas among men who do not have urethritis and the difficulty of identifying M. genitalium do not allow precise estimation of the proportion of cases of NGU caused by each of these mycoplasmas. U. urealyticum and M. genitalium do, however, appear to cause most of the nonchlamydial cases.

Epididymitis and Prostatitis Ureaplasmas may be an occasional cause of epididymitis. M. hominis has not been implicated in this disease. Neither organism has been convincingly associated with prostatitis.

Pelvic Inflammatory Disease (PID) M. hominis and U. urealyticum are both prominent components of the complex microbial flora of bacterial vaginosis. Since bacterial vaginosis is associated with PID, it is difficult to determine whether either organism plays an independent role in this condition. Although M. genitalium is not associated with bacterial vaginosis, preliminary studies have linked it to PID in women.

<td>Disorders of Reproduction Ureaplasmas have been considered as causes of involuntary infertility in both men and women, but there is no convincing evidence for such an association. These organisms have been associated with chorioamnionitis and late abortion. Given the close association of ureaplasmas with bacterial vaginosis, a condition that is strongly associated with chorioamnionitis and late abortion, it is difficult to define an independent role for ureaplasmas in this condition. In infants of very low birth weight, ureaplasmas have been shown to cause pneumonia and chronic lung disease.</td>
</tr>
<tr>
<td>4. Intravenous or oral moxifloxacin (400 mg qd)</td>
<td>Exogenous Infections Sexually acquired reactive arthritis and Reiter’s syndrome may be triggered by ureaplasmas, although C. trachomatis is the usual triggering agent. Patients who have hypogammaglobulinemia may develop chronic arthritis due to ureaplasmas and some other mycoplasmal species. M. hominis has been identified in patients with postthoracotomy sternal wound infection and in rare instances of prothetic heart valve and prosthetic joint infection.</td>
</tr>
</tbody>
</table>

**DIAGNOSIS** There is seldom any reason to examine specimens from the lower genital tract (vagina, male urethra) for mycoplasmas. The ubiquity of the organisms among healthy individuals makes a positive result uninterpretable. The organisms should be sought only in specimens from normally sterile areas, such as joint fluid with evidence of inflammation and cultures negative for conventional microorganisms. M. hominis can replicate in many routine blood culture media without changing the appearance of the media; although it forms nonhemolytic pinpoint colonies on blood agar, organisms cannot be visualized in gram-stained smears of these colonies. Neither U. urealyticum nor M. genitalium will grow in ordinary microbiologic media. Microbiologic diagnosis of genital mycoplasmal infection requires specially prepared media and is beyond the capability of all but reference and research laboratories. Nucleic acid amplification tests such as PCR have been developed and may become commercially available.

**TREATMENT** Ureaplasmas, M. genitalium, and M. hominis are usually susceptible to tetracyclines (e.g., doxycycline). Infections caused by tetracycline-resistant ureaplasmas can be treated with erythromycin, while those due to tetracycline-resistant strains of M. hominis respond to treatment with clindamycin. As noted above, a specific microbiologic diagnosis of mycoplasmal infection is seldom made. Appropriate treatment provides antimicrobial coverage for the organisms that cause the particular syndrome. Accordingly, NGU is treated with doxycycline (100 mg orally twice a day for 7 days) or azithromycin (1.0 g as a single oral dose) to provide activity against C. trachomatis, U. urealyticum, and M. genitalium. Recommended regimens for the treatment of PID provide antimicrobial activity against gonococci, chlamydiae, and anaerobes as well as genital mycoplasmas.

CHLAMYDIAL INFECTIONS

The genus Chlamydia contains three species that infect humans: Chlamydia psittaci, C. trachomatis, and C. pneumoniae (formerly the TWAR agent). C. psittaci is widely distributed in nature, producing genital, conjunctival, intestinal, or respiratory infections in many mammalian and avian species. Genital infections with C. psittaci have been well characterized in several species and cause abortion and infertility. Although mammalian strains of C. psittaci are not known to infect humans, avian strains occasionally do so, causing pneumonia and the systemic illness known as psittacosis.

C. pneumoniae is a fastidious chlamydial species that appears to be a common cause of upper respiratory tract infection and pneumonia, primarily in children and young adults, and is a cause of recurrent respiratory infections in older adults. Studies have also linked C. pneumoniae infection to atherosclerotic cardiovascular disease and perhaps to asthma and sarcoidosis. No animal reservoir has been identified for C. pneumoniae; it appears to be an exclusively human pathogen spread via the respiratory route through close personal contact. To date, all strains of C. pneumoniae studied have been serologically homologous.

C. trachomatis is also an exclusively human pathogen and was identified as the cause of trachoma in the 1940s. Since then, C. trachomatis has been recognized as a major cause of sexually transmitted and perinatal infection.

Chlamydiae are obligate intracellular bacteria that are classified in their own order (Chlamydiales). They possess both DNA and RNA, have a cell wall and ribosomes similar to those of gram-negative bacteria, and are inhibited by antibiotics such as tetracycline.

A unique feature of all chlamydiae is their complex reproductive cycle. Two forms of the microorganism—the extracellular elementary body and the intracellular reticulate body—participate in this cycle. The elementary body is adapted for extracellular survival and is the infective form transmitted from one person to another. Elementary bodies attach to susceptible target cells (usually columnar or transitional epithelial cells) and enter the cells inside a phagosome. Within 8 h of cell entry, the elementary bodies reorganize into reticulate bodies, which are adapted to intracellular survival and multiplication. They undergo binary fission, eventually producing numerous replicates contained within the intracellular membrane-bound “inclusion body,” which occupies much of the infected host cell. Chlamydial inclusions resist lysosomal fusion until late in the developmental cycle. After 24 h, the reticulate bodies condense and form elementary bodies still contained within the inclusion. The inclusion then ruptures, releasing elementary bodies from the cell to initiate infection of adjacent cells or transmission to another person.

Studies with monoclonal antibodies to and nucleotide sequencing of the major outer-membrane protein have delineated at least 20 serotypes of C. trachomatis. According to the classification of Wang and Grayston, strains associated with trachoma have generally been those of the A, B, Ba, and C serovars, while serovars D through K have largely been associated with sexually transmitted and perinatally acquired infections. Serovars L1, L2, and L3 produce lymphogranuloma venereum (LGV) and hemorrhagic proctocolitis. The LGV strains demonstrate unique biologic behavior in that they are more invasive than the other serovars, produce disease in lymphatic tissue, grow readily in cell culture systems and macrophages, and are lethal when in-oculated intracerebrally into mice and monkeys. Non-LGV strains of C. trachomatis characteristically produce infections involving the superficial columnar epithelium of the eye, genitalia, and respiratory tract.

C. trachomatis has been reported as an infrequent cause of endocarditis, peritonitis, pleuritis, and possibly periappendicitis and may occasionally cause respiratory infections in older children and adults. Some immunosuppressed patients with pneumonia have had either serologic or cultural evidence of C. trachomatis infection, but more data are necessary to define a pathogenic role for Chlamydia in these patients.

C. TRACHOMATIS INFECTIONS

Genital infections caused by C. trachomatis represent the most common bacterial sexually transmitted diseases (STDs) in the United States (Chap. 115). An estimated 4 million cases occur each year. In adults, the clinical spectrum of sexually transmitted C. trachomatis infections parallels that of gonococcal infections. Both infections have been associated with urethritis, proctitis, and conjunctivitis in both sexes; with epididymitis in men; and with mucopurulent cervicitis (MPC), acute salpingitis, Bartholinitis, and the Fitz-Hugh–Curtis syndrome (perihepatitis) in women. Moreover, both types of infection can be associated with septic arthritis. In general, however, chlamydial infections produce fewer symptoms and signs than corresponding gonococcal infections at the same anatomic site; in fact, chlamydial infections are often totally asymptomatic. Increasing evidence suggests that many chlamydial infections of the genital tract, especially in women, persist for months without producing symptoms. Simultaneous infection with C. trachomatis often occurs in women with cervical gonococcal infection and in heterosexual men with gonococcal urethritis.

Epidemiology Infections due to C. trachomatis have been reportable in the United States since 1985, and national incidence data show steadily rising numbers of reported infections, undoubtedly reflecting both increased testing and increased reporting. Most testing to date has focused upon women, and thus the reported incidence is severalfold greater among women than among men; this difference likely represents a surveillance artifact.

The age of peak incidence of genital C. trachomatis infections, as of other sexually transmitted infections, is the late teens and early twenties. The prevalence of chlamydial urethral infection among young men is at least 3 to 5% for those seen in general medical settings or in urban high schools, >10% for asymptomatic soldiers undergoing routine physical examination, and 15 to 20% for heterosexual men seen in STD clinics. In areas where chlamydial control programs have been implemented, prevalence may be markedly reduced. In short, prevalence varies widely with the population group studied and with the geographic locale. With the newer, more sensitive nucleic acid amplification tests such as polymerase chain reaction (PCR) and ligase chain reaction (LCR), prevalences in most populations have been 10 to 30% higher than those measured with older, less sensitive tests.

The prevalence of cervical infection among women is ~5% for asymptomatic college students and prenatal patients in the United States, ~10% for women seen in family planning clinics, and >20% for women seen in STD clinics. As in men, prevalence varies substantially by geographic locale, with the highest rates in the southeast. However, substantial prevalences (~8%) of asymptomatic chlamydial
infection have been demonstrated among young female military recruits from all parts of the United States. In this country, the prevalence of \textit{C. trachomatis} in the cervix of pregnant women is 5 to 10 times higher than that of \textit{Neisseria gonorrhoeae}. The prevalence of genital infection with either agent is highest among individuals who are between the ages of 18 and 24, single, and non-Caucasian (e.g., African American or Latino). Recurrent chlamydial infections occur frequently in these same risk groups, often acquired from untreated sexual partners. Oral contraceptive pill use and the presence of cervical ectopy also confer an increased risk of chlamydial infection. The proportion of infections that are asymptomatic appears to be higher for \textit{C. trachomatis} than for \textit{N. gonorrhoeae}, and symptomatic \textit{C. trachomatis} infections are clinically less severe. Mild or asymptomatic chlamydial infections of the fallopian tubes nonetheless cause ongoing tubal damage and infertility. Furthermore, because the total number of \textit{C. trachomatis} infections exceeds the total number of \textit{N. gonorrhoeae} infections in industrialized countries, the total morbidity caused by \textit{C. trachomatis} genital infections in these countries equals or exceeds that caused by \textit{N. gonorrhoeae}. The prevalence of \textit{C. trachomatis} is higher than that of \textit{N. gonorrhoeae} in industrialized countries, in part because measures such as treatment of sex partners and routine cultures for case detection in asymptomatic individuals have been applied much longer and more effectively to the control of gonorrhoea than to the control of \textit{C. trachomatis} infection.

**Pathogenesis** \textit{C. trachomatis} preferentially infects the columnar epithelium of the eye and the respiratory and genital tracts. The infection induces an immune response but often persists for months or years in the absence of antimicrobial therapy. Serious sequelae often occur in association with repeated or persistent infections. The precise mechanism through which repeated infection elicits an inflammatory response that leads to tubal scarring and damage in the female upper genital tract is not yet clear. One antigen, the chlamydial 60-kDa heat-shock protein, may be involved in inducing the pathologic immune response or may elicit antibodies that cross-react with human heat-shock proteins. The recent sequencing of the chlamydial genome may soon offer further insights into the pathogenic mechanisms of \textit{C. trachomatis}.

**Clinical Manifestations**

**Nongonococcal and Postgonococcal Urethritis**

Nongonococcal urethritis (NGU) is a diagnosis of exclusion that is applied to men with symptoms and/or signs of urethritis who do not have gonorrhea. Postgonococcal urethritis (PGU) refers to nongonococcal urethritis developing in men 2 to 3 weeks after treatment of gonococcal urethritis with single doses of agents such as amoxicillin or cephalosporins that lack antimicrobial activity against chlamydiae. Since current treatment regimens for gonorrhea also include tetracyclines or cephalosporins that lack antimicrobial activity against chlamydiae, the diagnosis of PGU should be considered when a patient presents with symptoms and signs of urethritis that do not resolve after treatment with agents active against gonococci. Since PGU may persist for months without treatment, the diagnosis should be considered in men who have symptoms and signs of urethritis and who have been treated previously for gonorrhea.

NGU is diagnosed by documentation of a leukocytic urethral exudate and by exclusion of gonorrhea by Gram’s staining or culture. \textit{C. trachomatis} urethritis is generally less severe than gonococcal urethritis, although in an individual patient these two forms of urethritis cannot be reliably differentiated solely on clinical grounds. Symptoms include urethral discharge (often whitish and mucoid rather than frankly purulent), dysuria, and urethral itching. Physical examination may reveal metal erythema and tenderness and a urethral exudate that is often demonstrable only by stripping of the urethra. At least one-third of males with \textit{C. trachomatis} urethral infection have no demonstrable signs or symptoms of urethritis. Use of nucleic acid amplification assays on first-void urine specimens to diagnose chlamydial infections in men has facilitated more broadly based testing for asymptomatic infection in males. As a result, asymptomatic chlamydial urethritis has been demonstrated in 5 to 10% of sexually active adolescent males screened in school-based clinics or community centers. Such patients generally have first-glass pyuria (≥15 leukocytes per 400× microscopic field in the sediment of first-void urine), a positive leukocyte esterase test, or an increased number of leukocytes on Gram-stained smear prepared from a urogenital swab inserted 1 to 2 cm into the anterior urethra. For the enumeration of leukocytes, the smear is first scanned at low power to identify areas of the slide containing the highest concentration of leukocytes. These areas are then examined under oil immersion (1000×). An average of four or more leukocytes in at least three of five 1000× (oil-immersion) fields is indicative of urethritis and correlates with the recovery of \textit{C. trachomatis}.

**Reiter’s Syndrome**

Reiter’s syndrome consists of conjunctivitis, urethritis (or cervicitis in females), arthritis, and characteristic mucocutaneous lesions (Chap. 205). \textit{C. trachomatis} has been recovered from the urethra of up to 70% of men with untreated nonidiopathic Reiter’s syndrome and associated urethritis. In the absence of overt urethritis, it is important to exclude subclinical urethritis in the men in whom this diagnosis is suspected.

**Epididymitis** \textit{C. trachomatis} is the foremost cause of epididymitis in sexually active homosexual men <35 years of age, accounting for ~70% of cases. \textit{N. gonorrhoeae} causes most of the remaining cases, and some men have simultaneous infections with both pathogens, usually accompanied by asymptomatic urethritis as defined above. In homosexual men, sexually transmitted coliform infection acquired via insertive rectal intercourse may cause epididymitis. Coliform bacteria and \textit{Pseudomonas aeruginosa}, usually in association with preceding urologic instrumentation or surgery, are the most common causes of epididymitis in men over 35. Men with chlamydial epididymitis typically present with unilateral scrotal pain, fever, and epididymal tenderness or swelling on examination. The illness may be mild enough to treat on an outpatient basis with oral antibiotics or severe enough to require hospitalization and parenteral therapy. Testicular torsion should be excluded promptly by radionuclide scan, Doppler flow study, or surgical exploration in a teenager or young adult who presents with acute unilateral testicular pain without urethritis. The possibility of testicular tumor or chronic infection (e.g., tuberculosis) should be excluded when a patient with unilateral intrascrotal pain and swelling does not respond to appropriate antimicrobial therapy.

**EPIDIDYMITS**

\textit{C. trachomatis} is the foremost cause of epididymitis in sexually active homosexual men <35 years of age, accounting for ~70% of cases. \textit{N. gonorrhoeae} causes most of the remaining cases, and some men have simultaneous infections with both pathogens, usually accompanied by asymptomatic urethritis as defined above. In homosexual men, sexually transmitted coliform infection acquired via insertive rectal intercourse may cause epididymitis. Coliform bacteria and \textit{Pseudomonas aeruginosa}, usually in association with preceding urologic instrumentation or surgery, are the most common causes of epididymitis in men over 35. Men with chlamydial epididymitis typically present with unilateral scrotal pain, fever, and epididymal tenderness or swelling on examination. The illness may be mild enough to treat on an outpatient basis with oral antibiotics or severe enough to require hospitalization and parenteral therapy. Testicular torsion should be excluded promptly by radionuclide scan, Doppler flow study, or surgical exploration in a teenager or young adult who presents with acute unilateral testicular pain without urethritis. The possibility of testicular tumor or chronic infection (e.g., tuberculosis) should be excluded when a patient with unilateral intrascrotal pain and swelling does not respond to appropriate antimicrobial therapy.

**Reiter’s Syndrome**

Reiter’s syndrome consists of conjunctivitis, urethritis (or cervicitis in females), arthritis, and characteristic mucocutaneous lesions (Chap. 205). \textit{C. trachomatis} has been recovered from the urethra of up to 70% of men with untreated nongonococcal Reiter’s syndrome and associated urethritis. In the absence of overt urethritis, it is important to exclude subclinical urethritis in the men in whom this diagnosis is suspected.

The pathogenesis of Reiter’s syndrome remains obscure. However, since more than 80% of affected patients have the HLA-B27 phenotype and since other mucosal infections (with \textit{Salmonella}, \textit{Shigella}, or \textit{Campylobacter}, for example) produce an identical syndrome, chlamydial infection is thought to initiate an aberrant and hyperactive immune response that produces inflammation at the involved target organs in these genetically predisposed individuals. Evidence of exaggerated cell-mediated and humoral immune responses to chlamydial antigens in Reiter’s syndrome supports this hypothesis. The presumptive demonstration of chlamydial elementary bodies and chlamydial DNA in the joint fluid and synovial tissue of patients with Reiter’s syndrome suggests that chlamydial infection can be detected in these tissues in these patients, perhaps in macrophages.
PROCTITIS C. trachomatis strains of either the genital immunotypes D through K or the LGV immunotypes cause proctitis in homosexual men who practice receptive anorectal intercourse. In the United States, the vast majority of cases are due to immunotypes D through K and present either as asymptomatic infection or as mild proctitis not unlike gonococcal proctitis. These infections may develop in heterosexual women as well. Patients present with mild rectal pain, mucous discharge, tenesmus, and (occasionally) bleeding. Nearly all have neutrophils in their rectal Gram’s stain. Anoscopy in these non-LGV cases of chlamydial proctitis reveals mild, patchy mucosal friability and mucopurulent discharge, and the disease process is limited to the distal rectum. LGV strains produce more severe ulcerative proctitis or proctocolitis that can be confused clinically with HSV proctitis (severe rectal pain, bleeding, discharge, and tenesmus) and that histologically resembles Crohn’s disease in that giant cell formation and granulomas can be seen (Chap. 276). In the United States, these cases occur almost exclusively in homosexual men.

MUCOPURULENT CERVICITIS Although many women with C. trachomatis infection of the cervix have no symptoms or signs, a careful speculum examination reveals evidence of MPC in 30 to 50% of cases. As is discussed more fully in Chap. 115, MPC is associated with yellow mucopurulent endocervical discharge and with ≥20 neutrophils per 1000× microscopic field within strands of cervical mucus on a thinly smeared, Gram-stained preparation of endocervical exudate. Other characteristic findings include edema of the zone of cervical ectopy and a propensity of the mucosa to bleed on minor trauma—e.g., when specimens are collected with a swab. A Pap smear shows increased numbers of neutrophils as well as a characteristic pattern of mononuclear inflammatory cells, including plasma cells, transformed lymphocytes, and histiocytes. Cervical biopsy shows a predominantly mononuclear cell infiltrate of the subepithelial stroma, often with follicular cervicitis.

PELVIC INFLAMMATORY DISEASE (PID) (See also Chap. 115) In the United States, C. trachomatis has been identified in the fallopian tubes or endometrium of up to 50% of women with PID, and its role as an important etiologic agent in this syndrome is well accepted. PID occurs via ascending intraluminal spread of C. trachomatis from the lower genital tract. MPC is thus followed by endometritis, endosalpingitis, and finally pelvic peritonitis. Evidence of MPC is usually found in women with laparoscopically verified salpingitis. Similarly, endometritis, demonstrated by endometrial biopsy showing plasma cell infiltration of the endometrial epithelium, is documented in most women with laparoscopically verified chlamydial (or gonococcal) salpingitis. Chlamydial endometritis can also occur in the absence of clinical evidence of salpingitis: ~40 to 50% of women with MPC have plasma cell endometritis. Histologic evidence of endometritis has been correlated with an “endometritis syndrome” consisting of vaginal bleeding, lower abdominal pain, and uterine tenderness in the absence of adnexal tenderness. Chlamydial salpingitis produces milder symptoms than does gonococcal salpingitis and may be associated with less marked adnexal tenderness. Thus mild adnexal or uterine tenderness in sexually active women with cervicitis suggests PID.

Infertility associated with fallopian-tube scarring has been strongly linked to antecedent C. trachomatis infection in serologic studies. Since many infertile women with tubal scarring and antichlamydial antibody have no history of PID, it appears that subclinical tubal infection (“silent salpingitis”) may produce scarring. Studies in animals and humans with salpingitis and tubal scarring suggest the continuing presence of persistent, slowly replicating chlamydial infection in tubal tissue. While the pathogenesis of Chlamydia-induced tubal scarring remains poorly understood, antibodies to the chlamydial 60-kDa heat-shock protein have been correlated with tubal infertility, ectopic pregnancy, and Fitz-Hugh–Curtis syndrome (see below). Thus this antigen may initiate an immune-mediated process that ultimately damages the fallopian tube. The least genetic susceptibility, as defined by HLA type, may also play an important role.

Perihepatitis, or the Fitz-Hugh–Curtis syndrome, was originally described as a complication of gonococcal PID. The syndrome should be suspected whenever a young, sexually active woman presents with an illness resembling cholecystitis (fever and right-upper-quadrant pain of subacute or acute onset). Symptoms and signs of salpingitis may be minimal. Cultural and/or serologic evidence of C. trachomatis infection is found in three-quarters of women with this syndrome.

URETHRAL SYNDROME IN WOMEN In the absence of infection with uropathogens such as coliforms or Staphylococcus saprophyticus, C. trachomatis is the pathogen most commonly isolated from college women with dysuria, frequency, and pyuria (Chap. 269). Chlamydia can also be isolated from the urethra of women without symptoms of urethritis, and up to 25% of female STD clinic patients with chlamydial urogenital infection have cultures positive for C. trachomatis from the urethra only.

C. TRACHOMATIS INFECTION IN PREGNANCY AND THE NEONATAL PERIOD Studies in the United States have demonstrated that 5 to 25% of pregnant women have C. trachomatis infections of the cervix. In these studies, approximately one-half to two-thirds of children exposed during birth have acquired C. trachomatis infection. Roughly half of the infected infants (or 25% of the group exposed) have developed clinical evidence of inclusion conjunctivitis. In addition to infecting the eye, C. trachomatis has been isolated frequently and persistently from the nasopharynx, rectum, and vagina of such infants, occasionally for periods exceeding 1 year in the absence of treatment. Pneumonia develops in ~10% of children infected perinatally, and otitis media may in some cases result from perinatally acquired chlamydial infection.

Neonatal chlamydial conjunctivitis has an acute onset 5 to 14 days after birth and often produces a profuse mucopurulent discharge. However, it is impossible to differentiate chlamydial conjunctivitis from other forms of neonatal conjunctivitis (such as that due to N. gonorrhoeae, Haemophilus influenzae, Streptococcus pneumoniae, or HSV) on clinical grounds; thus laboratory diagnosis is required. Inclusions within epithelial cells are often detected in Giemsa-stained conjunctival smears, but these smears are considerably less sensitive than cultures, antigen detection tests, or nucleic acid hybridization tests for chlamydial. Gram-stained smears may show gonococcal or occasional small gram-negative coccobacilli in Haemophilus conjunctivitis, but smears should be accompanied by cultures for these agents.

C. trachomatis causes a distinctive pneumonia syndrome in infants. Recent epidemiologic studies have linked chlamydial pulmonary infection in infants with increased occurrence of subacute lung disease (bronchitis, asthma, wheezing) in later childhood.

Lymphogranuloma Venereum ■ DEFINITION LGV is a sexually transmitted infection caused by C. trachomatis strains of the L1, L2, and L3 serovars. In the United States, most cases are caused by L2 organisms. Acute LGV is characterized by a transient primary genital lesion followed by multilocular suppurative regional lymphadenopathy. Patients exposed via insertive rectal intercourse may develop hemorrhagic proctitis with regional lymphadenitis. Acute LGV is almost always associated with systemic symptoms such as fever and leukocytosis but is rarely associated with systemic complications such as meningoencephalitis. After a period of years, late complications include genital elephantiasis due to lymphatic involvement; strictures; and fistulas of the penis, urethra, and rectum.

EPIDEMIOLOGY LGV is usually sexually transmitted, but occasional transmission by nonsexual personal contact, fomites, or laboratory accidents has been documented. Laboratory work involving the creation of aerosols of LGV organisms (e.g., sonication, homogenization) must be conducted only with appropriate measures for biologic containment.

The peak incidence of LGV corresponds to the age of greatest sexual activity; the second and third decades of life. The worldwide incidence of LGV is falling, but the disease is still endemic and a major cause of morbidity in Asia, Africa, South America, and parts of
The frequency of infection following exposure is believed to be much lower than that for gonorrhea and syphilis. Early manifestations are recognized far more often in men than in women, who usually present with late complications. In the United States, where the reported male-to-female ratio of cases is 3:4:1, most cases have involved homosexually active men and persons returning from abroad (travelers, sailors, and military personnel). The main reservoir of infection, although it has not been directly demonstrated, is presumed to be asymptptomatically infected individuals.

**Clinical Manifestations** A primary genital lesion develops from 3 days to 3 weeks after exposure. It is a small, painless vesicle or noninflamed ulcer or papule located on the penis in men and on the labia, posterior vagina, or fourchette in women. The primary lesion is noticed by fewer than one-third of men with LGV and only rarely by women. It heals in a few days without scarring and, even when noticed, is usually recognized as LGV only in retrospect. LGV strains of *C. trachomatis* have occasionally been recovered from genital ulcers and from the urethra of men and the endocervix of women who present with inguinal adenopathy; these areas may be the primary site of infection in some cases.

Primary anal or rectal infection develops after receptive anorectal intercourse. In women, rectal infection with LGV (or non-LGV) strains of *C. trachomatis* presumably can also arise by the contiguous spread of infected secretions along the perineum (as in rectal gonococcal infections in women) or perhaps by spread to the rectum via the pelvic lymphatics.

From the site of the primary urethral, genital, anal, or rectal infection, the organism spreads via the regional lymphatics. Penile, vulvar, or anal infection can lead to inguinal and femoral lymphadenitis. Rectal infection produces hypogastric and deep iliac lymphadenitis. Upper vaginal or cervical infection results in enlargement of the obturator and iliac nodes.

The most common presenting picture in heterosexual men is the inguinal syndrome, which is characterized by painful inguinal lymphadenopathy beginning 2 to 6 weeks after presumed exposure; in rare instances, the onset comes after a few months. The inguinal adenopathy is unilateral in two-thirds of cases, and palpable enlargement of the iliac and femoral nodes is often evident on the same side as the enlarged inguinal nodes. The nodes are initially discrete, but progressive periadenitis results in a matted mass of nodes that becomes fluctuant and suppurative. The overlying skin becomes fixed, inflamed, and thin and finally develops multiple draining fistulas. Extensive enlargement of chains of inguinal nodes above and below the inguinal ligament (“the sign of the groove”) is not specific and, although not uncommon, is documented in only a minority of cases. On histologic examination, infected nodes are initially found to have characteristic small stellate abscesses surrounded by histiocytes. These abscesses coalesce to form large, necrotic, suppurative foci. Spontaneous healing usually takes place after several months; inguinal scars or granulomatous masses of various sizes persist for life. Massive pelvic lymphadenopathy may lead to exploratory laparotomy.

As cultures and serologic tests for *C. trachomatis* are being used more often, increasing numbers of cases of LGV proctitis are being recognized in homosexual men. Such patients present with anorectal pain and mucopurulent, bloody rectal discharge. Although these patients may complain of diarrhea, they are often referring not to diarrhea but rather to frequent, painful, unsuccessful attempts at defecation (tenesmus). Proctosigmoidoscopy reveals ulcerative proctitis or proctocolitis, with purulent exudate and mucosal bleeding. The histopathologic findings in the rectal mucosa include granulomas with giant cells, crypt abscesses, and extensive inflammation. These clinical, sigmoidoscopic, and histopathologic findings may closely resemble those of Crohn’s disease of the rectum.

Constitutional symptoms are common during the stage of regional lymphadenopathy and, in cases of proctitis, may include fever, chills, headache, meningismus, anorexia, myalgias, and arthralgias. These findings in the presence of lymphadenopathy are sometimes mistakenly interpreted as representing malignant lymphoma. Other systemic complications are infrequent but include arthritis with sterile effusion, aseptic meningitis, meningoencephalitis, conjunctivitis, hepatitis, and erythema nodosum. Chlamydiae have been recovered from the cerebrospinal fluid and in one case were isolated from the blood of a patient with severe constitutional symptoms—a result indicating the disseminated nature of infection. Laboratory-acquired infections suspected of being due to the inhalation of aerosols have been associated with mediastinal lymphadenitis, pneumonitis, and pleural effusion.

Complications of untreated anorectal infection include perirectal abscess; fistula in ano; and rectovaginal, rectovesical, and ischiorectal fistulas. Secondary bacterial infection probably contributes to these complications. Rectal stricture is a late complication of anorectal infection and usually develops 2 to 6 cm from the anal orifice—i.e., at a site within reach on digital rectal examination. Proximal extension of the stricture for several centimeters may lead to a mistaken clinical and radiographic diagnosis of carcinoma.

A small percentage of cases of LGV in men present as chronic progressive infiltrative, ulcerative, or fistulous lesions of the penis, urethra, or scrotum. Associated lymphatic obstruction may produce elephantiasis. When urethral stricture occurs, it usually involves the posterior urethra and causes incontinence or difficulty with urination.

**Approach to the Diagnosis and Treatment of C. trachomatis Genital Infections**

Four types of laboratory procedure are available to confirm *C. trachomatis* infection: direct microscopic examination of tissue scrapings for typical intracytoplasmic inclusions or elementary bodies; isolation of the organism in cell culture; detection of chlamydial antigens or nucleic acid by immunologic or hybridization methods; and detection of antibody in serum or in local secretions.

Except in conjunctivitis, direct microscopic examination of Giemsa-stained cell scrapings for typical inclusions has an unacceptably low degree of sensitivity, and false-positive interpretations by inexperienced observers are common. Even for conjunctivitis, this approach has been replaced by direct fluorescent antibody staining of conjunctival smears to identify chlamydial elementary bodies with specific monoclonal antibodies (see below).

Cell culture techniques for isolation of *C. trachomatis* are available in most large medical centers but not in other clinical settings. In addition to limited availability, other disadvantages of cell culture include its low and variable level of sensitivity (60 to 80%), its requirement for rigorous transport conditions, and its high cost and technically demanding nature. Therefore, nonculture alternatives involving antigen detection or nucleic acid hybridization have been developed. In the direct immunofluorescent antibody (DFA) slide test, potentially infected genital or ocular secretions are smeared onto a slide, fixed, and stained with fluorescein-conjugated monoclonal antibody specific for chlamydial antigens. The observation of fluorescing elementary bodies confirms the diagnosis. Enzyme-linked immunosorbent assay (ELISA) techniques for the detection of chlamydial antigens provide another alternative to culture. The reported sensitivity and specificity of these tests for genital infections (as compared with culture) have been 60 to 80% and 97 to 99%, respectively, in high-risk populations. Assays with nucleic acid probes have also been developed for chlamydial diagnosis. One such test uses DNA-RNA hybridization and appears to be approximately equal to the best ELISAs in terms of sensitivity and specificity. Nucleic acid probes have also been developed for use in amplification assays such as LCR and PCR. These tests are not yet available as nonculture chlamydial diagnostic methods available, being the first nonculture assays to surpass culture itself in sensitivity.

In addition, the ability of these tests to detect chlamydial genes in...
urine with a high degree of sensitivity and specificity allows—for the first time—the use of urine specimens rather than conventional urethral and cervical swabs. The use of urine specimens is particularly appealing for public-health chlamydial screening programs because of the ease of sample collection, even in community-based settings.

Serologic tests are of limited usefulness in the diagnosis of chlamydial ocuogenital infections. The complement fixation test with heat-stable, genus-specific antigen has been used with some success to diagnose LGV but is insensitive in infections due to non-LGV strains of *C. trachomatis*. The microimmunofluorescence (micro-IF) test with *C. trachomatis* antigens is more sensitive but is generally available only in research laboratories. The test measures antibodies by serovar specificity and by immunoglobulin class (IgM, IgG, IgA) in both serum and local secretions. Serologic diagnosis by the micro-IF test may be useful in infant pneumonia (in which high-titer IgM antibody and/or fourfold rises in titer are often demonstrated), in chlamydial salpingitis (especially Fitz-Hugh–Curtis syndrome), and in LGV. In all of these more invasive syndromes, high antibody levels are present.

Table 160-1 summarizes the diagnostic tests of choice for patients with suspected *C. trachomatis* infection. It is clear that, in most settings and for most purposes, sensitivity and specificity will be greatest with nucleic acid amplification techniques. For patients to whom medical considerations may apply (victims of sexual or child abuse), cultures or nucleic acid amplification methods should always be used. In men with suspected urethritis, PCR or LCR testing of a first-void urine specimen offers a more sensitive and noninvasive diagnostic method than the use of urethral swabs. For the diagnosis of urogenital (cervical or urethral) infections in women, testing of a first-void urine specimen by nucleic acid amplification methods is at least as sensitive as testing of a cervical swab. Patient-collected vaginal swabs tested by PCR or LCR have also been used successfully. Since chlamydial diagnostic testing has become more widely available and is now more sensitive and specific than in the past, its use for specific diagnosis in patients with suspected chlamydial syndromes (such as MPC, NGU, and PID) and their partners should be promoted. High priority should also be given to the screening of asymptomatic high-risk women who would not otherwise receive treatment for presumptive chlamydial infection, especially those seen in high-risk settings (e.g., STD clinics or abortion clinics) and those with a high-risk profile (e.g., sexually active and ≤21 years of age, new sex partner within the preceding 2 months, or more than one current sex partner). Similar screening programs should be used to detect and treat asymptomatic urethritis in high-risk adolescent males. Where implemented, screening programs of this type have been associated with reductions in the prevalence of chlamydial infection and of its complications, such as PID.

* Note: CF, complement-fixing; FA, fluorescent antibody; LGV, lymphogranuloma venereum; micro-IF, microimmunofluorescence; MPC, mucopurulent cervicitis; NAAT, nucleic acid amplification test; NGU, nongonococcal urethritis; PGU, postgonococcal urethritis.
with doxycycline or tetracycline must be given for genital infections. A 2-week course is recommended for complicated chlamydial infections (e.g., PID, epididymitis) and at least a 3-week course of doxycycline (100 mg orally bid) or erythromycin base (500 mg orally qid) for LGV. Failure of treatment of genital infections with a tetracycline usually indicates poor compliance or reinfection rather than the involvement of a drug-resistant strain. To date, clinically significant drug resistance has not been observed in *C. trachomatis* infection.

**Therapy for *C. trachomatis* urethritis** is more efficacious than therapy for nonchlamydial NGU. *C. trachomatis* is eradicated from the urethra in nearly all cases by treatment with tetracycline hydrochloride (500 mg qid for 7 days) or doxycycline (100 mg by mouth bid for 7 days).

Eradication of *C. trachomatis* from the cervix by tetracycline and doxycycline, with doses and durations similar to those specified above for urethritis, has been demonstrated. Erythromycin base (500 mg bid for 10 to 14 days) is the regimen of choice for pregnant women with *C. trachomatis* infection. Amoxicillin (500 mg tid for 10 days) has also been used successfully in pregnant women. Tetracycline hydrochloride (500 mg qid) or doxycycline (100 mg bid) for 14 days produces clinical and microbiologic cure of epididymitis and PID associated with *C. trachomatis* infection, but in this situation a tetracycline should always be used together with a drug that is highly effective against gonorrhea.

Azithromycin is highly active against *C. trachomatis*, exhibits prolonged bioavailability, is concentrated intracellularly, and has made possible single-dose therapy for chlamydial infection for the first time. In comparative trials, a 1-g single dose of azithromycin has been as effective as 7 days of doxycycline therapy for uncomplicated chlamydial infection. Azithromycin causes fewer adverse gastrointestinal reactions than do older macrolides such as erythromycin. The single-dose regimen of azithromycin has great appeal for the treatment of pregnant women, the 1-g single-dose dose regimen is concentrated intracellularly, and has made possible single-dose therapy for chlamydial infection for the first time.

Epithelial cells infected with *C. trachomatis* shed prokaryotic particles called elementary bodies, which are highly infectious. The organisms are present for weeks to months in the absence of symptoms and those with a likelihood of poor compliance and of sexual partners of infected patients. These advantages must be weighed against the considerably greater cost of azithromycin. Whenever possible, the single 1-g dose should be given as directly observed therapy. Although not approved by the U.S. Food and Drug Administration for the treatment of pregnant women, the 1-g single-dose regimen of azithromycin appears to be safe and effective for this purpose.

Of the newer fluoroquinolones, ofloxacin (300 mg by mouth bid for 7 days) has been shown to be as effective as doxycycline for the treatment of chlamydial infection and appears to be safe and well tolerated. It cannot be used in pregnancy.

**Treatment of Sex Partners** The continued high prevalence of chlamydial infections in most parts of the United States is due primarily to the failure to diagnose—and therefore treat—patients with symptomatic or asymptomatic infection and their sex partners. *C. trachomatis* urethral or cervical infection has been well documented in a high proportion of the sex partners of patients with NGU, epididymitis, Reiter’s syndrome, salpingitis, or endocervicitis. If possible, confirmatory laboratory tests for *Chlamydia* should be undertaken in these individuals, but even those without positive tests or evidence of clinical disease who have recently been exposed to proven or possible chlamydial infection (e.g., NGU) should be offered therapy.

**Treatment of Neonates and Infants** In neonates with conjunctivitis or infants with pneumonia, erythromycin ethylsuccinate or estolate can be given orally in a dose of 50 mg/kg per day, preferably in four divided doses, for 2 weeks. Careful attention must be given to compliance with therapy—a frequent problem. Relapses of eye infection are common following treatment with topical erythromycin or tetracycline ophthalmic ointment and may also occur after oral erythromycin therapy. Thus follow-up cultures should be performed after treatment. Both parents should be examined for *C. trachomatis* infection and, if diagnostic testing is not readily available, should be treated with doxycycline or azithromycin.

**Prevention** Efforts to develop a vaccine for chlamydial infection have not yet been successful. Early diagnosis and treatment shorten the duration of infectiousness and therefore constitute primary prevention of chlamydial infection. By the early 1990s, one of the 10 regions of the United States (Region X, the Pacific Northwest) had formally undertaken a chlamydial control program involving widespread screening of women attending family planning clinics. Approximately 500,000 tests per year were conducted at 150 such clinics throughout the region in women meeting the criteria for high risk. Within 5 years, the prevalence of chlamydial infection had been reduced by >50% in this population. While most regions of the United States have now initiated similar programs, some family planning and STD clinics still do not offer chlamydial testing. The availability of highly sensitive and specific diagnostic tests that can be done with urine specimens and of single-dose therapy makes it feasible to mount an effective chlamydial control program nationwide, with screening of high-risk persons both in traditional health care settings and in novel community- and school-based settings.

**TRACHOMA AND ADULT INCLUSION CONJUNCTIVITIS**

**Definition** Trachoma is a chronic conjunctivitis associated with infection by *C. trachomatis* serovar A, B, Ba, or C. It has been responsible for an estimated 20 million cases of blindness throughout the world and remains an important cause of preventable blindness. Inclusion conjunctivitis is an acute ocular infection caused by sexually transmitted *C. trachomatis* strains (usually serovars D through K) in adults exposed to infected genital secretions and in their newborn offspring.

**Epidemiology** In trachoma-endemic areas where the classic eye disease is seen, transmission is from eye to eye via hands, flies, towels, and other fomites and usually involves serovar A, B, Ba, or C. The worldwide incidence and severity of trachoma have decreased dramatically during the past 35 years, mainly as a result of improving hygienic and economic conditions. Endemic trachoma is still the major cause of preventable blindness in northern Africa, sub-Saharan Africa, the Middle East, and parts of Asia. Transmission occurs primarily through close personal contact, particularly among young children in rural communities with limited water supplies. In endemic areas, trachoma is associated with repeated exposure and reinfection, but the infection can also become chronic and persistent. Acute relapse of old trachoma occasionally follows treatment with cortisone eye ointment or develops in very old persons who were exposed in their youth.

**Clinical Manifestations** Both endemic trachoma and adult inclusion conjunctivitis present initially as a conjunctivitis characterized by small lymphoid follicles in the conjunctiva. In regions with hyperendemic classic blinding trachoma, the disease usually starts insidiously before the age of 2 years. Reinfec tion is common and probably contributes to the pathogenesis of trachoma. Studies using PCR techniques indicate that chlamydial DNA is often present in the ocular secretions of patients with trachoma, even in the absence of positive cultures. Thus persistent infection may be more common than was previously thought.

The cornea becomes involved, with inflammatory leukocytic infiltrations and superficial vascularization (pannus formation). As the inflammation continues, conjunctival scarring eventually distorts the eyelids, causing them to turn inward so that the intumescent lashes constantly abrade the eyeball (trichiasis and entropion); eventually the corneal epithelium is abraded and may ulcerate, with subsequent corneal scarring and blindness. Destruction of the conjunctival goblet cells, lacrimal ducts, and lacrimal gland may produce a “dry-eye” syndrome, with resultant corneal opacity due to drying (xerosis) or secondary bacterial corneal ulcers.

Communities with blinding trachoma often experience seasonal epidemics of conjunctivitis due to *H. influenzae* that contribute to the intensity of the inflammatory process. In such areas the active infectious process usually resolves spontaneously in affected persons be-
between 10 and 15 years of age, but the conjunctival scars continue to shrink, producing trichiasis and entropion and subsequent corneal scarring in adults. In areas with milder and less prevalent disease, the process may be much slower, with active disease continuing into adulthood; blindness is rare in these cases.

Eye infection with genital C. trachomatis strains in sexually active young adults presents as the acute onset of unilateral follicular conjunctivitis and preauricular lymphadenopathy similar to that seen in acute adenovirus or herpesvirus conjunctivitis. If untreated, the disease may persist for 6 weeks to 2 years. It is frequently associated with corneal inflammation in the form of discrete opacities (“infiltrates”), punctate epithelial erosions, and minor degrees of superficial corneal vascularization. Very rarely, conjunctival scarring and eyelid distortion occur. A particularly in patients treated for meningitis, photophobia is also a common complaint. Photophobia is also a common complaint.

Diagnosis The clinical diagnosis of classic trachoma can be made if two of the following signs are present: (1) lymphoid follicles on the upper tarsal conjunctiva; (2) typical conjunctival scarring; (3) vascular pannus; or (4) limbal follicles or their sequelae, Herbert’s pits.

The clinical diagnosis of endemic trachoma should be confirmed by laboratory tests in children with more marked degrees of inflammation. Intracytoplasmic chlamydial inclusions are found in 10 to 60% of Giemsa-stained conjunctival smears in such populations, but chlamydial PCR or LCR is more sensitive and is often positive when smears or cultures are negative. Follicular conjunctivitis in adults or Americans living in trachomatous regions is rarely due to trachoma.

TREATMENT

Public health control programs for endemic trachoma have consisted of the mass application of tetracycline or erythromycin ointment to the eyes of all children in affected communities for 21 to 60 days or on an intermittent schedule. These programs also include surgical correction of inturmed eyelids by a mobile surgical team that visits each locale. Mass treatment of entire villages with single-dose azithromycin may be an alternative approach.

Adult inclusion conjunctivitis responds well to treatment with full doses of oral tetracycline or erythromycin administered for 3 weeks. Simultaneous treatment of all sexual consorts of the patient is also necessary to prevent ocular reinfection and to avoid genital disease due to chlamydial infection. Topical antibiotic treatment is not required for patients who receive systemic antibiotics.

Prevention Efforts to develop a trachoma vaccine have not yet been successful. General hygienic measures associated with improved living standards are effective in the elimination of endemic trachoma. An adequate water supply for personal cleanliness may be a key factor. In some areas the reduction of numbers of flies in the household is adequate water supply for personal cleanliness may be a key factor. In some areas the reduction of numbers of flies in the household is important.

C. PSITTACI INFECTIONS

Definition Psittacosis is primarily an infectious disease of birds and mammals that is caused by C. psittaci. Transmission of infection from birds to humans results in a febrile illness characterized by pneumonia and systemic manifestations. Inapparent infections or mild influenza-like illnesses may also occur. The term ornithosis is sometimes applied to infections contracted from birds other than parrots or parakeets, but psittacosis is the preferred generic term for all forms of the disease.

Epidemiology Almost any avian species can harbor C. psittaci. Psittacine birds (parrots, parakeets, budgerigars) are most commonly infected, but human cases have been traced to contact with pigeons, ducks, turkeys, chickens, and many other birds. Psittacosis may be considered an occupational disease of pet-shop owners, poultry workers, pig farmers, taxidermists, veterinarians, and poultry workers. During the past 20 years, there has been an increase in incidence, with cases and outbreaks occurring primarily among employees of poultry-processing plants. It is suspected that many cases go undiagnosed and unreported.

The agent is present in nasal secretions, excreta, tissues, and feathers of infected birds. Although the disease can be fatal, infected birds frequently show only minor evidence of illness, such as ruffled feathers, lethargy, and anorexia. Asymptomatic avian carriers are common, and complete recovery may be followed by continued shedding of the organism for many months.

Pathogenesis The psittacosis agent gains entrance to the body through the upper part of the respiratory tract, spreads via the bloodstream, and eventually localizes in the pulmonary alveoli and in the reticuloendothelial cells of the spleen and liver. Invasion of the lung probably takes place by way of the bloodstream rather than by direct extension from the upper air passages. A lymphocytic inflammatory response occurs on both the interstitial and the respiratory surfaces of the alveoli as well as in the perivascular spaces. The alveolar walls and interstitial tissues of the lung are thickened, edematous, necrotic, and occasionally hemorrhagic. Histologic examination of the affected areas reveals alveolar spaces filled with fluid, erythrocytes, and lymphocytes. The picture is not pathognomonic of psittacosis unless macrophages containing characteristic cytoplasmic inclusion bodies (Levinthal-Coles-Lilie bodies) can be identified. The respiratory epithelium of the bronchi and bronchioles usually remains intact.

Clinical Manifestations The clinical manifestations and course of psittacosis are extremely variable. After an incubation period of 7 to 14 days or longer, the disease may start abruptly with shaking chills and fever, with temperatures ranging as high as 40.5°C (105°F); however, the onset is often gradual, with fever increasing over a 3- to 4-day period. Headache is almost always a prominent symptom; it is usually diffuse and exocrutiating and is often the patient’s chief complaint.

Many patients present with a dry hacking cough that is usually nonproductive, but small amounts of mucoid or bloody sputum may be raised as the disease progresses. Cough may begin early in the course of the disease or as late as 5 days after the onset of fever. Chest pain, pleurisy with effusion, or a friction rub may all occur but are rare. Pericarditis and myocarditis have been reported. Most patients have a normal or slightly increased respiratory rate; marked dysnea with cyanosis occurs only in severe psittacosis with extensive pulmonary involvement. In psittacosis, as in mycoplasmal pneumonias, the physical signs of pneumonitis tend to be less prominent than symptoms and x-ray findings would suggest. The initial examination may reveal fine sibilant rales, or clinical evidence of pneumonia may be completely lacking. Rales usually become audible and more numerous as the illness progresses. Signs of frank pulmonary consolidation are usually absent. Symptoms of upper respiratory tract infection are not prominent, although mild sore throat, pharyngitis, and cervical adenopathy are often documented; on occasion, the last may be the only manifestation of illness. Epistaxis is encountered early in the course of nearly one-fourth of cases. Photophobia is also a common complaint. Patients often report generalized myalgia, and spasm and stiffness of the muscles of the back and neck may lead to an erroneous diagnosis of meningitis. Lethargy, mental depression, agitation, insomnia, and disorientation have been prominent features of the illness in some
epidemics but not in others; delirium and stupor develop near the end of the first week in severe cases. Occasional patients are comatose when first seen, and the diagnosis of psittacosis may be elusive in these cases. Gastrointestinal manifestations such as abdominal pain, nausea, vomiting, or diarrhea are noted in some cases; constipation and abdominal distention sometimes occur as late complications. Icterus, the result of severe hepatic involvement, is a rare and ominous finding. A faint macular rash (Horder’s spots) resembling the rose spots of typhoid fever has been described.

Patients without cough or other clinical evidence of respiratory involvement present with fever of unknown origin (Chap. 18). The pulse rate is slow in relation to the fever. When splenomegaly is present in a patient with acute pneumonitis, psittacosis should be considered; the reported incidence of splenomegaly in this disease ranges from 10 to 70%. Nontender hepatic enlargement also occurs, but jaundice is rare. Thrombophlebitis is not unusual during convalescence; indeed, pulmonary infarction is sometimes a late complication and may be fatal.

In untreated cases of psittacosis, sustained or mildly remittent fever persists for 10 days to 3 weeks or occasionally for as long as 3 months. Over this period, the respiratory manifestations gradually abate. Psittacosis contracted from parrots or parakeets is more likely to be a severe, prolonged illness than infection acquired from pigeons or barnyard fowl. Relapses occur but are rare. Occasional patients develop endocarditis, and *C. psittaci* infection should be considered in cases of culture-negative endocarditis. Secondary bacterial infections are uncommon. Immunity to reinfection is probably permanent.

**Laboratory Findings** The chest x-ray in psittacosis is nonspecific and may show pneumatic lesions that are usually patchy in appearance but can be hazy, diffuse, homogeneous, lobar, atelectatic, wedge-shaped, nodular, or miliary. The white blood cell count is normal or moderately decreased in the acute phase of the disease but may rise in convalescence. The erythrocyte sedimentation rate frequently is not elevated. Transient proteinuria is common. The cerebrospinal fluid sometimes contains a few mononuclear cells but is otherwise normal. Despite hepatomegaly, the results of liver function tests are generally normal or only mildly elevated.

The diagnosis can be confirmed only by isolation of the causative microorganism or by serologic studies. The agent is present in the blood during the acute phase of the disease and in the bronchial secretions for weeks or sometimes years after infection, but it is difficult to isolate. Further, the organism is hazardous to work with in the laboratory, and most clinical laboratories do not offer culture for *C. psittaci*. Thus psittacosis is most readily diagnosed by the demonstration of a rising titer of complement fixation antibody in the serum of a patient with a compatible clinical syndrome. Both an acute-phase and a convalescent-phase specimen should always be tested. *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* all share a genus-specific “group” antigen, which is the basis of the complement fixation test. Thus acute infections with *C. trachomatis* or *C. pneumoniae* can also produce titer rises in this test. However, these three species have different major outer-membrane proteins that are the principal antigens in the micro-IF test. If there is doubt as to the interpretation of the complement fixation test, the micro-IF test can be used to differentiate among these antigens. The prompt initiation of treatment with tetracycline has been shown to delay an antibody rise in convalescence for several weeks or months.

**Differential Diagnosis** A history of exposure to birds may be the only clinical basis for differentiating psittacosis from a variety of infectious and noninfectious febrile disorders. The list of pulmonary diseases that may be confused with psittacosis includes *Mycoplasma pneumoniae*, *C. pneumoniae* pneumonia, legionellosis, viral pneumonia, Q fever, coccidioidomycosis, tuberculosis, enterovirus infection, carcinoma of the lung with bronchial obstruction, and common bacterial pneumonias. In the early stages, before pneumonitis appears, psittacosis may be mistaken for influenza, typhoid fever, miliary tuberculosis, or infectious mononucleosis.

**TREATMENT**

The tetracyclines are consistently effective in the treatment of psittacosis. Defervescence and alleviation of symptoms usually take place within 24 to 48 h after the institution of therapy with 2 g daily in four divided doses. To avoid relapse, treatment should probably be continued for at least 7 to 14 days after defervescence. In severe cases, hospitalization and pulmonary intensive care may be indicated. Sulfonamides are not active against *C. psittaci*. Erythromycin can be used in patients allergic to or intolerant of tetracyclines.

**C. PNEUMONIAE INFECTIONS**

**Definition** A third chlamydial species that causes disease in humans, *C. pneumoniae*, has been described in the past quarter century. *C. pneumoniae* can be distinguished from the other two species on the basis of DNA hybridization and elementary body morphology. Although *C. pneumoniae* can be grown in a variety of cell cultures, it is considerably more difficult to culture than other chlamydiae, especially from clinical specimens. HL cells appear to be the most effective cell line for isolation of *C. pneumoniae*.

**Epidemiology** Knowledge of the epidemiology of *C. pneumoniae* infections has been derived primarily from serologic studies. Infections begin to occur in late childhood, achieve peak incidence in young adults, but continue throughout adult life. Seroprevalence in the majority of adult populations that have been tested throughout the world exceeds 40%—a figure suggesting that *C. pneumoniae* infections are ubiquitous. Secondary episodes (reinfections) appear to occur commonly in older adults throughout life. *C. pneumoniae* also produces epidemics of pneumonia and respiratory illness, especially in close residential quarters such as military barracks. The incidence of infections outside of epidemics remains poorly defined. Transmission appears to be from person to person, probably primarily in schools and family units.

**Pathogenesis** Little is known about the pathogenesis of *C. pneumoniae* infection. The infection begins in the upper respiratory tract and in many persons is a long-lived asymptomatic condition of the upper respiratory mucosal surfaces. However, in at least some individuals, the organism is transported to distant sites—perhaps within macrophages—since evidence exists for replication within arteries and synovial membranes of joints. A *C. pneumoniae* outer-membrane protein may induce host immune responses whose cross-reaction with human proteins results in an autoimmune reaction.

**Clinical Manifestations** The clinical spectrum of *C. pneumoniae* infection includes acute pharyngitis, sinusitis, bronchitis, and pneumonitis, primarily in young adults. The clinical manifestations of primary infection appear to be more severe and prolonged than those of reinfection. The pneumonitis resembles that of *M. pneumoniae* pneumonia in that leukocytosis is frequently lacking and patients often have prominent antecedent upper respiratory tract symptoms, fever, nonproductive cough, a mild to moderate degree of illness, minimal findings on chest auscultation, and small segmental infiltrates on chest x-ray. In elderly patients, pneumonia due to *C. pneumoniae* can be especially severe and may necessitate hospitalization and respiratory support.

Epidemiologic studies have demonstrated an association between serologic evidence of *C. pneumoniae* infection and atherosclerotic disease of the coronary and other arteries. In addition, *C. pneumoniae* has been identified in atherosclerotic plaques by electron microscopy, DNA hybridization, and immunocytochemistry. The organism has been recovered in culture from atheromatous plaque—a result indicating the presence of viable replicating bacteria in vessels. Evidence from animal models supports the hypothesis that *C. pneumoniae* infection of the upper respiratory tract is followed by recovery of the organism from atheromatous lesions in the aorta and that the infection accelerates the process of atherosclerosis, especially in hypercholester-
terolymic animals. Antimicrobial treatment of the infected animals reverses the increased risk of atherosclerosis. In humans, two small trials in patients with unstable angina or recent myocardial infarction also suggested that antibiotics reduce subsequent untoward cardiac events. Larger trials have been initiated to determine more definitively whether antibiotics affect the risk of atherosclerosis.

Diagnosis Diagnosis of *C. pneumoniae* infection is currently difficult because cell culture techniques are not available for routine clinical use and nonculture tests using antigen detection methods or DNA probes have not been developed for commercial use. Acute- and convalescent-phase sera can be tested for chlamydial complement fixation antibody to make a retrospective diagnosis. However, this test does not distinguish *C. pneumoniae* infection from infection due to *C. trachomatis* or *C. psittaci.*

### TREATMENT

Although controlled treatment trials have not been conducted, *C. pneumoniae* is inhibited in vitro by erythromycin and tetracycline. Recommended therapy consists of 2 g per day of either agent for 10 to 14 days. Other macrolides, such as azithromycin, and some fluoroquinolones, such as levofloxacin, also appear to be effective.

---

**DEFINING A VIRUS**

Viruses consist of a nucleic acid surrounded by one or more proteins. Some viruses also have an outer-membrane envelope. Viruses are obligate intracellular parasites; they can replicate only within cells since their nucleic acids do not encode the many enzymes necessary for protein, carbohydrate, or lipid metabolism and for the generation of high-energy phosphates. Typically, viral nucleic acids encode proteins necessary for replicating and packaging the nucleic acids within the biochemical milieu of host cells.

Viruses differ from viroids, prions, and virusoids. **Virusoids** are nucleic acids that depend on helper viruses to package their nucleic acids into virus-like particles. **Viroids** are naked, cyclical, mostly double-stranded, small RNAs. Viroids, which appear to be restricted to plants, spread from cell to cell and are replicated by cellular RNA polymerase II. **Prions** (Chap. 362) are abnormal protein molecules that can spread and change the structure of their normal counterparts (cellular proteins). Prions have been implicated in neurodegenerative conditions such as Creutzfeldt-Jakob disease, Gerstmann-Sträussler disease, kuru, and human bovine spongiform encephalopathy (“mad cow disease”).

### VIRAL STRUCTURE

Viruses have from a few to several hundred genes. These genes may be in a single-strand or double-strand DNA genome or in a single-strand sense, a single-strand or segmented antisense, or a double-strand segmented RNA genome. Sense-strand RNA genomes can be translated directly into protein. Sense and antisense genomes are also referred to as positive-strand and negative-strand genomes, respectively. The viral nucleic acid is usually associated with one or more virus-encoded nucleoproteins in the core of the viral particle. The viral nucleic acid and nucleoproteins are almost always enclosed in a protein shell called a capsid. Because of the limited genetic complexity of viruses, their capsids are usually composed of multimers of identical capsomers. Capsomers are in turn composed of one or a few proteins. Capsids have icosahedral or helical symmetry. Icosahedral structures approximate spheres but have two-, three-, and fivefold axes of symmetry, while helical structures have only a twofold axis of symmetry. The entire structural unit of nucleic acid, nucleoprotein(s), and capsid is called a nucleocapsid. Many human viruses are simply composed of a core and a capsid. For these viruses, the outer surface of the capsid mediates contact with uninfected cells. Other viruses are more complex and have an outer lipid-containing envelope derived from virus-modified membranes of the infected cell. The piece of infected-cell membrane that becomes the viral envelope has usually been modified during infection by the insertion of virus-encoded glycoproteins. Virus-encoded glycoproteins usually mediate contact of enveloped viruses with uninfected cells. Matrix or tegument proteins fill the space between the nucleocapsid and the envelope in many enveloped viruses. In general, enveloped viruses are sensitive to lipid solvents and nonionic detergents that can dissolve the envelope, while viruses that consist only of nucleocapsids are somewhat resistant. A schematic diagram for large and complex herpesviruses is shown in Fig. 161-1. Prototypic pathogenic human viruses are listed in Table 161-1. The relative sizes and structures of typical pathogenic human viruses are shown in Fig. 161-2.
Further subclassification into genus is dependent on similarities in epidemiology and biologic effects and on the degree of colinear nucleic acid sequence homology. Most human viruses have a common name related to their pathologic effects or the circumstances of their discovery. Formal species names have been assigned by the International Committee on Taxonomy of Viruses. The latter designation consists of the name of the host followed by the family or genus of the virus and a number. This dual terminology has created a confusing situation in which viruses are referred to and referenced by either name—e.g., varicella-zoster virus (VZV) or human herpesvirus (HHV) 3.

**VIRAL INFECTION IN VITRO**

**STAGES OF VIRAL INFECTION AT THE CELLULAR LEVEL**

**Viral Interactions with the Cell Surface and Cell Entry**

Viral infection is initiated by adsorption of the virus to the cell surface. Adsorption results from the molecular interaction of viral surface proteins with receptors on the cell’s plasma membrane. For example, a poliovirus capsid protein binds to a cell plasma-membrane protein of the immunoglobulin superfAMILY type. A rhinovirus capsid protein binds to intracellular adhesion molecule 1. An echovirus capsid protein binds to an integrin. The influenza A virus envelope hemagglutinin protein binds to sialic acid. The HIV envelope glycoprotein binds to CD4 and then engages one of several chemokine receptors that function as coreceptors for the virus. Herpes simplex virus (HSV) envelope glycoproteins bind to heparan sulfate on cell surfaces and then engage one of several immunoglobulin superfamily or tumor necrosis factor (TNF) receptors. Epstein-Barr virus (EBV) glycoprotein gp350 binds to the B lymphocyte complement receptor CD21. Adsorption characteristically proceeds almost as well at 4°C as at 37°C. Adsorbed virus can still be neutralized by antibody. Adsorption frequently initiates changes in virion surface proteins that destabilize the viral surface proteins and prepare the way for the next stage of entry into the cell.

After adsorption, viruses penetrate the cell membrane by fusing with the membrane. The fusion reaction results in the virus’s partial decomposition. The virus becomes insensitive to neutralizing antibody as it penetrates, becomes uncoated, and enters the cytoplasm. Penetration and uncoating result in viral nucleocapsid or nucleoprotein entry into the cytoplasm. Penetration and uncoating as well as subsequent steps in viral replication depend on the cell’s energy metabolism and on biochemical changes in the cell’s plasma membrane and cytoskeleton. Therefore, penetration proceeds slowly at temperatures <37°C. Interaction of viral surface proteins with cell receptors can induce receptor aggregation at the site of adsorption. Receptor aggregation can trigger signaling events within the cytoplasm and changes in the plasma membrane. The cell frequently misperceives that the receptor has encountered its “normal ligand.” Aggregated receptor may be internalized with the attached virus in an endocytic process. Viral endocytosis may proceed through clathrin-coated pits. Endocy-

*Including the coronavirus causing severe acute respiratory syndrome (SARS).*

*Also called human herpesvirus (HHV) 1 and 2, respectively; also called HHV-3; also called HHV-4; also called HHV-5; also called HHV-8.*

**Abbreviations:** ds, double-strand; ss, single-strand.

**TAXONOMY OF PATHOGENIC HUMAN VIRUSES**

As is apparent from Table 161-1 and Fig. 161-2, the classification of viruses into orders and families is based on nucleic acid composition, nucleocapsid size and symmetry, and presence or absence of an envelope. Viruses of a single family have similar types of genomes and are often morphologically indistinguishable in electron micrographs.
tosis is important in the entry of viruses as diverse as picornaviruses, influenza viruses, HIV, adenoviruses, and herpesviruses. In many cases, entry of the virus into the cytoplasm depends on acidification of the viral endosome.

One of the best-studied examples of the effect of low pH on viral penetration is influenza virus. Influenza hemagglutinin mediates adsorption, receptor aggregation, and endocytosis. In low-pH endosomes, changes in the conformation of the hemagglutinin expose amphipathic domains that interact chemically with the cell membrane and initiate fusion of the viral and cellular membranes. The HIV envelope glycoprotein undergoes similar conformational changes after interaction with CD4 and chemokine receptors. For influenza virus, the M2 membrane protein also plays a key role in the uncoating of the viral envelope by providing an ion channel in the envelope. Fusion of viral and cell membranes results in the mixing of viral envelope lipids and proteins with cell membrane lipids and proteins and the penetration of the influenza nucleocapsid into the cytoplasm. With more complex viruses, such as herpesviruses, different glycoproteins interact with specific receptors on different cell types or on different surfaces of polarized epithelial cells. Viral glycoproteins other than the protein that mediates initial adsorption may be critical in mediating envelope fusion with cell membranes. The fusion of viral proteins with cell membranes is a crucial step in viral infection, which involves hydrophobic interactions. Hydrophobic interactions can be susceptible to chemical inhibition or blockade.

Viral Gene Expression and Replication After uncoating and release of viral nucleoprotein into the cytoplasm, the viral genome is transported to a site for expression and replication. In order to produce infectious progeny, viruses must (1) produce proteins necessary to replicate their nucleic acid, (2) produce structural proteins, and (3) assemble the nucleic acid and proteins into progeny virions. Different viruses use different strategies and gene repertoires to accomplish these goals. DNA viruses, except for poxviruses, replicate their nucleic acid and assemble into nucleocapsid complexes in the cell nucleus. RNA viruses, except for influenza viruses, transcribe and replicate their nucleic acid and assemble entirely in the cytoplasm. Thus, the replication strategies of DNA and RNA viruses are presented separately below. Positive-strand and negative-strand RNA viruses are discussed separately. Medically important viruses of each group are used for illustrative purposes.

**POSITIVE-STRAND RNA VIRUSES** Medically important positive-strand RNA viruses include picornaviruses, flaviviruses, togaviruses, caliciviruses, and coronaviruses. Genomic RNA from positive-strand RNA viruses is released into the cytoplasm without associated enzymes. Cell ribosomes recognize and associate with an internal ribosome entry sequence in the viral genomic RNA and translate a polyprotein that is a fusion of many or all of the viral proteins. The viral RNA polymerase and other viral proteins are cleaved from the polyprotein by protease components of the polyprotein. Antigenomic RNA is then transcribed from the genomic RNA template. Positive-strand genomes and mRNAs are next transcribed from the antigenomic RNA by the viral RNA polymerase. Positive-strand genomic RNA is encapsidated in the cytoplasm.

**NEGATIVE-STRAND RNA VIRUSES** Medically important negative-strand RNA viruses include rhabdoviruses, filoviruses, paramyxoviruses, myxoviruses, and bunyaviruses. Negative-strand RNA virus genomes are released into the cytoplasm with an associated RNA polymerase and one or more accessory proteins. Some of these genomes are segmented. Except for influenza viruses, negative-strand RNA viruses replicate entirely in the cytoplasm. The viral RNA polymerase transcribes messenger RNAs (mRNAs) as well as full-length antigenomic RNA, which is the template for replication of genomic RNA. These mRNAs encode for the viral RNA polymerase and accessory factors as well as for viral structural proteins. Influenza virus is an unusual negative-strand RNA virus that transcribes its mRNAs and antigenomic RNAs in the cell’s nucleus. The influenza genome RNA snatches cellular mRNA cap sequences to enhance translation of viral mRNAs and uses cell splicing machinery to encode additional viral mRNAs. All negative-strand RNA viruses, including influenza viruses, assemble in the cytoplasm.

**DOUBLE-STRAND SEGMENTED RNA VIRUSES** These viruses, which are taxonomically grouped in the reovirus family, have 10 to 12 RNA segments that make up their genome. The medically important viruses in this group are rotaviruses and Colorado tick fever virus. Reovirus virions include an RNA polymerase complex. Reoviruses replicate and assemble in the cytoplasm.

**DNA VIRUSES** Medically important DNA viruses include paroviruses, papovaviruses (e.g., human papillomaviruses, or HPV’s, and polyomaviruses), adenoviruses, herpesviruses, and poxviruses. Other than poxviruses, most DNA viruses must get to the cell’s nucleus for DNA transcription by cellular RNA polymerase II. For example, after receptor binding and fusion, herpesvirus nucleocapsids are released into the cytoplasm along with tegument proteins. The complex is then transported along microtubules to nuclear pores, and the DNA is released into the nucleus.
Transcriptional regulation and mRNA processing for nuclear DNA viruses depend on both viral and cellular proteins. For herpesviruses, the viral tegument protein activates transcription of viral immediate-early genes, a class of genes expressed immediately after infection. Transcription of immediate-early genes requires the viral tegument protein and preexisting cellular transcription factors. One of the key preexisting cellular factors for HSV-1 immediate-early gene transcription is docked in the cytoplasm in neurons. Nuclear absence of this critical cell factor important for viral gene transcription may explain why HSV-1 goes into a latent state in neurons and how lytic infection is activated by signaling in a latently infected cell.

DNA virus gene transcription is usually regulated and proceeds in an organized cascade. Transcription and expression of adenovirus and herpesvirus immediate-early genes turn on the promoters for early genes in a sequential fashion, whereas poxvirus virions carry all the factors necessary for early-gene transcription. Smaller DNA viruses are not as dependent on transactivators encoded from the viral genome for early-gene transcription. Most early genes encode proteins that are necessary for viral DNA synthesis and for the turn-on of late-gene transcription. Late genes encode mostly viral structural proteins or viral proteins necessary for the assembly and egress of the virus from the infected cell. Late-gene transcription is continuously dependent on DNA replication. Therefore, inhibitors of DNA replication also stop late-gene transcription.

Each DNA virus family uses unique mechanisms for replicating its DNA. Herpesvirus DNAs are linear in the virion but circularize in the infected cell. In lytic virus infection, circular herpesvirus genomes are replicated into linear concatemers through a “rolling-circle” mechanism. Herpesviruses encode a DNA polymerase and at least six other viral proteins necessary for viral DNA replication; these viruses also encode several enzymes that increase the pool of precursor deoxyribonucleotide triphosphates. Adenovirus genomes are linear in the virion and are replicated into complementary linear copies by a virus-encoded DNA polymerase and an initiator protein complex. The double-strand circular papovavirus genomes are replicated into progeny circular DNA molecules by cellular DNA replication enzymes. Two viral early proteins contribute to viral DNA replication and to the persistence of papovavirus DNA in latently infected cells. Early papovavirus proteins stimulate cells to remain in cycle, thus facilitating viral DNA replication. Occasionally, HPV integrates into the host chromosome; overexpression of viral early proteins and excessive stimulation of cellular growth can result. Sometimes the consequence is the development of malignancies such as cervical cancer (see “Persistent Viral Infections and Cancer,” below).

Parvoviruses are the smallest DNA viruses: their genomes are half the size of the papovavirus genomes and include only two genes. Parvoviruses have negative single-strand DNA genomes. The replication of autonomous parvoviruses, such as B19, depends on cellular DNA replication and requires the virus-encoded Rep protein. Other parvoviruses, such as adeno-associated virus (AAV), are not autonomous but require helper viruses of the adenovirus or herpesvirus family for their replication. AAV has been touted as a potentially safe human gene therapy vector because its Rep protein causes its integration at a single chromosomal site.

Poxviruses are the largest DNA viruses and are unique among DNA viruses in replicating and assembling in the cytoplasm. Poxviruses encode transcription factors and an RNA polymerase as well as enzymes for RNA capping and polyadenylation and for DNA synthesis. Poxvirus DNA also has a unique structure. The two strands of the double-strand linear DNA are covalently linked at the ends so that the genome is also a covalently closed single-strand circle. In addition, there are inverted repeats at the ends of the DNA. During DNA replication, the genome is cleaved within the terminal inverted repeat, and the inverted repeats self-prime complementary-strand synthesis by the virus-encoded DNA polymerase. Like herpesviruses, poxviruses encode several enzymes that increase deoxynucleotide triphosphate precursor levels and thus facilitate viral DNA synthesis.

**Viruses with Both RNA and DNA Genomes**

Retroviruses and hepatitis B virus (HBV) are not purely RNA or DNA viruses. Retroviruses are enveloped RNA viruses with two identical sense-strand genomes and associated reverse transcriptase and integrase enzymes. Retroviruses differ from all other viruses in that they reverse-transcribe themselves into partially duplicated double-strand DNA copies and then routinely integrate into the host genome as part of their replication strategy. Cellular RNA polymerase II and transcription factors regulate transcription from the integrated provirus genome. Some retroviruses also encode for regulators of transcription and RNA processing, such as Tax and Rex in human T-lymphotropic virus (HTLV) types I and II and Tat and Rev in HIV-1 and HIV-2. HIV genomes also encode for the additional accessory proteins Vpr, Vpu, and Vif, which are important for efficient infection and immune escape. Full-length proviral transcripts are made from a promoter in the viral terminal repeat and serve as both genomic RNAs that will be packaged in the nucleocapsids and mRNAs that encode for the viral Gag protein, polymerase/integrase, and envelope glycoprotein. The Gag protein includes a protease that cleaves it into several components, including a viral matrix protein that coats the viral RNA. Viral RNA polymerase/integrase, matrix protein, and cellular tRNA are key components of the viral nucleocapsid. The HIV Gag protease has been an important target for inhibition of HIV replication. Remnants and even complete copies of simple retroviral DNA in the human genome indicate that there may be replication-competent simple human retroviruses. However, replication has not been documented or associated with any disease. Integrated retroviral DNAs are also present in other animal species, such as pigs. These porcine retroviruses are a potential cause for concern in xenotransplantation because retroviral replication could cause disease in humans. Since the retroviral DNA is integrated into the porcine genome, special pathogen-free breeding practices cannot cleanse the donor herd of retroviral infection.

HBV is unique because virion DNA expression in infected cells results in the packaging of reverse transcriptase and genomic RNA in the virion. The genomic RNA is then copied into an incomplete double-strand circular DNA genome before the virion matures and is released from the infected cell. On entry of HBV into the cytoplasm of an infected cell, the virion reverse transcriptase/DNA polymerase completes DNA synthesis, and the covalently closed circular genome resides in the nucleus. Viral mRNAs are transcribed from the closed circular viral epismes by cellular RNA polymerase II. A capped and polyadenylated, full-genome-length, terminally redundant transcript is packaged into virus core particles in the cytoplasm of infected cells. This RNA associates with the viral reverse transcriptase. The reverse transcriptase converts the full-length, terminally redundant, core-particle, encapsidated RNA genome into partially double-strand DNA. HBV is believed to mature by budding through the cell’s plasma membrane, which has been modified by the insertion of viral surface antigen protein.

**Viral Assembly and Egress**

For most viruses, nucleic acid and structural protein synthesis are accompanied by the assembly of protein and nucleic acid complexes. The assembly and egress of mature infectious virus mark the end of the eclipse phase of infection, during which infectious virus cannot be recovered from the infected cell. Nucleic acids from RNA viruses and poxviruses assemble into nucleocapsids in the cytoplasm. For all DNA viruses except poxviruses, viral DNA assemblies into nucleocapsids in the nucleus. In general, the capsid proteins of viruses with icosahedral nucleocapsids can self-assemble into densely packed and highly ordered capsid structures. Herpesviruses require an assemblin protein as a scaffold for capsid assembly. Viral nucleic acid then spoils into the assembled capsid. For herpesviruses, a full unit of the viral DNA genome is packaged into the capsid, and a capsid-associated nuclease cleaves the viral DNA at both ends. In the case of viruses with helical nucleocapsids, the protein
component appears to assemble around the nucleic acid, which contributes to capsid organization.

Viruses must egress from the infected cell and not bind back to the outer surface of the plasma membrane. In many cases, enveloped viruses simply egress and acquire their envelope by budding through the cell’s plasma membrane. Excess viral membrane glycoproteins are synthesized to saturate cell receptors and facilitate virus separation from the infected cell. Some viruses encode membrane proteins with enzymatic activity for receptor degradation. Influenza virus, for example, encodes a glycoprotein with neuraminidase activity, which destroys sialic acid on the infected cell’s plasma membrane. Herpesvirus nucleocapsids acquire their initial envelope by assembling in the nucleus and then budding through the nuclear membrane into the endoplasmic reticulum space. The enveloped herpesvirus is then released from the cell either by maturation in cytoplasmic vesicles, which fuse with the plasma membrane and release the virus by exocytosis, or by “de-envelopment” into the cytoplasm and “re-envelopment” at the plasma membrane. In most instances, nonenveloped viruses appear to depend on the death and dissolution of the infected cell for their release.

**FIDELITY OF VIRAL REPLICATION** Cells grow by doubling their genome and dividing, whereas viruses typically make large quantities of viral nucleic acid and structural proteins, and thousands of progeny may be produced from a single virus-infected cell. Many particles partially assemble and never mature into virions. Many mature-appearing virions are imperfect and have only incomplete or nonfunctional genomes. Despite the inefficiency of assembly, a typical virus-infected cell releases 10 to 1000 infectious progeny. Some of these progeny may contain genomes that differ from those of the virus that infected the cell. Smaller, “defective” virus genomes have been noted with the replication of many RNA and DNA viruses. Virions with defective genomes can be produced in large numbers through packaging of incompletely synthesized nucleic acid. Adenovirus packaging is notoriously inefficient, and a high particle-to-infectious virus ratio may limit the amount of recombinant adenovirus that can be administered for gene therapy. Mutant viral genomes are also produced and can be of medical significance. In general, viral nucleic acid replication is more error-prone than cellular nucleic acid replication. RNA polymerases and reverse transcriptases are significantly more error-prone than DNA polymerases. Mutant viruses can be virulent and may preferentially cause disease through evasion of the host immune response or through resistance to antiviral drugs. Persistent hepatitis C virus (HCV) infection appears to be due to genome mutation and persistent immune escape. Viral nucleic acids can also mutate by recombination or reassortment between two related viruses in a single cell. While this occurrence is unusual under most circumstances of natural infection, the changes can be substantial and can significantly alter virulence or epidemiology. Reassortment of an avian or mammalian influenza A hemagglutinin gene into a human influenza background is believed to play a role in the emergence of new epidemic influenza A strains.

**VIRAL GENES NOT REQUIRED FOR VIRAL REPLICATION** Viruses frequently have genes encoding proteins that are not directly involved in replication or packaging of the viral nucleic acid, in virion assembly, or in regulation of the transcription of viral genes involved in those processes. Most of these proteins fall into five classes: (1) proteins that directly or indirectly alter cell growth; (2) proteins that inhibit cellular RNA or protein synthesis so that viral mRNA can be efficiently transcribed or translated; (3) proteins that promote cell survival or inhibit apoptosis so that progeny virus can mature and escape from the infected cell; (4) proteins that inhibit the host interferon response; and (5) proteins that downregulate host inflammatory or immune responses so that virus infection can proceed in an infected person to the maximum extent consistent with the survival of the virus and its efficient transmission to a new host. More complex viruses of the poxvirus or herpesvirus family encode many proteins that serve these functions. Some of these viral proteins have motifs similar to those of cell proteins, while others are quite novel. Virology has increasingly focused on these more sophisticated strategies evolved by viruses to permit the establishment of long-term infection in humans and other animals. These strategies often provide unique insights into the control of cell growth, cell survival, macromolecular synthesis, proteolytic processing, immune or inflammatory suppression, immune resistance, cytokine mimicry, or cytokine blockade.

**HOST RANGE** The concept of host range was originally based on the cell types in which a virus replicated in tissue culture. For the most part, the host range is limited by specific cell-surface proteins required for viral adsorption or penetration. Another common basis for host-range limitation is transcription from viral promoters. Most DNA viruses depend not only on cellular RNA polymerase II and the basal components of the cellular transcription complex but also on activated components and transcriptional accessory factors, both of which differ among differentiated tissues, among cells at various phases of the cell cycle, and between resting and cycling cells.

The concept of host range for virus infection in humans includes these factors and others since (1) most viruses infect more than one cell type in vivo, and (2) the viral life cycle and extent of viral replication can be affected by the differentiation and activation state of a given cell type. This point is particularly relevant for human papovavirus, herpesvirus, and lentivirus infections, in which vigorous replication during initial infection may be followed by quiescent or latent infection—a situation that allows the virus to persist.

**VIRAL CYTOPATHIC EFFECTS AND INHIBITORS OF APOPTOSIS** The replication of almost all viruses has adverse effects on the infected cell, inhibiting cellular synthesis of DNA, RNA, or proteins. This inhibitory effect probably stems from the viruses’ need to prevent or limit nonspecific, innate host resistance factors, including interferon (IFN). Most commonly, viruses specifically inhibit host protein synthesis by attacking a component of the translational initiation complex—frequently, a component that is not required for efficient translation of viral RNAs. Poliovirus protease 2A, for example, cleaves a cellular component of the complex that ordinarily facilitates translation of cell mRNAs by interacting with their cap structure. Poliovirus RNA is efficiently translated without a cap since it has an internal ribosome entry sequence. Influenza virus inhibits the processing of mRNA by snatching cap structures from nascent cell RNAs and using them as primers in the synthesis of viral mRNA. HSV has a virion tegument protein that inhibits cellular mRNA translation.

Apoptosis is the expected consequence of virus-induced inhibition of cellular macromolecular synthesis and viral nucleic acid replication. While the induction of apoptosis may be important for the release of some viruses (particularly nonenveloped viruses), many viruses have acquired genes or parts of genes that enable them to forestall infected cell apoptosis. This delay may be advantageous in allowing the completion of viral replication. Adenoviruses and herpesviruses encode analogues of the cellular Bcl12 protein, which blocks mitochondrial enhancement of proapoptotic stimuli. Poxviruses and some herpesviruses encode caspase inhibitors. Many viruses, including HPVs and adenoviruses, encode proteins that inhibit p53 or its downstream proapoptotic effects.

**VIRAL INFECTION IN VIVO** The capsid and envelope of a virus protect its genome and permit its efficient transmission from cell to cell and to prospective hosts. Most common viral infections are spread by aerosolized particles, by ingestion of contaminated water or food, or by direct contact. In all these situations, infection begins on an epithelial or mucosal surface and spreads along it or from it to deeper tissues. Infection may then spread through the body via the bloodstream, lymphatics, or neural circuits. Parenteral inoculation also serves to transmit some viral infections among humans or from animals, including insects, to humans.
PRIMARY INFECTION The first (primary) episode of viral infection usually lasts from several days to several weeks. During this period, the concentration of virus at sites of infection rises and then falls, usually to unmeasurable levels. The rate at which the intensity of viral infection rises and falls at a given site depends on the accessibility of that organ or tissue to both the virus and systemic immune effectors, the intrinsic ability of the virus to replicate at that site, and endogenous non-specific and specific resistance. Typically, infections with enterovirus, mumps virus, measles virus, rubella virus, rotavirus, influenza virus, AAV, adenovirus, HSV, and VZV are cleared from all sites within 3 to 4 weeks. Some of these viruses are especially profi cient in altering or evading the innate and acquired immune responses; thus primary infection with AAV, EBV, or cytomegalovirus (CMV) can last for several months. Characteristically extending beyond several weeks are primary infections due to HBV, HCV, hepatitis D virus (HDV), HIV, HPV, and molluscum contagiosum virus. For some of these viruses (e.g., HPV, HBV, HCV, HDV, and molluscum contagiosum virus), the primary phase of infection is almost indistinguishable from the persistent phase.

Disease manifestations usually arise as a consequence of viral replication and the resultant inflammatory response at a specific site but do not necessarily correlate with levels of replication at that site. For example, the clinical manifestations of limited infection with poliovirus, enterovirus, rabies virus, measles virus, mumps virus, or HSV in neural cells are severe relative to the level of viral replication at mucosal surfaces. Similarly, significant morbidity may accompany in utero fetal infection with rubella virus or CMV.

Primary infections are cleared by nonspecific innate and specific adaptive immune responses. Thereafter, an immunocompetent host is usually immune to the disease manifestations of reinfection by the same virus. Immunity frequently does not prevent transient surface colonization on reexposure, persistent colonization, or even limited deeper infection.

PERSISTENT AND LATENT INFECTIONS Relatively few viruses cause persistent or latent infections. HBV, HCV, rabies virus, measles virus, HIV, HTLV, HPV, HHV, and some poxviruses are notable exceptions. The mechanisms for persistent infection vary widely. In persistent HCV infection and to a lesser extent in HIV infection, the high mutation rates in viral genome replication or reverse transcription significantly facilitate persistent infection, continuously yielding mutant viruses that have lost antigenic determinants to which the host has developed effective immune responses. HIV is also directly immunosuppressive, depleting CD4+ T lymphocytes and compromising CD8+ cytotoxic T-cell immune responsiveness. Moreover, HIV encodes a Nef protein that downmodulates major histocompatibility complex (MHC) class I expression, rendering HIV-infected cells partially resistant to immune CD8+ cytosis. The high mutation rate and the magnitude of the viral load conspire to promote persistent infection with drug-resistant HIV mutants.

In contrast, DNA viruses have much lower mutation rates. Their persistence is due to their ability to establish latent infection and to reactivate from latency. In this instance, latency is defined as a state of infection in which the virus is not replicating. The complete viral genome is present and may be replicated by cellular DNA polymerase in conjunction with the cell genome replication. Viral genes associated with lytic infection are not expressed and infectious virus is not made. HSVs establish latent infection in basal epithelial cells, which replicate. Some of the progeny cells provide a stable supply of latently infected basal cells, while others go on to squamous differentiation and, in the process, become permissive for lytic viral infection. For herpesviruses, latent infection is established in nonreplicating neural cells (HSV and VZV) or in replicating cells of hematopoietic lineages (EBV and HHV-6) or in neuronal and glioma cells (CMV, HHV-5, and HHV-8). Reactivation of herpesassociated herpesvirus (KSHV, also known as HHV-8]), Reactivation from neural latency appears to be an intermittent process provoked by external stimuli, whereas reactivation from hematopoietic precursors appears to be a more continuous process. In their latent stage, HPV and herpesvirus genomes are largely hidden from the normal immune response. It is still not fully understood how partially latent and reactivated HPV and herpesvirus infections escape immediate and effective immune responses in highly immune hosts. HPV, HSV, and VZV may be somewhat protected because of their replication in middle and upper layers of the squamous epithelium—sites not routinely visited by immune and inflammatory cells. HSV and CMV are also known to encode proteins that downregulate MHC class I expression and antigenic peptide presentation on infected cells, thereby enabling these cells to escape CD8+ T lymphocyte cytotoxicity. Latent infection and intermittent reactivation perpetuate herpesvirus infections in human populations by allowing the viruses to persist in immune hosts and to be transmitted to the next generation of naive hosts.

Like other poxviruses, molluscum contagiosum virus cannot establish latent infection but rather causes persistent infection in hyperrophic lesions that last for months or years. This virus encodes a chemokine homologue that probably blocks inflammatory responses and an MHC class I analogue that may block cytotoxic T lymphocyte attack.

PERSISTENT VIRAL INFECTIONS AND CANCER Persistent viral infection is estimated to be the root cause of as many as 20% of human malignancies. For the most part, cancer is an accidental and highly unusual or long-term effect of infection with oncogenic human viruses. In these malignancies, viral infection is a critical and ultimately determinative early step, putting infected cells into cycle and enhancing their survival. An unusual virus-infected cell undergoes the subsequent genetic changes that permit the enhanced autonomous growth and survival characteristic of a highly malignant cell.

Most hepatocellular carcinoma is now believed to be caused by chronic inflammatory, immune, and regenerative responses to HBV or HCV infection. Epidemiologic data firmly link HBV and HCV infection to hepatocellular carcinoma. Studies in murine experimental models indicate that chronic liver injury and repair induced by virus-encoded proteins can result in hepatocellular cancer. In rare instances, HBV DNA integrates into cellular DNA—an event that probably contributes to the development of some tumors.

Almost all cervical carcinoma is caused by long-term persistent replication of “high-risk” genital HPV strains. Persistent, high-level HPV replication can result in the integration of a small fragment of the HPV genome encoding the HPV E6 and E7 proteins into chromosomal DNA. Integrations that result in overexpression of HPV type 16 or 18 E6 and E7 cause the loss of at least two major tumor-suppressive functions mediated by pRB and p53. This loss in turn causes profound changes in cell growth and survival. Nevertheless, subsequent chromosomal changes must occur over ensuing cycles of cell growth if a sufficiently malignant cell is to invade the surrounding tissues.

Similarly, long-term EBV infection and expression of the EBV oncogene LMP1 in latently infected epithelial cells appear to be critical early steps in the evolution of anaplastic nasopharyngeal carcinoma, a common malignancy in Chinese and North African populations. High-level LMP1 expression is also a hallmark of many cases of Hodgkin’s disease. Among younger age groups, >50% of Hodgkin’s disease tumors are clonally derived from an EBV-infected cell. The HTLV-I Tax and Rex proteins appear to be critical to the initiation of cutaneous adult T cell lymphoma/leukemias that may occur long after primary HTLV-I infection.

The EBV-related herpesvirus KSHV was identified in a search for the postulated sexually transmitted etiologic agent of Kaposi’s sarcoma in HIV-infected individuals. Molecular data confirm the presence of KSHV DNA in all Kaposi’s tumors, including those associated with HIV infection, transplantation, and familial transmission. KSHV infection is also etiologically implicated in pleural-effusion lymphomas and multicentric Castleman’s disease, which are more common among HIV-infected than among HIV-uninfected people.
Evidence supporting a causal role of viral infection in these malignancies includes epidemiologic data, the presence of viral DNA in all tumor cells, the ability of the viruses to transform human cells in culture, the results of in vitro assays for transforming effects of specific viral genes on cell growth, and pathologic data indicating the expression of transforming viral genes in premalignant or malignant cells in vivo.

EBV is a unique example of a human virus that relies on the normal immune response to contain the potentially unrestrained growth of infected cells. In the initial stages of normal primary EBV infection, EBV “latently” infects B lymphocytes and expresses at least eight viral proteins that play no role in viral replication but cause the expansion of latently infected cells. These infected cells can grow indefinitely. Most of the viral proteins that cause this proliferative state are highly antigenic. These virus-infected cells, which can transiently constitute 10% of the circulating B lymphocyte population, are met with an overwhelming helper and cytotoxic T cell response during primary infection. The number of virus-infected cells then falls rapidly, and the one EBV-infected cell in a million that persists does not express most of the viral proteins that cause B cell proliferation. These persisting cells are the site of normal latent infection. Breakthrough growth of the EBV-infected B lymphocytes almost never occurs in immunocompetent hosts. However, in immunosuppressed AIDS patients or organ transplant recipients, EBV-infected B lymphocytes expressing the full set of growth-transforming genes may grow and cause self-sustained and potentially fatal lymphoproliferative disease. Clinical investigation has resulted in novel strategies for treating these virus-induced malignancies with EBV-specific T cells or with antibody to B cells.

Resistance to viral infection is initially provided by factors that are not virus-specific. Physical protection is afforded by the cornified layers of the skin and by mucous secretions that continuously sweep over mucosal surfaces. Once the first cell is infected, viral infection induces IFNs, which are important local resistance factors. Viral infection may also trigger the release of other cytokines from infected cells; these cytokines may be chemotactic to inflammatory and immune cells. Viral protein epitopes expressed on the cell surface in the context of MHC class I and II HLA proteins attract T cells with appropriate receptors. Cytokines, inflammatory agents, and antigens released by virus-induced cell death further attract inflammatory cells, dendritic cells, granulocytes, natural killer (NK) cells, and B lymphocytes to the sites of initial infection and to draining lymph nodes. IFNs and NK cells are particularly important in containing viral infection for the first several days. Granulocytes and macrophages are also important in the phagocytosis and degradation of viruses, especially after an initial antibody response.

Some 7 to 10 days after infection, virus-specific antibody responses, virus-specific HLA class II–restricted CD4+ helper T lymphocyte responses, and virus-specific HLA class I–restricted CD8+ cytotoxic T lymphocyte responses emerge. These responses, whose magnitude typically increases over the second and third weeks of infection, are important in rapid recovery. Between the second and third weeks of infection, the antibody type usually changes from IgM to IgG; IgA antibody can then be detected at initially infected mucosal surfaces. Antibody may directly neutralize virus by binding to its surface and preventing its adsorption or penetration. Complement usually enhances antibody-mediated virus neutralization. Antibody and complement can also lyse virus-infected cells that express viral proteins on their surface. A cell infected with an enveloped virus usually expresses viral envelope glycoprotein components on its surface and is subject to destruction by antibodies and complement.

Antibody and CD4+/CD8+ T lymphocyte responses tend to persist for several months after primary infection. Antibody-producing lymphocytes persist in small numbers as memory cells and begin to proliferate rapidly in response to a second infection, providing an early boost to the response. During reexposure with the same virus, the memory for T cell responses appears to be shorter-lived. Redevelopment of T cell immunity may take longer than secondary antibody responses, particularly when many years have elapsed between primary infection and reexposure. Persistent or latent and reactivating viral infections can result in sustained high-level T cell responses.

Some viruses have genes that alter innate and acquired host defenses. Adenoviruses encode small RNAs that inhibit IFN shutoff of infected-cell protein synthesis. Adenovirus E1A inhibits IFN-mediated changes in cell gene transcription. Adenovirus E3 proteins prevent TNF-induced cytolysis and block HLA class I antigen synthesis by the infected cell. HSV ICp47 and CMV US11 block class I antigen presentation. EBV encodes an interleukin (IL) 10 homologue that inhibits NK and T cell responses. Vaccinia virus B15R is an IL-1 receptor decoy. Vaccinia virus CrmA inhibits the ability of CD8+ cytotoxic cells to kill virus-infected cells. Some poxviruses and herpesviruses encode blockers of chemokines and thereby inhibit cellular inflammatory responses. The adoption of these strategies by viruses highlights the importance of these host resistance factors in containing viral infection as well as the importance of redundancy in host resistance. The ultimate success of a virus requires a live host to help it disseminate infection.

Much has been written about the role of specific aspects of the host immune response in containment of specific virus infections. Certainly, T lymphocyte disorders and T cell immunosuppression for the purpose of transplantation or as a consequence of HIV infection are associated with severe primary and reactivated herpesvirus infections. Antibody responses are important in most viral infections and may be fully protective in many RNA virus infections. Specific immunoglobulin therapy can ameliorate even herpesvirus infections. T lymphocyte responses may play a significant role in resistance to RNA virus infections. Cytotoxic T cells specific for influenza virus nucleoprotein may provide a measure of protection that is independent of viral changes in hemagglutinin.

Host resistance does not come without a price. Clearly, aspects of the host response contribute to the pathophysiologic manifestations and symptoms of viral infection. Inflammation at sites of viral infection can increase rates of local cell death. Moreover, immune responses to viral infection could, in principle, result in immune attack of related epitopes on normal cells, with consequent autoimmunity. While such effects have been demonstrated in experimental models, their role in the autoimmune manifestations of primary or recurrent human viral infections is uncertain.

All human cells can synthesize IFN-α or -β in response to viral infection. These IFNs are usually induced by the presence of double-strand viral RNA, which can be made by both RNA and DNA viruses. IFN-γ is not highly related to IFN-α or β and is produced mainly by NK cells and by immune T lymphocytes responding to IL-12. IFN-α and -β bind to the IFN-α receptor, while IFN-γ binds to a different but related receptor. Both receptors signal through receptor-associated JAK kinases and other cytoplasmic proteins, including “STAT” proteins. STAT proteins are tyrosine-phosphorylated by JAK kinases, translocate to the nucleus, and transactivate promoters for specific cell genes. Three types of antiviral effects are induced by IFN at the transcriptional level. The first effect is attributable to the induction of 2′-5′ oligo(A) synthetases, which require double-strand RNA for their activation. Activated synthetase polymerizes oligo(A) and thereby activates RNase L, which in turn degrades single-strand RNA. The second effect takes place through the induction of PKR, a serine and threonine kinase that is also activated by double-strand RNA. PKR phosphorylates and negatively regulates the translational initiation factor eIF2-α, shutting down protein synthesis in the infected cell. A third effect is initiated through the induction of Mx proteins, a family of GTPases that is particularly important in inhibiting the replication of influenza virus and vesicular stomatitis virus (VSV) in Vero cells. Mx proteins block viral replication by inhibiting the expression of the viral protein nsP3. None of these IFN effects is directed specifically against the virus; infected-cell RNA and protein synthesis are globally inhibited by inhibiting
cell protein synthesis. IFN probably contributes to the death of the infected cell.

**DIAGNOSTIC VIROLOGY** A wide variety of methods are now used to diagnose viral infection. Serology and viral isolation in tissue culture remain important standards. Acute- and convalescent-phase sera with rising titers of antibody to virus-specific antigens and a shift from IgM to IgG antibodies are generally accepted as diagnostic of acute viral infection. Traditionally, virus-specific antibodies have been detected by hemadsorption, hemagglutination, or indirect immunofluorescence. Immunoassays use fixed virus-infected cells as a target for serum antibodies. Hemadsorption and hemagglutination assays measure the ability of serum antibodies to inhibit RNA virus–induced erythrocyte adsorption or agglutination. Serologic diagnosis is based on a greater-than-fourfold rise in IgG antibody concentration when acute- and convalescent-phase serum samples are analyzed at the same time. A simultaneous fall in IgM antibody confirms recent primary viral infection. Immunofluorescence, hemadsorption, and hemagglutination assays for antiviral antibodies are labor-intensive and are being replaced by enzyme-linked immunosorbent assays (ELISAs). ELISAs generally use specific viral proteins purified from virus-infected cells or produced by recombinant DNA technology. These viral antigens are attached to a solid phase, where they can be incubated with serum, washed to eliminate nonspecific antibodies, and reacted with an enzyme-linked reagent to detect human IgG or IgM antibody specifically adhering to the viral antigen on the solid phase. The amount of antibody can then be quantitated by the intensity of a color reaction mediated by the linked enzyme. ELISAs can be sensitive and automated. Western blots can confirm the presence of antibody to multiple specific viral proteins simultaneously. The proteins are separated by size and transferred to an inert membrane, where they are incubated with serum antibodies. Western blots have an internal specificity control, since the level of reactivity for viral proteins can be compared with that for cellular proteins in the same sample. Western blots require individual evaluation and are inherently difficult to quantitate or automate.

Virus isolation in tissue culture is dependent on the infection of susceptible cells and amplification by viral replication in infected cells. Virus growing in tissue culture cells can frequently be identified by its effect under light microscopy. For example, HSV produces a typical cytopathic effect in rabbit kidney cells within 3 days. Other viral cytopathic effects may not be as diagnostically useful. Identification may require confirmation by staining with virus-specific monoclonal antibodies. Viruses growing in tissue culture can also be identified by hemadsorption or by interference; e.g., epithelial cells obtained by nasopharyngeal aspiration can be stained with a variety of monoclonal antibodies to respiratory viruses. The Tzanck preparation can be used to detect multinucleated giant cells in HSV- or VZV-induced lesions. Tzanck preparations can be enhanced by the use of HSV- or VZV-specific monoclonal antibodies. Monoclonal antibodies can also be used in histopathology to identify virus-infected cells.

Advances in nucleic acid technology are revolutionizing diagnostic virology. The speed and sensitivity of tests that directly amplify minute amounts of viral nucleic acids present in specimens mean that detection no longer depends on viable virus and its replication. For example, amplification and detection of HSV nucleic acids in the CSF of patients with HSV encephalitis is a more sensitive detection method than culture of virus from CSF. The extreme sensitivity of these tests can be a problem, since subclinical infection or contamination can lead to false-positive results. Detection of viral nucleic acids does not necessarily indicate virus-induced disease. Herpesviruses can cause persistent asymptomatic infection.

Measurement of the amount of viral RNA or DNA in peripheral blood is becoming an important means for determining which patients are at increased risk for virus-induced disease and for evaluating clinical responses to antiviral chemotherapy. Nucleic acid technologies for RNA quantification are routinely used in AIDS patients to evaluate responses to antiviral agents and to detect resistance to or noncompliance with therapy. Viral-load measurements may also be useful for evaluating the treatment of patients with HBV and HCV infections. Direct staining with CMV-specific monoclonal antibodies to quantitate virus-infected cells in the peripheral blood or CMV antigenemia can be useful in identifying which immunosuppressed patients may be at risk for CMV-induced disease. CMV assays employing nuclear acid technologies for the same purpose have been approved for clinical use.

**DRUG TREATMENT FOR VIRAL INFECTIONS** Specific antiviral drugs have revolutionized treatment of herpes and HIV infections. Effective drugs have also been developed for influenza A and moderately effective drugs for respiratory syncytial virus and HCV infections. However, the emergence of drug-resistant strains in treated patients can limit therapeutic efficacy. The increased number of antiviral agents with different viral targets has made the identification of drug-resistant viruses clinically relevant, especially for HIV infection. Drug resistance in herpesviruses is a more unusual problem. HIV genotyping is a new method for the rapid identification of drug-resistant viruses. Resistance to reverse transcriptase or protease inhibitors has been associated with specific mutations in the reverse transcriptase or protease genes. Identification of these mutations by polymerase chain reaction amplification and nucleic acid sequencing can be clinically useful for determining which antiviral agents may still be effective. HCV genotyping may also identify patients who can benefit from combination chemotherapy.

**IMMUNIZATION FOR THE PREVENTION OF VIRAL INFECTIONS** Viral vaccines are among the outstanding accomplishments of medical science. Smallpox has been eradicated except as a potential weapon of biolog-
Viruses are being experimentally developed for the delivery of biotherapeutics or novel vaccines. Foreign genes can be inserted into viral nucleic acids, and the recombinant virus vectors can be used to infect the patient or the patient’s cells ex vivo. Retroviruses integrate into the cell genome and have been used to functionally replace the abnormal gene in T cells of patients with severe combined immunodeficiency (SCID), thereby restoring immune function. Recombinant adenovirus, AAV, and retroviruses are being explored for use in diseases due to single-gene defects, such as cystic fibrosis and hemophilia. Recombinant poxviruses and adeno-viruses are also being used experimentally as vaccine vectors. Viral vectors are being experimentally tested for expressing cytokines to improve immunity against tumor cells or for expressing proteins that can increase the sensitivity of tumor cells to chemotherapy.

For improved safety, nonreplicating viruses are frequently employed in clinical trial settings. Potential adverse events associated with virus-mediated gene transfer include the induction of inflammatory and antiviral immune responses. Adenoviruses contain many immunogenic proteins, and, since wild-type adenovirus infection is prevalent, immunity to adenovirus infection may reduce the efficacy of or enhance inflammatory responses to adenovirus gene therapy. Integration, another complication of virus-mediated gene therapy, is useful for permanent gene therapy, but integrations can induce disease by enhancing or disrupting the expression of important cellular genes.

**ANTIVIRAL CHEMOTHERAPY, EXCLUDING ANTIRETROVIRAL DRUGS**

Lindsey R. Baden, Raphael Dolin

The development of drugs for antiviral chemotherapy and chemoprophylaxis is a relatively recent but extremely active area of biomedical research. Significant progress has been made in recent years on new drugs for several viral infections. Despite these advances, the field of antiviral therapy—both the number of antiviral drugs and our understanding of their optimal use—continues to lag behind the field of antibacterial drug treatment, in which more than 60 years of experience have now been accumulated.

The development of antiviral drugs poses several challenges. Viruses replicate intracellularly and often employ host cell enzymes, macromolecules, and organelles for synthesis of viral particles. Therefore, useful antiviral compounds must discriminate between host and viral functions with a high degree of specificity; agents without such selectivity are likely to be too toxic for clinical use.

The development of laboratory assays to assist clinicians in the appropriate use of antiviral drugs is also in its infancy. Phenotypic and genotypic assays for resistance to antiviral drugs are becoming more widely available, and correlations of laboratory results with clinical outcomes in various settings are beginning to be defined. Of particular note has been the development of highly sensitive and specific methods to measure the concentration of virus in blood (virus load), which permit direct assessment of the antiviral effect of a given drug regimen in the host. Virus load measurements have been useful in recognizing the risk of disease progression in patients with certain viral infections and in identifying patients in whom antiviral chemotherapy might be of greatest benefit. Like any in vitro laboratory test, these tests yield results that are highly dependent on (and likely to vary with) the laboratory techniques employed.

Information regarding the pharmacokinetics of some antiviral drugs, particularly in diverse clinical settings, is limited. Assays to measure the concentrations of these drugs, especially of their active moieties within cells, are primarily research procedures and are not widely available to clinicians. Thus, there are relatively few guidelines for adjusting dosages of antiviral agents to maximize antiviral activity and minimize toxicity. Clinical use of antiviral drugs must therefore be accompanied by particular vigilance with regard to unanticipated adverse effects.

Like that of other infections, the course of viral infections is profoundly affected by an interplay of the pathogen with a complex set of host defenses. The presence or absence of preexisting immunity and the ability to mount humoral and/or cell-mediated immune responses are important determinants of the outcome of viral infections. The state of the host’s defenses needs to be considered when antiviral agents are utilized or evaluated.

As with any therapy, the optimal use of antiviral compounds requires a specific and timely diagnosis. For some viral infections, such as herpes zoster, the clinical manifestations are so characteristic that a diagnosis can be made on clinical grounds alone. For other viral infections, such as influenza A, epidemiologic information (e.g., the documentation of a community-wide outbreak) can be used to make a presumptive diagnosis with a high degree of accuracy. However, for most other viral infections, including herpes simplex encephalitis, cytomegaloviral infections other than retinitis, and enteroviral infections, diagnosis on clinical grounds alone cannot be accomplished with certainty. For such infections, rapid viral diagnostic techniques are of great importance. Considerable progress has been made in recent years in the development of such tests, which are now widely available for a number of viral infections.

Despite these complexities, the efficacy of a number of antiviral compounds has been clearly established in rigorously conducted and controlled studies. As summarized in Table 162-1, this chapter reviews the antiviral drugs that are currently approved or are likely to be considered for approval in the near future for use against viral infections other than those caused by HIV. Antiretroviral drugs are reviewed in Chap. 173.
TABLE 162-1 Antiviral Chemotherapy and Chemoprophylaxis

<tr>
<th>Infection</th>
<th>Drug</th>
<th>Route</th>
<th>Dosage</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Influenza A and B</td>
<td>Amantadine&lt;sup&gt;a&lt;/sup&gt; or rimantadine&lt;sup&gt;a&lt;/sup&gt;</td>
<td>Oral</td>
<td>Adults: 200 mg/d for period at risk</td>
<td>Therapy must continue for duration of outbreak. Dosage should be reduced for amantadine and rimantadine in patients with renal failure and the elderly. Drugs can be administered along with inactivated vaccine.</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>Children ≤9 yrs: 5 mg/kg per day (maximum, 150 mg/d)</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Oseltamivir</td>
<td>Oral</td>
<td>10 mg q12h for 5 days in adults and children ≥7 yrs old</td>
<td>Zanamivir and oseltamivir reduce symptoms by 1.0–1.5 and 1.3 days, respectively, in uncomplicated disease when started within 2 days of onset and are under study in complicated disease. Zanamivir may exacerbate bronchospasm in patients with asthma. OseLtamivir’s side effects of nausea and vomiting can be reduced in frequency by administration with food. Both amantadine and rimantadine are effective in uncomplicated influenza. None of the above drugs has been thoroughly studied in complicated cases (e.g., pneumonia).</td>
</tr>
<tr>
<td>Treatment</td>
<td>Zanamivir</td>
<td>Inhaled</td>
<td>75 mg bid for 5 days in adults and 2 mg/kg for 5 days up to a total of 45 mg bid in children 1–12 yrs old</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Oseltamivir</td>
<td>Oral</td>
<td>100–200 mg/d in adults and dosage for children as above for 5–7 days</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Amantadine&lt;sup&gt;a&lt;/sup&gt;</td>
<td>Oral</td>
<td>100–200 mg/d for 5–7 days in adults</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Rimantadine&lt;sup&gt;a&lt;/sup&gt;</td>
<td>Oral</td>
<td>100–200 mg/d for 5–7 days in adults</td>
<td></td>
</tr>
<tr>
<td>RSV infection</td>
<td>Ribavirin</td>
<td>Small-particle aerosol</td>
<td>Administered continuously from reservoir containing 20 mg/mL for 3–6 days</td>
<td>Ribavirin is used for treatment of infants and young children hospitalized with RSV pneumonia and bronchiolitis.</td>
</tr>
<tr>
<td>CMV retinitis in immunocompromised host (AIDS)</td>
<td>Ganciclovir</td>
<td>IV</td>
<td>5 mg/kg bid for 14–21 days; then 5 mg/kg per day as maintenance dose</td>
<td>Ganciclovir, valganclovir, foscarnet, and cidofovir are approved for treatment of CMV retinitis in patients with AIDS. They are also used for colitis, pneumonia, or “wasting” syndromes associated with CMV and for prevention of CMV disease in transplant recipients. Valganclovir has largely supplanted oral ganciclovir and is frequently used in place of IV ganciclovir. Foscarnet is not myelosuppressive and is active against acyclovir- and ganciclovir-resistant herpesviruses.</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>1 g tid as maintenance dose</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Valganclovir</td>
<td>Oral</td>
<td>900 mg bid for 21 days; then 900 mg/d as maintenance dose</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Foscarnet</td>
<td>IV</td>
<td>60 mg/kg q8h for 14–21 days; then 90–120 mg/kg per day as maintenance dose</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Cidofovir</td>
<td>IV</td>
<td>5 mg/kg once weekly for 2 weeks, then once every other week; given with probenecid</td>
<td></td>
</tr>
<tr>
<td>Varicella</td>
<td>Acyclovir</td>
<td>Oral</td>
<td>20 mg/kg (maximum, 800 mg) 4 500 mg/m² q8h for 7 days</td>
<td>Treatment confers modest clinical benefit when administered within 24 h of rash onset. A change to oral valacyclovir can be considered once fever has subsided and there is no evidence of visceral involvement.</td>
</tr>
<tr>
<td>Immunocompetent host</td>
<td>Acyclovir</td>
<td>IV</td>
<td>10 mg/kg q8h for 14–21 days</td>
<td>Results are optimal when therapy is initiated early. Some authorities recommend treatment for 21 days to prevent relapses.</td>
</tr>
<tr>
<td>Immunocompromised host</td>
<td>Acyclovir</td>
<td>Oral</td>
<td>10 mg/kg q8h for 14–21 days</td>
<td>Serious morbidity is frequent despite therapy. Prolonged oral administration of acyclovir after initial IV therapy has been suggested because of long-term sequelae associated with cutaneous recurrences of HSV infection.</td>

</table>
The half-life of amantadine is 12 to 17 hours and peak plasma concentrations of 0.4 μg/mL are reached. Pharmacokinetic studies of the two compounds are different. Amantadine is not metabolized and is excreted almost entirely by the kidney, with a half-life of 12 to 17 hours and peak plasma concentrations of 0.4 μg/mL. Rimantadine is extensively metabolized to hydroxylated derivatives and has a half-life of 30 hours. Only 30 to 40% of an orally administered dose is recovered in the urine. The peak plasma levels of rimantadine are approximately half those of amantadine, but rimantadine is concentrated in respiratory secretions to a greater extent than amantadine. For prophylaxis, the compounds must be administered daily for the period at risk (i.e., the peak duration of the outbreak). For therapy, amantadine or rimantadine is generally administered for 5 to 7 days.

Although these compounds are generally well tolerated, 5 to 10% of amantadine recipients experience mild central nervous system side effects consisting primarily of dizziness, anxiety, insomnia, and difficulty in concentrating. These effects are rapidly reversible upon cessation of the drug’s administration. At a dose of 200 mg/d, rimantadine is better tolerated than amantadine; in a large-scale study of young adults, adverse effects were no more frequent among rimantadine recipients than among placebo recipients. Seizures and worsening of congestive heart failure have also been reported in patients treated with amantadine, although a causal relationship has not been established. The dosage of amantadine should be reduced to ≤100 mg/d in patients with renal insufficiency [i.e., a creatinine clearance (CrCl) rate of <50 mL/min] and in the elderly. A rimantadine dose of 100 mg/d should be used for patients with a CrCl of <10 mL/min and in the elderly. Resistance to amantadine and rimantadine can be induced readily in vitro. The emergence and probable transmission of virus resistant to these drugs have also been noted in vivo after their use for the treatment of children or adults. In the United States, both amantadine and rimantadine are approved for the prophylaxis and treatment of influenza A in adults and for prophylaxis in children. Amantadine is also approved for the treatment of influenza A in children.

**ZANAMIVIR AND OSELTAMIVIR** Influenza viral neuraminidase is essential for release of the virus from infected cells and for its subsequent spread throughout the respiratory tract of the infected host. The enzyme cleaves terminal sialic acid residues, thus destroying the cellular receptors recognized by the viral hemagglutinin. Zanamivir, a sialic acid

</table>

* Influenza A only.
* Not approved for this indication by the U.S. Food and Drug Administration (FDA).
* Approved by the FDA for treatment of HIV-infected individuals.

**Antiviral Drugs Active against Respiratory Infections**

**Amantadine and Rimantadine** Amantadine and the closely related compound rimantadine are primary symmetric amines. Their antiviral activity is limited to influenza A viruses, whose replication they inhibit by interfering with the uncoating of virus after infection of the cell. This interference is attributable to the agents’ interaction with the influenza A M2 matrix protein, during which the ion channel function of M2 is inhibited. A substitution of a single amino acid at critical sites in the M2 protein can result in a virus that is resistant to amantadine and rimantadine.

Amantadine and rimantadine have been demonstrated to be effective in the prophylaxis of influenza A in large-scale studies of young adults and in less extensive studies of children and elderly subjects. In such studies, efficacy rates of 55 to 80% in the prevention of influenza-like illness were noted, and even higher rates were reported when virus-specific attack rates were calculated. Amantadine and rimantadine have also been demonstrated to be effective in the treatment of influenza A infection in studies involving predominantly young adults and, to a lesser extent, children. Administration of these compounds within 24 to 72 hours after the onset of illness has resulted in a reduction of the duration of signs and symptoms by ~50% from that in a placebo-treated group. The effect on signs and symptoms of illness is superior to that of commonly used antipyretic-antalgic drugs. Only anecdotal reports are available concerning the efficacy of amantadine or rimantadine in the prevention or treatment of complications of influenza (e.g., pneumonia).

Amantadine and rimantadine are available only in oral formulations and are ordinarily administered to adults once or twice daily, with a dosage of 100 to 200 mg/d. Despite their structural similarities, the pharmacokinetics of the two compounds are different. Amantadine is not metabolized and is excreted almost entirely by the kidney, with a half-life of 12 to 17 hours and peak plasma concentrations of 0.4 μg/mL. Rimantadine is extensively metabolized to hydroxylated derivatives.
analogue, is a highly active and specific inhibitor of the neuraminidases of influenza A and B viruses. Oseltamivir is another neuraminidase inhibitor that is a transition-state analogue of sialic acid cleavage. Its neuraminidase activity is similar to that of zanamivir. Oseltamivir phosphate is an ethyl ester prodrug that is converted to oseltamivir carboxylate by esterases in the liver. Both zanamivir and oseltamivir act through competitive and reversible inhibition of the active site of influenza A and B viral neuraminidases and have relatively little effect on mammalian cell enzymes. As would be expected from their different mechanisms of action, zanamivir and oseltamivir are active against strains of influenza A virus that are resistant to amantadine and rimantadine.

Zanamivir has low oral bioavailability. It is inhaled orally via a hand-held inhaler. By this route, ~15% of the dose is deposited in the lower respiratory tract, and low plasma levels of the drug are detected. Orally administered oseltamivir has a bioavailability of >60% and a plasma half-life of 7 to 9 h. The drug is excreted unmetabolized, primarily by the kidneys.

Intranasal inhaled zanamivir is generally well tolerated, although exacerbations of asthma may occur. The toxicities most frequently encountered with orally administered oseltamivir are nausea, gastrointestinal discomfort, and (less commonly) vomiting. Gastrointestinal discomfort is usually transient and is less likely if the drug is administered with food. No serious clinical or laboratory toxicities have yet been reported with zanamivir or oseltamivir in clinical trials.

Inhaled zanamivir and orally administered oseltamivir have been effective in the treatment of naturally occurring influenza A or B in otherwise-healthy adults. In placebo-controlled studies, illness has been shortened by 1 to 1.5 days of therapy with either of these drugs when administered within 2 days of onset. Once-daily inhaled zanamivir or orally administered oseltamivir provides effective prophylaxis against laboratory-documented influenza A–associated illness. The emergence of viruses resistant to zanamivir or oseltamivir appears to be infrequent in clinical studies carried out thus far.

Zanamivir and oseltamivir have been approved by the U.S. Food and Drug Administration (FDA) for treatment of influenza in adults and in children (those ≥7 years old for zanamivir and those ≥1 year old for oseltamivir) who have been symptomatic for ≥2 days. Oseltamivir is approved for prophylaxis of influenza in individuals ≥13 years of age.

RIBAVIRIN Ribavirin is a synthetic nucleoside analogue that inhibits a wide range of RNA and DNA viruses. The mechanism of action of ribavirin is not completely defined and may be different for different groups of viruses. Ribavirin-5'-monophosphate blocks the conversion of inosine-5'-monophosphate to xanthosine-5'-monophosphate and interferes with the synthesis of guanine nucleotides as well as that of both RNA and DNA. Ribavirin-5'-monophosphate also inhibits capping of virus-specific messenger RNA in certain viral systems. In studies demonstrating the effectiveness of ribavirin in the treatment of respiratory syncytial virus (RSV) infection in infants, the compound has been administered as a small-particle aerosol. It has been used less extensively to treat parainfluenza virus infections in children and influenza A and B virus infections in young adults. In infants with RSV infection who were given ribavirin by continuous aerosol for 3 to 6 days, illness and lower respiratory tract signs resolved more rapidly and arterial oxygen desaturation was less pronounced than in placebo-treated groups. Ribavirin has also had a beneficial clinical effect in infants with RSV infection who require mechanical ventilation. Aerosolized ribavirin has been administered to older children and adults with severe RSV and parainfluenza virus infections (including immunosuppressed patients), but the benefit of this treatment, if any, is unclear. In RSV infections in immunosuppressed patients, ribavirin is often given in combination with immunoglobulins.

Orally administered ribavirin has not been effective in the treatment of influenza A virus infections. Intravenous or oral ribavirin has reduced mortality among patients with Lassa fever; it has been partic-ularly effective in this regard when given within the first 6 days of illness. Intravenous ribavirin has been reported to be of clinical benefit in the treatment of hemorrhagic fever with renal syndrome caused by Hantaan virus and as therapy for Argentinian hemorrhagic fever. Moreover, oral ribavirin has been recommended for the treatment and prophylaxis of Congo-Crimean hemorrhagic fever. Intravenous ribavirin is being evaluated as therapy for the hemorrhagic fever with pulmonary syndrome caused by newly described hantaviruses in the United States. Oral administration of ribavirin reduces serum aminotransferase levels in patients with chronic hepatitis C virus (HCV) infection; since it appears not to reduce serum HCV RNA levels, the mechanism of this effect is unclear. The drug provides an added beneficial effect when given by mouth in doses of 800 to 1200 mg/d in combination with interferon (IFN) α2b or α2a (see below), and the ribavirin/IFN combination has been approved for the treatment of patients with chronic HCV infection.

Large doses of ribavirin administered orally (800 to 1000 mg/d) have been associated with reversible hematopoietic toxicity. This effect has not been observed with aerosolized ribavirin, apparently because little drug is absorbed systemically. Aerosolized administration of ribavirin is generally well tolerated but occasionally is associated with bronchospasm, rash, or conjunctival irritation. Aerosolized ribavirin has been licensed for treatment of RSV infection in infants and should be administered under close supervision—particularly in the setting of mechanical ventilation, where precipitation of the drug is possible. Health care workers exposed to the drug have experienced minor toxicity, including eye and respiratory tract irritation. Because ribavirin is mutagenic, teratogenic, and embryotoxic, its use is generally contraindicated in pregnancy. Its administration as an aerosol poses a risk to pregnant health care workers.

PLECONARIL Pleconaril is an investigational drug active in vitro against picornavirus replication, including >90% of the most commonly isolated enterovirus types and 80% of rhinovirus serotypes. Its mechanism of action is through binding to a specific hydrophobic pocket in the viral capsid, which prevents attachment and/or uncoating of the virus. Pleconaril is poorly water soluble and is formulated as an oral suspension. It is generally well tolerated; the most frequently reported adverse effects are headache, nausea, diarrhea, and gastrointestinal discomfort, which have occurred at rates similar to those among placebo recipients. Pleconaril treatment of adults with enterovirus meningitis decreased the overall duration of illness and headache and reduced the use of analgesics from that by placebo recipients. A large-scale clinical study demonstrated a mild therapeutic effect on rhinovirus-associated colds, but pleconaril was deemed to be of insufficient benefit to gain approval by an FDA advisory panel.

ANTIVIRAL DRUGS ACTIVE AGAINST HERPESVIRUS INFECTIONS ACYCLOVIR AND VALACYCLOVIR Acyclovir is a highly potent and selective inhibitor of the replication of certain herpesviruses, including herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). It is relatively ineffective in the treatment of human cytomegalovirus (CMV) infections; however, some studies have indicated its effectiveness in the prevention of CMV-associated disease in immunosuppressed patients. Valacyclovir, the L-valyl ester of acyclovir, is converted almost entirely to acyclovir by intestinal and hepatic hydrolysis after oral administration. Valacyclovir has pharmacokinetic advantages over orally administered acyclovir: it exhibits significantly greater oral bioavailability, results in higher blood levels, and can be given less frequently than acyclovir (two or three rather than five times daily).

The high degree of selectivity of acyclovir is related to its mechanism of action, which requires that the compound first be phosphorylated to acyclovir monophosphate. This phosphorylation occurs efficiently in herpesvirus-infected cells by means of a virus-coded
Acyclovir is available in intravenous, oral, and topical forms, while valacyclovir is available in an oral formulation. Intravenous acyclovir is markedly effective in the treatment of mucocutaneous HSV infections in immunocompromised hosts, reducing the frequency of cutaneous dissemination and visceral complications and—in one comparative trial—was more effective than vidarabine. Acyclovir, administered orally at doses of 800 mg five times a day, has a modest beneficial effect on localized herpes zoster lesions in both immunocompromised and immunocompetent patients. Combination of acyclovir with a tapering regimen of prednisone appeared to be more effective than acyclovir alone in terms of quality-of-life outcomes in immunocompetent herpes zoster patients over age 50. A comparative study of acyclovir (800 mg orally five times daily) and valacyclovir (1 g orally tid) in immunocompetent patients with herpes zoster indicated that the latter drug may be more effective in eliciting the resolution of zoster-associated pain. Orally administered acyclovir (600 mg five times a day) reduced complications of herpes zoster ophthalmicus in a placebo-controlled trial.

In normal children with chickenpox, acyclovir—administered at 20 mg/kg (up to a maximum of 800) four times daily, within 24 h of the onset of rash—resulted in a modest overall clinical benefit. Intravenous acyclovir has also been reported to be effective in the treatment of immunocompromised children with chickenpox.

The most widespread use of acyclovir is in the treatment of genital HSV infections. Intravenous or oral acyclovir or oral valacyclovir has shortened the duration of symptoms, reduced virus shedding, and accelerated healing when employed for the treatment of primary genital HSV infections. Oral acyclovir and valacyclovir have also had a modest effect in treatment of recurrent genital HSV infections. However, the failure of treatment of either primary or recurrent disease to reduce the frequency of subsequent recurrences has indicated that acyclovir is ineffective in eliminating latent infection. Chronic oral administration of acyclovir 1 to 6 years or longer or of valacyclovir for 1 year or longer has reduced the frequency of recurrences markedly during therapy; once the drug is discontinued, lesions recur. In one study, suppressive therapy with valacyclovir (500 mg once daily for 8 months) reduced transmission of HSV-2 genital infections among discordant couples by 50%. A modest effect on herpes labialis (i.e., a reduction of disease duration by 1 day) was seen when valacyclovir was administered upon detection of the first symptom of a lesion at a dose of 2 g every 12 h for 1 day. In AIDS patients, chronic or intermittent administration of acyclovir has been associated with the development of HSV and VZV strains resistant to the action of the drug and with clinical failures. The most common mechanism of resistance is a deficiency of the virus-induced thymidine kinase. Patients with HSV or VZV infections resistant to acyclovir have frequently responded to foscarnet.

With the availability of the oral and intravenous forms, there are few indications for topical acyclovir, although treatment with this formulation has been modestly beneficial in primary genital HSV infections and in mucocutaneous HSV infections in immunocompromised hosts.

Overall, acyclovir is remarkably well tolerated and is generally free of toxicity. The most frequently encountered form of toxicity is renal dysfunction, particularly after rapid intravenous administration or with inadequate hydration. Central nervous system changes, including lethargy and tremors, are occasionally reported, primarily in immunocompromised patients. However, whether these changes are related to acyclovir to concurrent administration of other therapy, or to underlying infection remains unclear. Acyclovir is excreted primarily unmetabolized by the kidney, via both glomerular filtration and tubular secretion. Approximately 15% of a dose of acyclovir is metabolized to 9-[carboxymethoxy]methylguanine or other minor metabolites. Reduction in dosage is indicated in patients with a $\text{CrCl} \leq 50 \text{ mL/min per 1.73 m}^2$. The half-life of acyclovir is $\approx 3$ h in normal adults, and the peak plasma concentration after a 1-h infusion of a dose of 5 mg/kg is 9.8 $\mu$g/mL. Approximately 22% of an orally administered acyclovir dose is absorbed, and peak plasma concentrations of 0.3 to 0.9 $\mu$g/mL are attained after administration of a 200-mg dose. Acyclovir penetrates relatively well into the cerebrospinal fluid (CSF), with concentrations approaching half of those found in plasma.

Acyclovir causes chromosomal breakage at high doses, but its administration to pregnant women has not been associated with fetal abnormalities. Nonetheless, the potential risks and benefits of acyclovir should be carefully assessed before the drug is used in pregnancy. Valacyclovir exhibits three to five times greater bioavailability than acyclovir. The concentration-time curve for valacyclovir, given as 1 g by mouth three times daily, is similar to that for acyclovir, given as 5 mg/kg intravenously every 8 h. The safety profiles of valacyclovir and acyclovir are similar, although thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome has been reported in immunocompromised patients who have received high doses (8 g/day) of valacyclovir.

Valacyclovir is approved for the treatment of herpes zoster and for initial and recurrent episodes of genital HSV infections in immunocompetent adults as well as for suppressive treatment of genital herpes. Although it has not been extensively studied in other herpesvirus infections, many consultants use valacyclovir rather than oral acyclovir in clinical settings where the latter has been approved because of valacyclovir’s superior pharmacokinetics and more convenient dosing schedule.

Cidofovir Cidofovir is a phosphonate nucleotide analogue of cytosine. Its major use is in CMV infections, particularly retinitis, but it is active against a broad range of herpesviruses, including HSV, human herpesvirus (HHV) type 6, HHV-8, and certain other DNA viruses such as polyomaviruses, papillomaviruses, adenoviruses, and poxviruses, including variola (smallpox) and vaccinia. Cidofovir does not require initial phosphorylation by virus-induced kinases; the drug is phosphorylated by host cell enzymes to cidofovir diphosphate, which is a competitive inhibitor of viral DNA polymerases and, to a lesser extent, of host cell DNA polymerases. Incorporation of cidofovir diphosphate slows or terminates nascent DNA chain elongation. Cidofovir is active against HSV isolates that are resistant to acyclovir because of absent or altered thymidine kinase and against CMV isolates that are resistant to ganciclovir because of UL97 mutations. Cidofovir is usually active against foscarnet-resistant CMV, although cross-resistance to foscarnet as well as to ganciclovir has been described.

Cidofovir has poor oral availability and is administered intravenously. It is excreted primarily by the kidney and has a plasma half-life of 2.6 h. Cidofovir diphosphate’s intracellular half-life of $\approx 48$ h is the basis for the recommended dosing regimen of 5 mg/kg once a week for the initial 2 weeks and then 5 mg/kg every other week. The major toxic effect of cidofovir is renal tubular injury, as manifested by elevated serum creatinine levels and proteinuria. The risk of nephrotoxicity can be reduced by vigorous fluid hydration and by concomitant oral administration of probenecid. Neutropenia, rashes, and gastrointestinal tolerance may also occur.
Intravenous cidofovir has been approved for the treatment of CMV retinitis in AIDS patients who are intolerant of ganciclovir or foscarnet or in whom those drugs have failed. In a controlled study, a maintenance dosage of 5 mg/kg a week administered to AIDS patients reduced the progression of CMV retinitis from that seen at 3 mg/kg. Intravenous cidofovir has been reported anecdotally to be effective therapy for acyclovir-resistant mucocutaneous HSV infections. Likewise, topically administered cidofovir is reportedly beneficial against these infections in HIV patients; it is also being studied for the treatment of anogenital warts. Intravenous cidofovir is being evaluated as therapy for progressive multifocal leukoencephalopathy and for Kaposi’s sarcoma. An ophthalmic formulation is being studied as treatment for adenosival keratoconjunctivitis. Intravitreal cidofovir has been used to treat CMV retinitis but has been associated with significant toxicity.

**FOMIVIRSEN** Fomivirsen is the first antisense oligonucleotide approved by the FDA for therapy in humans. This phosphorothioate oligonucleotide, 21 nucleotides in length, inhibits CMV replication through interaction with CMV messenger RNA. Fomivirsen is complementary to messenger transcripts of the major immediate early region 2 (IE2) of CMV, which codes for proteins regulating viral gene expression. In addition to its antisense mechanism of action, fomivirsen may exert activity against CMV through inhibition of viral adsorption to cells as well as direct inhibition of viral replication. Because of its different mechanism of action, fomivirsen is active against CMV isolates that are resistant to nucleoside or nucleotide analogues, such as ganciclovir, foscarnet, or cidofovir.

Fomivirsen has been approved for intravitreal administration in the treatment of CMV retinitis in AIDS patients who have failed to respond to other treatments or cannot tolerate them. Injections of 330 mg every 2 weeks have resulted in significant reductions in the rate of progression of CMV retinitis. The major toxicity is ocular inflammation, including vitritis and iritis, which usually responds to topically administered glucocorticoids.

**GANCICLOVIR AND VALGANCLOVIR** An analogue of acyclovir, ganciclovir is active against HSV and VZV and is markedly more active than acyclovir against CMV. Ganciclovir triphosphate inhibits CMV DNA polymerase and can be incorporated into CMV DNA, whose elongation it eventually terminates. In HSV- and VZV-infected cells, ganciclovir is phosphorylated by virus-encoded thymidine kinases; in CMV-infected cells, it is phosphorylated by a viral kinase encoded by the UL97 gene. Ganciclovir triphosphate is present in tenfold higher concentrations in CMV-infected cells than in uninfected cells. Ganciclovir is approved for the treatment of CMV retinitis in immunosuppressed patients and for the prevention of CMV disease in transplant recipients. It is widely used for the treatment of other CMV-associated syndromes, including pneumonia, esophagogastrointestinal infections, hepatitis, and “wasting” illness.

Ganciclovir is available for intravenous or oral administration. Because its oral bioavailability is low (5 to 9%), relatively large doses (1 g three times daily) must be administered by this route. Oral ganciclovir has largely been supplanted by valganciclovir, which is the L-valyl ester of ganciclovir. Valganciclovir is well absorbed orally, with a bioavailability of 60%, and is rapidly hydrolyzed to ganciclovir in the intestine and liver. The area under the curve for a 900-mg dose of valganciclovir is equivalent to that for 5 mg/kg of ganciclovir given intravenously, although peak serum concentrations are ~40% lower for valganciclovir. The serum half-life is 3.5 h after intravenous administration of ganciclovir and 4.0 h after oral administration of valganciclovir. Ganciclovir is excreted primarily by the kidneys in unmetabolized form, and its dosage should be reduced in cases of renal failure. The most commonly employed dosage for initial intravenous therapy is 5 mg/kg every 12 h for 14 to 21 days; this regimen is followed by an intravenous maintenance dose of 5 mg/kg per day or five times per week, possibly for as long as immunosuppression persists. For oral therapy with valganciclovir, the dose is 900 mg twice daily for 21 days followed by 900 mg once a day for maintenance, with dose adjustment in patients with renal dysfunction. Intracocular ganciclovir, given by either intravitreal injection or intraocular implantation, has also been used to treat CMV retinitis. Ganciclovir is effective as prophylaxis against CMV-associated disease in organ and bone marrow transplant recipients. Oral ganciclovir administered prophylactically to AIDS patients with CD4+ cell counts of <100/μL has provided protection against the development of CMV retinitis. However, the long-term benefits of this approach to prophylaxis in AIDS patients have not been established, and most experts do not recommend the use of oral ganciclovir for this purpose. As already mentioned, valganciclovir has supplanted oral ganciclovir in settings where oral prophylaxis or therapy is required.

The administration of ganciclovir has been associated with profound bone marrow suppression, particularly neutropenia, which significantly limits the drug’s use in many patients. Bone marrow toxicity is potentiated when other bone marrow suppressants, such as zidovudine, are used concomitantly.

Resistance has been noted in CMV isolates obtained after therapy with ganciclovir, especially in patients with AIDS. Such resistance may develop through a mutation in either the viral UL97 gene or the viral DNA polymerase. Ganciclovir-resistant isolates are usually sensitive to foscarnet (see below) or cidofovir (see above).

**FAMCICLOVIR AND PENCICLOVIR** Famciclovir is the diacetyl 6-deoxyester of the guanosine analogue penciclovir. Penciclovir is well absorbed orally, has a bioavailability of 77%, and is rapidly converted to penciclovir by deacetylation and oxidation in the intestine and liver. Penciclovir’s spectrum of activity and mechanism of action are similar to those of acyclovir; thus penciclovir is usually not active against acyclovir-resistant viruses. Penciclovir is phosphorylated initially by a virus-encoded thymidine kinase and subsequently by cellular kinases to penciclovir triphosphate, which inhibits HSV-1, HSV-2, and VZV DNA polymerases as well as hepatitis B virus (HBV). The serum half-life of penciclovir is 2 h, but the intracellular half-life of penciclovir triphosphate is 7 to 20 h—markedly longer than that of acyclovir triphosphate. The latter is the basis for the less frequent (twice-daily) dosing schedule for famciclovir than for penciclovir. Penciclovir is eliminated primarily in the urine by both glomerular filtration and tubular secretion. The usually recommended dosage interval should be adjusted for renal insufficiency.

Clinical trials involving immunocompetent adults with herpes zoster showed that famciclovir was superior to placebo in eliciting the resolution of skin lesions and virus shedding and in shortening the duration of postherpetic neuralgia; moreover, it was at least as effective as acyclovir administered orally at a dose of 800 mg five times daily. Famciclovir was also effective in the treatment of herpes zoster in immunosuppressed patients. Clinical trials have demonstrated its effectiveness in the suppression of genital HSV infections for up to 1 year and in the treatment of initial and recurrent episodes of genital herpes. Famciclovir is effective as therapy for mucocutaneous HSV infections in HIV-infected patients. Application of a 1% penciclovir cream reduces the duration of signs and symptoms of herpes labialis in immunocompetent patients (by 0.5 to 1.0 day) and has been approved for that purpose by the FDA. Famciclovir is generally well tolerated, with occasional headache, nausea, and diarrhea reported in frequencies similar to those among placebo recipients. The administration of high doses of famciclovir for 2 years was associated with an increased incidence of mammary adenocarcinomas in female rats, but the clinical significance of this effect is unknown. Intravenous penciclovir is being investigated for the treatment of mucocutaneous HSV infections in immunosuppressed patients.

**FOSCARNET** Foscarnet (phosphonoformic acid) is a pyrophosphate-containing compound that potently inhibits herpesviruses, including CMV. Foscarnet inhibits viral DNA polymerases at the pyrophosphate binding site at concentrations that have relatively little effect on cellular polymerases. Foscarnet does not require phosphorylation to exert its
antiviral activity and is therefore active against HSV and VZV isolates that are resistant to acyclovir because of deficiencies in thymidine kinase as well as against most ganciclovir-resistant strains of CMV. Foscarnet also inhibits the reverse transcriptase of HIV and is active against HIV in vivo.

Foscarnet is poorly soluble and must be administered intravenously via an infusion pump in a dilute solution over 1 to 2 h. The plasma half-life of foscarnet is 3 to 5 h and increases with decreasing renal function, since the drug is eliminated primarily by the kidneys. It has been estimated that 10 to 28% of a dose may be deposited in bone, where it can persist for months. The most common initial dosage of foscarnet—60 mg/kg every 8 h for 14 to 21 days—is followed by a maintenance dose of 90 to 120 mg/kg once a day.

Foscarnet is approved for the treatment of CMV retinitis in patients with AIDS and of acyclovir-resistant mucocutaneous HSV infections. In a comparative clinical trial, the drug appeared to be as efficacious as ganciclovir against CMV retinitis but was associated with a longer survival period, possibly because of its anti-HIV activity. Intraocular foscarnet has been used to treat CMV retinitis. Foscarnet has also been employed to treat acyclovir-resistant HSV and VZV infections as well as ganciclovir-resistant CMV infections, although resistance to foscarnet has been reported in CMV isolates obtained during therapy.

The major form of toxicity associated with foscarnet is renal impairment. Thus renal function should be monitored closely, particularly during the initial phase of therapy. Since foscarnet binds divalent metal ions, hypocalcemia, hypomagnesemia, hypokalemia, and hypoor hyperphosphatemia can develop. Saline hydration and slow infusion appear to protect the patient against nephrotoxicity and electrolyte disturbances. Although hematologic abnormalities have been documented (most commonly anemia), foscarnet is not generally myelosuppressive and may be administered concomitantly with myelosuppressive medications such as zidovudine.

TRIFLURIDINE
Trifluridine is a pyrimidine nucleoside active against HSV-1, HSV-2, and CMV. Trifluridine monophosphate irreversibly inhibits thymidylate synthetase, and trifluridine triphosphate inhibits viral and, to a lesser extent, cellular DNA polymerases. Because of systemic toxicity, its use is limited to topical therapy. Trifluridine is approved for treatment of HSV keratitis, for which trials have shown that it is more effective than topical idoxuridine but similarly effective to topical vidarabine. The drug has benefited some patients with HSV keratitis who have failed to respond to idoxuridine or vidarabine. Topical application of trifluridine to sites of acyclovir-resistant HSV mucocutaneous infections has also been beneficial in some cases.

VIDARABINE
Vidarabine is a purine nucleoside analogue with activity against HSV-1, HSV-2, VZV, and EBV. Vidarabine inhibits viral DNA synthesis through its 5′-triphosphorylated metabolite, although its precise molecular mechanisms of action are not completely understood. Intravenously administered vidarabine has been shown to be effective in the treatment of herpes simplex encephalitis, mucocutaneous HSV infections, herpes zoster in immunocompromised patients, and neonatal HSV infections. Its use has been supplanted by that of intravenous acyclovir, which is more effective and easier to administer. Production of the intravenous preparation has been discontinued by the manufacturer, but vidarabine is available as an ophthalmic ointment, which is effective in the treatment of HSV keratitis.

ANTIVIRAL DRUGS ACTIVE AGAINST HEPATITIS VIRUSES

LAMIVUDINE
Lamivudine is a pyrimidine nucleoside analogue that is used primarily in combination therapy against HIV infection (Chap. 175). It is also active against HBV through inhibition of the viral DNA polymerase and has been approved for the treatment of chronic HBV infection. At doses of 100 mg/d for 1 year, lamivudine was well tolerated and resulted in suppression of HBV DNA levels, normalization of serum aminotransferase levels in 50 to 70% of patients, and reduction of hepatic inflammation and fibrosis in 50 to 60% of patients. Loss of hepatitis B e antigen (HBeAg) occurred in 30% of patients. Resistance to lamivudine develops in 24% of patients treated for 1 year and is associated with changes in the YMDD motif of HBV DNA polymerase. This is an important limitation of monotherapy with the drug. Studies of lamivudine as a component of combination therapy for hepatitis B are under way. Lamivudine also appears to be useful in the prevention or suppression of HBV infection associated with liver transplantation.

ADEFOVIR
Adefovir dipivoxil is an acyclic nucleotide analogue of adenosine monophosphate that has activity against HBV, HIV, HSV, and CMV. It is phosphorylated by cellular kinases to the active triphosphate moiety, which is a competitive inhibitor of HBV DNA polymerase and results in chain termination after incorporation into nascent viral DNA. Adefovir is administered orally and is eliminated primarily by the kidneys, with a plasma half-life of 7.5 h. In clinical studies, therapy with adefovir at a dose 10 μg/d for 48 weeks resulted in normalization of alanine aminotransferase (ALT) levels in 48 to 72% of patients and improved liver histology in 53 to 64%; it also resulted in a 3.6-log₁₀ reduction in the number of HBV DNA copies per milliliter of plasma. Adefovir was effective in treatment-naive patients as well as in those infected with lamivudine-resistant HBV. This agent was generally well tolerated. Significant nephrotoxicity attributable to adefovir was uncommon at the dose employed in the treatment of HBV infections (10 μg/d) but was a treatment-limiting adverse effect if the higher doses used in the treatment of HIV infections (30 to 120 μg/d). In any case, renal function should be monitored in patients taking adefovir, even at the lower dose. Adefovir is approved only for treatment of chronic hepatitis B infection.

TENOFOVIR
Tenofovir disoproxil fumarate is a nucleotide analogue with activity against both retroviruses and hepadnaviruses. In one small study of patients coinfected with HIV and HBV, tenofovir reduced HBV loads by >10³ copies/mL at 24 weeks. The drug is approved only for treatment of HIV infection, but its use should be considered in HIV/HBV-coinfected patients. ~For a more detailed discussion of tenofovir, see Chap. 173.

INTERFERONS
Interferons are cytokines that exhibit a broad spectrum of antiviral activities as well as immunomodulating and antiproliferative properties. The IFNs are not available for oral administration but must be given intramuscularly, subcutaneously, or intravenously. Early studies with human leukocyte IFN demonstrated an effect in the prophylaxis of experimentally induced rhinovirus infections in humans and in the treatment of VZV infections in immunosuppressed patients. DNA recombinant technology has made available highly purified α, β, and γ IFNs that have been evaluated in a variety of viral infections. Results of such trials have confirmed the effectiveness of intranasally administered IFN in the prophylaxis of rhinovirus infections, although its use has been associated with nasal mucosal irritation. Studies have also demonstrated a beneficial effect of intranasally or systemically administered IFNs on genital warts. The effect of systemic administration consists primarily of a reduction in the size of lesions, and this mode of therapy may be useful in persons who have numerous warts that cannot easily be treated by individual intralesional injections. However, lesions frequently recur after either intralesional or systemic IFN therapy is discontinued.

Interferons have undergone extensive study in the treatment of chronic HBV infection. The administration of IFN-α2b (5 million units daily or 10 million units three times a week for 16 weeks) to patients with stable chronic HBV infection resulted in loss of markers of HBV replication, such as HBeAg and HBV DNA, in 33 to 37% of cases; 8% of patients also became negative for hepatitis B surface antigen. In >80% of patients who lose HBeAg and HBV DNA markers, serum aminotransferases return to normal levels, and both short- and long-term improvements in liver histopathology have been described. Predictors of a favorable response to therapy include low pretherapy levels
of HBV DNA, high pretherapy serum levels of ALT, a short duration of chronic HBV infection, and active inflammation in liver histopathology. Poor responses are seen in immunosuppressed patients, including those with HIV infection. Adverse effects of the above dose of IFN are common and include fever, chills, myalgia, fatigue, neurotoxicity (primarily manifested as somnolence and confusion), and leukopenia. Approximately 25% of patients receiving a daily dose of 5 million units require dose reduction, but <5% require discontinuation of therapy.

Several IFN preparations, including IFN-α2a, IFN-α2b, IFN-α/α1, and IFN-αr1 (lymphoblastoid), have been studied as therapy for chronic HCV infections. A variety of regimens have been employed, of which the most common is IFN-α2b or -α2a at 3 million units three times per week for 12 to 18 months. The addition of oral ribavirin to IFN-α2b—either as initial therapy or after failure of interferon therapy alone—results in significantly higher rates of sustained virologic and/or serum ALT responses (40 to 50%) than were obtained with monotherapy. Pegylated IFN-α2b or -α2a, in which the IFNs are covalently linked with monomethoxy polyethylene glycol, have been approved by the FDA for the treatment of chronic HCV infection. These interferons have a markedly reduced clearance rate and can therefore be administered less frequently than standard IFNs (i.e., once a week). Comparative studies indicate that pegylated IFN therapy may be more effective than standard IFN treatment against chronic HCV infection. The combination of intramuscular pegylated IFN and oral ribavirin appears to be a particularly convenient and effective regimen for treatment of chronic hepatitis C. Prognostic factors for a favorable response include an age of <45 years, a short duration of disease, low levels of HCV RNA, and infection with HCV genotypes other than 1. IFN alfacon-1, a synthetic “consensus” α interferon, appears to produce response rates similar to those elicited by IFN-α2a or -α2b alone and is also approved in the United States for the treatment of chronic hepatitis C. In early clinical trials, pegylated IFN alfas also appear promising as therapy for hepatitis B.

Treatment of acute hepatitis C with IFN has been investigated relatively little. In one study, the administration of IFN-α2b to patients recently infected with HCV (with a dose of 5 million units per day for 4 weeks followed by 3 million units per week for 20 weeks) resulted in clearance of HCV from blood and normalization of ALT levels in 43 of 44 patients at 48 weeks. Additional studies are required to establish the role of IFN therapy in this setting.

The efficacy of IFN-α treatment for chronic hepatitis D remains unestablished. Anecdotal reports suggested that doses of 5 million units daily to 9 million units three times per week for 12 months elicited biochemical and virologic responses. Results from small controlled trials have been inconsistent, and observed responses have not generally been sustained.

**Section 12 Infections Due to DNA Viruses**

**HERPES SIMPLEX VIRUSES**

**Lawrence Corey**

**DEFINITION** Herpes simplex viruses (HSV-1, HSV-2; *Herpesvirus hominis*) produce a variety of infections involving mucocutaneous surfaces, the central nervous system (CNS), and—on occasion—visceral organs. Prompt recognition and treatment reduce the morbidity and mortality of HSV infections.

**ETIOLOGIC AGENT** The genome of HSV is a linear, double-stranded DNA molecule (molecular weight, ~100 × 10^6 units) that encodes >90 transcription units with 84 identified proteins. The genomic structures of the two HSV subtypes are similar, and the overall sequence homology between HSV-1 and HSV-2 is ~50%. The homologous sequences are distributed over the entire genome map, and most of the polypeptides specified by one viral type are antigenically related to polypeptides of the other viral type. Many type-specific regions unique to HSV-1 and HSV-2 proteins do exist, however, and a number of them appear to be important in host immunity. These type-specific regions have been used to develop serologic assays that distinguish between the two viral subtypes. Either restriction endonuclease analysis of viral DNA or DNA sequencing can be used to distinguish between the two subtypes and among strains of each subtype. The variability of nucleotide sequences from clinical strains of HSV-1 and HSV-2 is such that HSV isolates obtained from two individuals can be differentiated by restriction enzyme patterns or genomic sequences unless the isolates are from epidemiologically related sources, such as sexual partners, mother-infant pairs, or persons involved in a common-source outbreak.

The viral genome is packaged in a regular icosahedral protein shell (capsid) composed of 162 capsomers. The outer covering of the virus is a lipid-containing membrane (envelope) derived from modified cell membrane and acquired as the DNA-containing capsid buds through the inner nuclear membrane of the host cell. Between the capsid and lipid bilayer of the envelope is the tegument. Viral replication has both nuclear and cytoplasmic phases. Attachment and fusion between the viral envelope and the cell membrane involve several ubiquitous heparin-like surface receptors. Replication is highly regulated. After fusion and entry, the nucleocapsid enters the cytoplasm and several viral proteins are released from the virion. Some of these viral proteins shut off host protein synthesis (by increasing cellular RNA degradation), while others “turn on” the transcription of early genes of HSV replication. These early gene products, designated α genes, are required for synthesis of the subsequent polypeptide group, the β polypeptides, many of which are regulatory proteins and enzymes required for DNA replication. Most current antiviral drugs interfere with β proteins, such as the viral DNA polymerase enzyme. The third (γ) class of HSV genes requires viral DNA replication for expression and constitutes most of the structural proteins specified by the virus.

After replication of the viral genome and synthesis of structural proteins, nucleocapsids are assembled in the nucleus of the cell. En...
velopment occurs as the nucleocapsids bud through the inner nuclear membrane into the perinuclear space. In some cells, viral replication in the nucleus forms two types of inclusion bodies: type A basophilic Feulgen-positive bodies that contain viral DNA and an eosinophilic inclusion body that is devoid of viral nucleic acid or protein and represents a “scar” of viral infection. Virions are then transported via the endoplasmic reticulum and the Golgi apparatus to the cell surface.

HSV infection of some neuronal cells does not result in cell death. Instead, viral genomes are maintained by the cell in a repressed state compatible with survival and normal activities of the cell, a condition called latency. Latency is associated with transcription of only a limited number of virus-encoded proteins. Subsequently, the viral genome may become activated; its activation results in the normal pattern of regulated viral gene expression, replication, and release of HSV. The release of virus from the neuron and its subsequent entry into epithelial cells result in viral replication and reappearance of virus on mucosal surfaces. This process is termed reactivation. Whereas infectious virus is rarely recovered from sensory or autonomic nervous system ganglia dissected from cadavers, maintenance and growth of the neural cells in tissue culture result in production of infectious virions (explantation) and in subsequent permissive infection of susceptible cells (cocultivation). The mechanisms by which latency is established, maintained, or recovered are incompletely understood. Two RNA “latency-associated” transcripts that overlap the immediate early (α) gene products, called ICP-O, are found in abundance in the nuclei of latently infected neurons. Deletion mutants of this region that can become latent have been made. However, the efficiency of their later reactivation is reduced; thus, the antisense transcripts may play a role in maintaining rather than in establishing latency. Data from animal models suggest that HSV-specific T cell immunity may influence the process of reactivation in neuronal cells. At present, strategies to interrupt latency or to maintain molecular latency in neurons are not available. In experimental animals, ultraviolet light, systemic and local immunosuppression, and trauma to the skin or ganglia are associated with reactivation.

**PATHOGENESIS** Exposure to HSV at mucosal surfaces or abraded skin sites permits entry of the virus and initiation of its replication in cells of the epidermis and dermis. HSV infections are usually acquired subclinically. Both clinical acquisition and subclinical acquisition are associated with sufficient viral replication to permit infection of either sensory or autonomic nerve endings. On entry into the neuronal cell, the virus—or, more likely, the nucleocapsid—is transported intraaxonally to the nerve cell bodies in ganglia. In humans, the interval from inoculation of virus in peripheral tissue to spread to the ganglia is unknown. During the initial phase of infection, viral replication occurs in ganglia and contiguous neural tissue. Virus then spreads to other mucosal skin surfaces through centrifugal migration of infectious virions via peripheral sensory nerves. This mode of spread helps explain the large surface area involved, the high frequency of new lesions distant from the initial crop of vesicles that is characteristic in patients with primary genital or oral-labial HSV infection, and the recovery of virus from neural tissue distant from neurons innervating the inoculation site. Contiguous spread of locally inoculated virus also may take place and allow further mucosal extension of disease.

Analysis of the DNA from sequentially isolated strains of HSV or from isolates from multiple infected ganglia in any one individual has revealed similar, if not identical, restriction endonuclease or DNA sequence patterns in most persons. Occasionally (most frequently in immunocompromised persons), multiple strains of the same viral subtype are detected in one individual. As exposure to mucosal shedding is relatively common during a person’s lifetime, these data suggest that exogenous infection with different strains of the same subtype is possible, albeit very uncommon.

**IMMUNITY** Host responses to infection with HSV influence the acquisition of disease, the severity of infection, resistance to the development of latency, the maintenance of latency, and the frequency of recurrences. Both antibody-mediated and cell-mediated reactions are clinically important. Immunocompromised persons with defects in cell-mediated immunity experience more severe and more extensive HSV infections than those with deficits in humoral immunity, such as agammaglobulinemia. Experimental ablation of lymphocytes indicates that T cells play a major role in preventing lethal disseminated disease, although antibodies help reduce virus titers in neural tissue. Some of the clinical manifestations of HSV disease appear to be related to the host immune response (e.g., stromal opacities associated with recurrent herpetic keratitis). The surface viral glycoproteins have been shown to be antigens recognized by antibodies mediating neutralization and immune-mediated cytosis (antibody-dependent cell-mediated cytotoxicity). Neutralization antibodies specific for each of the known viral glycoproteins have, in experimental infections, conferred protection against subsequent neurologic disease or ganglionic latency. However, the use of subunit glycoprotein vaccines in humans has been, up to the present, only partially successful in reducing acquisition of infection. Multiple cell populations, including natural killer cells, macrophages, and a variety of T lymphocytes, play a role in host defenses against HSV infections, as do lymphokines generated by T lymphocytes. In animals, passive transfer of primed lymphocytes confers protection from subsequent challenge. Maximum protection usually requires the activation of multiple T cell subpopulations, including cytotoxic T cells and T cells responsible for delayed hypersensitivity. The latter cells may confer protection by the antigen-stimulated release of lymphokines (e.g., interferons), which may have a direct antiviral effect and may activate and enhance a variety of specific and nonspecific effector cells. Increasing evidence suggests that HSV-specific CD8+ T cell responses are critical for clearance of virus from lesions. In addition, immunosuppressed patients with frequent and prolonged HSV lesions have fewer functional CD8+ T cells directed at HSV. The HSV virion contains a variety of genes that are directed at the inclusion site. Contiguous spread of locally inoculated virus also may take place and allow further mucosal extension of disease.

**EPIGENETICS** Seroepidemiologic studies have documented HSV infections worldwide. Serologic assays with whole-virus antigen preparations, such as complement fixation, neutralization, indirect immunofluorescence, passive hemagglutination, radioimmunoassay, and enzyme-linked immunosorbent assay, are useful for differentiating uninfected (seronegative) persons from those with past HSV-1 or HSV-2 infection, but they do not reliably distinguish between the two viral subtypes. Serologic assays that identify antibodies to type-specific surface proteins (epitopes) of the two viral subtypes have been developed and can distinguish reliably between the human antibody responses to HSV-1 and HSV-2. The most commonly used assays are those that measure antibodies to glycoprotein G of HSV-1 (gG1) and HSV-2 (gG2). A western blot assay that can detect several HSV type-specific proteins can also be used.

Infection with HSV-1 is acquired more frequently and earlier than infection with HSV-2. More than 90% of adults have antibodies to HSV-1 by the fifth decade of life. In populations of low socioeconomic status, most persons acquire HSV-1 infection before the third decade of life. Antibodies to HSV-2 are not detected routinely until puberty. Antibody prevalence rates correlate with past sexual activity and vary greatly among different population groups. Serosurveys indicate that
—20% of the U.S. population has antibodies to HSV-2. In most routine obstetric and family planning clinics, 25% of women have HSV-2 antibodies, although only 10% report a history of genital lesions. As many as 50% of heterosexual adults attending sexually transmitted disease clinics have antibodies to HSV-2. A wide variety of serologic surveys have indicated a similar or even higher seroprevalence of HSV-2 in most parts of Europe, Central and South America, and Africa. Antibody prevalence rates average ~5% higher among women than among men. Several studies suggest that much of this “asymptomatic” infection is largely unrecognized: when “asymptomatic” seropositive persons are shown pictures of genital lesions, more than 60% subsequently identify episodes of symptomatic reactivation. Most important, these asymptomatic seropositive persons with reactivation shed virus on mucosal surfaces as frequently as those with symptomatic disease. The large reservoir of unidentified carriers of HSV-2 and the frequent asymptomatic reactivation of virus from the genital tract have fostered the continued spread of genital herpes throughout the world. HSV-2 infection is an independent risk factor for the acquisition and transmission of infection with HIV type 1. Among coinfected persons, HIV-1 virions can be shed from herpetic lesions of the genital region. This shedding may facilitate the spread of HIV through sexual contact.

HSV infections occur throughout the year. Transmission can result from contact with persons with active ulcerative lesions or with persons without clinical manifestations of infection who are shedding HSV or on whose mucosal surfaces the virus is replicating. Studies using the polymerase chain reaction (PCR) have shown that HSV reactivation on mucosal surfaces is much more frequent than previously recognized. Among immunocompetent adults, HSV-2 can be isolated by culture from the genital tract on 2 to 10% of days, and HSV DNA can be detected on 20 to 30% of days by PCR. Corresponding figures for HSV-1 in oral secretions are similar. Shedding rates are highest during the initial years after acquisition, and viral shedding may occur on as many as 30 to 50% of days during this period. Immunosuppressed patients shed HSV on mucosal sites at even higher frequency (20 to 70% of days). Daily antiviral chemotherapy can markedly reduce shedding rates, as measured by PCR. These data indicate that potential exposure to HSV from sexual or other close contact (kissing, sharing of glasses or silverware) is common, and these high rates of mucosal reactivation are consistent with the continuing spread and high seroprevalence of HSV infections worldwide.

**CLINICAL SPECTRUM** HSV has been isolated from nearly all visceral and mucocutaneous sites. The clinical manifestations and course of HSV infection depend on the anatomical site involved, the age and immune status of the host, and the antigenic type of the virus. Primary HSV infections (i.e., first infections with either HSV-1 or HSV-2 in which the host lacks HSV antibodies in acute-phase serum) are frequently accompanied by systemic signs and symptoms. Primary infections involve both mucosal and extramucosal sites; compared with recurrent episodes of disease, they are characterized by a longer duration of symptoms and virus isolation from lesions as well as a higher rate of complications. The incubation period ranges from 1 to 26 days (median, 6 to 8 days). Both viral subtypes can cause genital and oral-facial infections, and the infections caused by the two subtypes are clinically indistinguishable. However, the frequency of reactivation of infection is influenced by anatomical site and virus type. Genital HSV-2 infection is twice as likely to reactivate and recurs 8 to 10 times more frequently than genital HSV-1 infection. Conversely, oral-labial HSV-1 infection recurs more frequently than oral-labial HSV-2 infection. Asymptomatic shedding rates follow the same pattern.

**Oral-Facial Infections** Gingivostomatitis and pharyngitis are the most frequent clinical manifestations of first-episode HSV-1 infection, while recurrent herpes labialis is the most frequent clinical manifestation of reactivation HSV infection. HSV pharyngitis and gingivostomatitis are the result of primary infection and are most commonly seen in children and young adults. Clinical symptoms and signs, which include fever, malaise, myalgias, inability to eat, irritability, and cervical adenopathy, may last from 3 to 14 days. Lesions may involve the hard and soft palate, gingiva, tongue, lip, and facial area. HSV-1 or HSV-2 infection of the pharynx usually results in exudative or ulcerative lesions of the posterior pharynx and/or tonsillar pillars. Lesions of the tongue, buccal mucosa, or gingiva may occur later in the course in one-third of cases. Fever lasting from 2 to 7 days and cervical adenopathy are common. It can be difficult to differentiate HSV pharyngitis clinically from bacterial pharyngitis. *Mycoplasma pneumoniae* infections, and pharyngeal ulcerations of noninfectious etiologies (e.g., Stevens-Johnson syndrome). No substantial evidence suggests that reactivation oral-labial HSV infection is associated with symptomatic reactivation oral-labial herpes.

Reactivation of HSV from the trigeminal ganglia may be associated with asymptomatic virus excretion in the saliva, development of introral mucosal ulcerations, or herpetic ulcerations on the vermilion border of the lip or external facial skin. About 50 to 70% of seropositive patients undergoing trigeminal nerve root decompression and 10 to 15% of those undergoing dental extraction develop oral-labial HSV infection a median of 3 days after these procedures.

In immunosuppressed patients, infection may extend into mucosal and deep cutaneous layers. Friability, necrosis, bleeding, severe pain, and inability to eat or drink may result. The lesions of HSV mucositis are clinically similar to mucosal lesions caused by cytotoxic drug therapy, trauma, or fungal or bacterial infections. Persistent ulcerative HSV infections are among the most common infections in patients with AIDS. HSV and *Candida* infections often occur concurrently. Systemic antiviral therapy speeds the rate of healing and relieves the pain of mucosal HSV infections in immunosuppressed patients. The frequency of HSV reactivation during the early phases of transplantation or induction chemotherapy is high (50 to 90%), and prophylactic systemic antiviral agents such as intravenous acyclovir or penciclovir are used to reduce reactivation rates. Patients with atopic eczema may also develop severe oral-facial HSV infections (*eczema herpeticum*), which may rapidly involve extensive areas of skin and occasionally disseminate to visceral organs. Extensive eczema herpeticum has resolved promptly with the administration of intravenous acyclovir. Erythema multiforme may also be associated with HSV infections (see Fig. 46-9); some evidence suggests that HSV infection is the precipitating event in ~75% of cases of cutaneous erythema multiforme. HSV antigen has been demonstrated both in circulatory immune complexes and in skin lesion biopsy samples from these cases. Patients with severe HSV-associated erythema multiforme are candidates for chronic suppressive oral antiviral therapy.

HSV-1 and varicella-zoster virus (VZV) have been implicated in the etiology of Bell’s palsy (flaccid paralysis of the mandibular portion of the facial nerve). Although uniform recommendations for treatment of this entity are not available, recent evidence suggests that antiviral chemotherapy, usually with a short course of glucocorticoids, may improve outcome.

**Genital Infections** First-episode primary genital herpes is characterized by fever, headache, malaise, and myalgias. Pain, itching, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy are the predominant local symptoms. Widely spaced bilateral lesions of the external genitalia are characteristic (Fig. 163-1). Lesions may be present in varying stages, including vesicles, pustules, or painful erythematous ulcers. The cervix and urethra are involved in >80% of women with first-episode infections. First episodes of genital herpes in patients who have had prior HSV-1 infection are associated with less frequent systemic symptoms and faster healing than primary genital herpes. The clinical courses of acute first-episode genital herpes among patients with HSV-1 and HSV-2 infections are similar. However, the recurrence rates of genital disease differ with the viral subtype: the 12-month recurrence rates among patients with first-episode HSV-2 and HSV-1 infections are ~90% and ~55%, respectively (median number of recurrences, 4 and <1, respectively). Recurrence rates...
for genital HSV-2 infections vary greatly among individuals and over time within the same individual. HSV has been isolated from the urethra and urine of men and women without external genital lesions. A clear mucoid discharge and dysuria are characteristics of symptomatic HSV urethritis. HSV has been isolated from the urethra of 5% of women with the dysuria-frequency syndrome. Occasionally, HSV genital tract disease is manifested by endometritis and salpingitis in women and by prostatitis in men. About 15% of cases of HSV-2 acquisition are associated with these nonlesional clinical syndromes, such as aseptic meningitis, cervicitis, or urethritis. →A more complete discussion of the differential diagnosis of genital herpes is presented in Chap. 115.

Both HSV-1 and HSV-2 can cause symptomatic or asymptomatic rectal and perianal infections. HSV proctitis is usually associated with rectal intercourse. However, subclinical perianal shedding of HSV is detected both in heterosexual men and in women who report no rectal intercourse. This phenomenon is due to the establishment of latency in the sacral dermatome from prior genital tract infection, with subsequent reactivation in epithelial cells in the perianal region. Such reactivations are often subclinical. Symptoms of HSV proctitis include anorectal pain, anorectal discharge, tenesmus, and constipation. Sigmoidoscopy reveals ulcerative lesions of the distal 10 cm of the rectal mucosa. Rectal biopsies show mucosal ulceration, necrosis, polymorphonuclear and lymphocytic infiltration of the lamina propria, and (in occasional cases) multinucleated intranuclear inclusion–bearing cells. Perianal herpetic lesions are also found in immunosuppressed patients receiving cytotoxic therapy. Extensive perianal herpetic lesions and/or HSV proctitis is common among patients with HIV infection.

**Herpetic Whitlow**

Herpetic whitlow—HSV infection of the finger—may occur as a complication of primary oral or genital herpes by inoculation of virus through a break in the epidermal surface or by direct introduction of virus into the hand through occupational or some other type of exposure. Clinical signs and symptoms include the abrupt onset of edema, erythema, and localized tenderness of the infected finger. Vesicular or pustular lesions of the fingertip that are indistinguishable from lesions of pyogenic bacterial infection are seen. Fever, lymphadenitis, and epiphora and auxiliary lymphadenopathy are common. The infection may recur. Prompt diagnosis (to avoid unnecessary and potentially exacerbating surgical therapy and/or transmission) is essential. Antiviral chemotherapy (to speed the healing of the process) is usually recommended (see below).

**Central and Peripheral Nervous System Infections**

HSV accounts for 10 to 20% of all cases of sporadic viral encephalitis in the United States. The estimated incidence is ~2.3 cases per 1 million persons per year. Cases are distributed throughout the year, and the age distribution appears to be bimodal, with peaks at 5 to 30 and >50 years of age. Subtype 1 virus causes >95% of cases of HSV encephalitis.

The pathogenesis of HSV encephalitis varies. In children and young adults, primary HSV infection may result in encephalitis; presumably, exogenously acquired virus enters the CNS by neurotropic spread from the periphery via the olfactory bulb. However, most adults with HSV encephalitis have clinical or serologic evidence of mucocutaneous HSV-1 infection before the onset of the CNS symptoms. In ~25% of the cases examined, the HSV-1 strains from the oropharynx and brain tissue of the same patient differ; thus some cases may result from reinfection with another strain of HSV-1 that reaches the CNS. Two theories have been proposed to explain the development of actively replicating HSV in localized areas of the CNS in persons whose ganglionic and CNS isolates are similar. Reactivation of latent HSV-1 infection in trigeminal or autonomic nerve roots may be associated with extension of virus into the CNS via nerves innervating the middle cranial fossa. HSV DNA has been demonstrated by DNA hybridization in brain tissue obtained at autopsy—even from healthy adults. Thus, reactivation of long-standing latent CNS infection may be another mechanism for the development of HSV encephalitis.

The clinical hallmark of HSV encephalitis has been the acute onset of fever and focal neurologic symptoms and signs, especially in the temporal lobe (Fig. 163-2). Clinical differentiation of HSV encephalitis from other viral encephalitides, focal infections, or noninfectious processes is difficult. The most sensitive noninvasive method for early diagnosis of HSV encephalitis is the demonstration of HSV DNA in cerebrospinal fluid (CSF) by PCR. Although titers of CSF and serum antibodies to HSV increase in most cases of HSV encephalitis, they rarely do so earlier than 10 days into the illness and therefore, while useful retrospectively, are generally not helpful in establishing an early clinical diagnosis. Demonstration of HSV antigen, HSV DNA, or HSV replication in brain tissue obtained by biopsy is highly sensitive and has a low complication rate; examination of such tissue also provides the best opportunity to identify alternative, potentially treatable causes of encephalitis. Antiviral chemotherapy reduces the rate of death from HSV encephalitis. Intravenous acyclovir is more effective than vidarabine. Even with therapy, however, neurologic sequelae are frequent, especially in persons >50 years of age. Most authorities recommend the administration of intravenous acyclovir to patients with presumed HSV encephalitis until the diagnosis is confirmed or an alternative diagnosis is made. Among proven cases of HSV encephalitis, intra-
venous therapy is usually recommended until HSV DNA levels in CSF are substantially reduced or at nearly undetectable levels.

HSV DNA has been detected in CSF from 3 to 15% of persons presenting to the hospital with aseptic meningitis. HSV meningitis, which is usually seen in association with primary genital HSV meningitis, is an acute, self-limited disease manifested by headache, fever, and mild photophobia and lasting from 2 to 7 days. Lymphocytic pleocytosis in the CSF is characteristic. Neurologic sequelae of HSV meningitis are rare. HSV is the most commonly identified cause of recurrent lymphocytic meningitis (Mollaret's meningitis). Demonstration of HSV antibodies in CSF or persistence of HSV DNA in CSF can establish the diagnosis. For persons with frequent recurrences of HSV meningitis, antiviral therapy has been successful in reducing the frequency of such episodes.

Autonomic nervous system dysfunction, especially of the sacral region, has been reported in association with both HSV and VZV infections. Numbness, tingling of the buttocks or perineal areas, urinary retention, constipation, CSF pleocytosis, and (in males) impotence may occur. Symptoms appear to resolve slowly over days to weeks. Occasionally, hypesthesia and/or weakness of the lower extremities may persist for many months. Rarely, transverse myelitis manifested by a rapidly progressive symmetric paralysis of the lower extremities or a Guillain-Barré syndrome may follow HSV infection. Similarly, peripheral nervous system involvement (Bell’s palsy) or cranial polyneuritis may also be related to reactivation of HSV-1 infection. Transitory hypesthesia of the area of skin innervated by the trigeminal nerve and vestibular system dysfunction as measured by electroneystagmography are the predominant signs of disease. Studies to determine whether antiviral chemotherapy may abort these signs or reduce their frequency and severity are unavailable.

Visceral Infections  HSV infection of visceral organs usually results from viremia, and multiple-organ involvement is common. Occasional, however, the clinical manifestations of HSV infection involve only the esophagus, lung, or liver. HSV esophagitis may result from direct extension of oral-pharyngeal HSV infection into the esophagus or may occur de novo by reactivation and spread of HSV to the esophageal mucosa via the vagus nerve. The predominant symptoms of HSV esophagitis are odynophagia, dysphagia, substernal pain, and weight loss. There are multiple oval ulcerations on an erythematous base with or without a patchy white pseudomembrane. The distal esophagus is most commonly involved. With extensive disease, diffuse friability may spread to the entire esophagus. Neither endoscopic nor barium examination can reliably differentiate HSV esophagitis from Candida esophagitis or from esophageal ulcerations due to thermal injury, radiation, or corrosives. Endoscopically obtained secretions for cytologic examination and culture provide the most useful material for diagnosis. Systemic antiviral chemotherapy usually reduces symptoms and heals esophageal ulcerations.

HSV pneumonitis is uncommon except in severely immunosuppressed patients and may result from extension of herpetic tracheobronchitis into lung parenchyma. Focal necrotizing pneumonitis usually ensues. Hematogenous dissemination of virus from sites of oral or genital mucocutanous disease may also occur and produce bilateral interstitial pneumonitis. Bacterial, fungal, and parasitic pathogens are commonly present in HSV pneumonitis. The mortality rate from untreated HSV pneumonia in immunosuppressed patients is high (>80%). HSV has also been isolated from the lower respiratory tract of persons with adult respiratory distress syndrome. However, the relationship between the isolation of HSV and the pathogenesis of this syndrome is unclear.

HSV is an uncommon cause of hepatitis in immunocompetent patients. HSV infection of the liver is associated with fever, abrupt elevations of bilirubin and serum aminotransferase levels, and leukopenia (<4000 white blood cells per microliter). Disseminated intravascular coagulation may also develop.

Other reported complications of HSV infection include monarticular arthritis, adrenal necrosis, idiopathic thrombocytopenia, and glomerulonephritis. Disseminated HSV infection in immunocompetent patients is rare. In immunocompromised, burned, or malnourished patients, HSV occasionally disseminates to other visceral organs, such as the adrenal glands, pancreas, small and large intestines, and bone marrow. Rarely, primary HSV infection in pregnancy disseminates and may be associated with the death of both mother and fetus. This uncommon event is usually related to the acquisition of primary infection in the third trimester.

Neonatal HSV Infection  Of all HSV-infected populations, neonates (infants younger than 6 weeks) have the highest frequency of visceral and/or CNS infection. Without therapy, the overall rate of death from neonatal herpes is 65%; <10% of neonates with CNS infection develop normally. Although skin lesions are the most commonly recognized features of disease, many infants do not develop lesions until well into the course of disease. Neonatal infection is usually acquired perinatally from contact with infected genital secretions at the time of delivery. Congenitally infected infants have been reported. In most series, 30% of neonatal HSV infections are due to HSV-1 and 70% to HSV-2. The risk of developing neonatal HSV infection is 10 times higher for an infant born to a mother who has recently acquired HSV than for other infants. Neonatal HSV-1 infections may also be acquired through postnatal contact with immediate family members who have symptomatic or asymptomatic oral-labial HSV-1 infection or through nosocomial transmission within the hospital. All neonates with presumed neonatal herpes should be treated with intravenous acyclovir (see below). Antiviral chemotherapy has reduced the rate of death from neonatal herpes to 25%. However, the rate of morbidity, especially among infants with HSV-2 infection involving the CNS, is still very high.

DIAGNOSIS  Both clinical and laboratory criteria are useful for establishing the diagnosis of HSV infections. A clinical diagnosis can be made accurately when characteristic multiple vesicular lesions on an erythematous base are present. However, it is increasingly being recognized that herpetic ulcerations may clinically resemble skin ulcer-
Herpes simplex virus (HSV) infection is best confirmed in the laboratory by isolation of the virus in tissue culture or by demonstration of HSV antigens or HSV DNA in scrapings from lesions. HSV causes a discernible cytopathic effect in a variety of cell culture systems, and this effect can be identified within 48 to 96 h after inoculation. Spin-amplified culture with subsequent staining for HSV antigen has shortened the time needed to identify HSV to <24 h. Increasingly, PCR is being used for the detection of HSV DNA, and several studies have shown this assay to be more sensitive than culture for detection of HSV in CSF and at mucosal sites. The sensitivity of viral isolation and of antigen or DNA detection depends on the stage of the lesions (with higher sensitivity in vesicular than in ulcerative lesions), on whether the patient has a first or a recurrent episode of the disease (with higher sensitivity in first than in recurrent episodes), and on whether the sample is from an immunosuppressed or an immunocompetent patient (with more antigen in immunosuppressed patients). Laboratory confirmation permits subtyping of the virus; information on subtype may be useful epidemiologically and may help to predict the frequency of reactivation after first-episode oral-labial or genital HSV infection.

Acute- and convalescent-phase serum can be useful in demonstrating seroconversion during primary HSV-1 or HSV-2 infection. However, only 5% of patients with recurrent mucocutaneous HSV infections have a fourfold or greater rise in titer of antibody to HSV in the interval between the collection of the first and second samples. Serologic assays, especially type-specific assays, should be used to identify asymptomatic carriers of HSV-1 or HSV-2 infection.

Several studies have shown that persons seropositive for HSV-2 to whom the clinical manifestations of HSV have been explained are able to identify symptomatic reactivations. Individuals seropositive for HSV-2 should be told about the high frequency of subclinical reactivation in mucosal surfaces not visible to the eye (e.g., cervix, urethra, perianal skin) or in microscopic ulcerations that may not be clinically symptomatic. Transmission of infection during such episodes is well established. HSV-2-seropositive persons should be educated about the high likelihood of subclinical shedding and the role condoms (male or female) may play in reducing transmission. Antiviral therapy with the drug valacyclovir (500 mg once daily) has been shown to reduce the transmission of HSV-2 between sexual partners.

Many aspects of mucocutaneous and visceral HSV infections are amenable to antiviral chemotherapy. For mucocutaneous infections, acyclovir and its congeners famciclovir and valacyclovir have been the mainstay of therapy. Several antiviral agents are available for topical use in HSV eye infections: idoxuridine, trifluorothymidine, topical vidarabine, and cidofovir. For HSV encephalitis and neonatal herpes, intravenous acyclovir is the treatment of choice.

All licensed antiviral agents for use against HSV inhibit the viral DNA polymerase. One class of drugs, typified by the drug acyclovir, is made up of substrates for the HSV enzyme thymidine kinase. Acyclovir, ganciclovir, famciclovir, and valacyclovir are all selectively phosphorylated to the monophosphate form in virus-infected cells. Cellular enzymes convert the monophosphate form of the drug to the triphosphate, which is then incorporated into the viral DNA chain.

Acyclovir is the most frequently used agent for the treatment of HSV infections and is available in intravenous, oral, and topical formulations. Valacyclovir is the valyl ester of acyclovir and offers greater bioavailability than acyclovir. Famciclovir, the oral formulation of penciclovir, is clinically effective in the treatment of a variety of HSV-1 and HSV-2 infections. Ganciclovir is active against both HSV-1 and HSV-2; however, it is more toxic than acyclovir, valacyclovir, and famciclovir and generally is not recommended for the treatment of HSV infections.

All three recommended compounds—acyclovir, valacyclovir, and famciclovir—have proven effective in shortening the duration of symptoms and lesions of mucocutaneous HSV infections in both immunocompromised and immunocompetent patients (Table 163-1). Intravenous and oral formulations prevent reactivation of HSV in seropositive immunocompromised patients during induction chemotherapy or in the period immediately after bone marrow or solid organ transplantation. Chronic daily suppressive therapy reduces the frequency of reactivation disease among patients with frequent genital or oral-labial herpes. Only valacyclovir has been shown to reduce transmission of HSV-2 infection between sexual partners.

Intravenous acyclovir (30 mg/kg per day, given as a 10-mg/kg infusion over 1 h at 8-h intervals) is effective in reducing rates of death and morbidity from HSV encephalitis. Early initiation of therapy is a critical factor in outcome. The major side effect associated with intravenous acyclovir is transient renal insufficiency, usually due to crystallization of the compound in the renal parenchyma. This adverse reaction can be avoided if the medication is given slowly over 1 h and the patient is well hydrated. Because CSF levels of acyclovir average only 30 to 50% of plasma levels, the dosage of acyclovir used for treatment of CNS infection (30 mg/kg per day) is double that used for treatment of mucocutaneous or visceral disease (15 mg/kg per day). Even higher doses of intravenous acyclovir are used for neonatal HSV infection (60 mg/kg per day in 3 divided doses).

Among immunocompetent patients, recent studies have shown the effectiveness of short-course oral therapy to reduce the signs and symptoms of oral and genital HSV infection. These regimens include valacyclovir (1 or 3 days) for oral-labial HSV and acyclovir (2 days) or valacyclovir (3 days) for recurrent-episode genital herpes (Table 163-1).

Suppression of Mucocutaneous Herpes Recognition of the high frequency of subclinical reactivation has provided an ever-greater rationale for the use of daily antiviral therapy to suppress reactivations of HSV, especially in persons with frequent clinical reactivations (e.g., those with recently acquired genital HSV infection). Immunocompromised persons, including those with HIV infection, may also benefit from daily antiviral therapy. Of the various regimens used, famciclovir (500 mg twice daily) and valacyclovir (1 g twice daily) are two of the most common; valacyclovir at a dose of 4 g daily was associated with thrombotic thrombocytopenic purpura in one study of HIV-infected persons.

Reduction in Transmission of HSV to Sexual Partners Once-daily valacyclovir (500 mg) has been shown to reduce transmission of HSV-2 between sexual partners. Transmission rates are higher from males to females and among persons with frequent HSV-2 reactivation. Serologic screening can be used to identify at-risk couples.

Acyclovir Resistance Acyclovir-resistant strains of HSV have been identified. Most of these strains have an altered substrate specificity for phosphorylating acyclovir. Thus, cross-resistance to famciclovir and valacyclovir is usually found. Occasionally, an isolate with altered thymidine kinase (TK) specificity arises and is sensitive to famciclovir but not to acyclovir. In some patients infected with TK-deficient virus, higher doses of acyclovir are associated with clearing of lesions. In others, clinical disease progresses despite high-dose therapy. Almost all clinically significant acyclovir resistance has been seen in immunocompromised patients, and HSV-2 isolates are more often resistant than HSV-1 strains. A study by the Centers for Disease Control and Prevention indicated that ~5% of HSV-2 isolates from HIV-positive persons exhibit some degree of in vitro resistance to acyclovir. Among immunocompetent patients attending sexually transmitted disease clin-

<tr>
<td>1. Acute symptomatic first or recurrent episodes: IV acyclovir (5 mg/kg q8h) or oral acyclovir (400 mg qid), famciclovir (500 mg tid), or valacyclovir (500 mg bid). Treatment duration may vary from 7 to 14 days.</td>
</tr>
<tr>
<td>2. Suppression of reactivation disease: IV acyclovir (5 mg/kg q8h) or oral valacyclovir (500 mg bid) or acyclovir (400–800 mg 3–5 times per day) prevents recurrences during the 30-day period immediately after transplantation. Longer-term HSV suppression is often used for persons with continued immunosuppression. In bone marrow and renal transplant recipients, oral valacyclovir (2 g/d) is also effective in preventing cytomegalovirus infection. Oral acyclovir at a dose of 4 g/d has been associated with thrombotic thrombocytopenic purpura after extended use in HIV-positive persons. In HIV-infected persons, oral famciclovir (500 mg bid) is effective in reducing clinical and subclinical reactivations of HSV-1 and HSV-2.</td>
</tr>
<tr>
<td>B. Genital herpes:</td>
</tr>
<tr>
<td>1. First episodes: Oral acyclovir (200 mg 5 times per day or 400 mg tid), valacyclovir (1 g bid), or famciclovir (250 mg bid) for 10–14 days is effective. IV acyclovir (5 mg/kg q8h for 5 days) is given for severe disease or neurologic complications such as aseptic meningitis.</td>
</tr>
<tr>
<td>2. Symptomatic recurrent genital herpes: Oral acyclovir (200 mg 5 times per day for 5 days, 300 mg tid for 2 days), valacyclovir (500 mg bid for 3 or 5 days), or famciclovir (125 mg bid for 5 days) is effective in shortening lesion duration.</td>
</tr>
<tr>
<td>3. Suppression of recurrent genital herpes: Oral acyclovir (200-mg capsules tid or qid, 400 mg bid, or 800 mg qd), famciclovir (250 mg bid), or valacyclovir (500 mg or 1 g qd or 500 mg bid) prevents symptomatic reactivation. Persons with frequent reactivation but ≤9 episodes per year can take valacyclovir (500 mg PO daily); those with &gt;9 episodes per year should take 1 g PO daily or 500 mg PO bid.</td>
</tr>
<tr>
<td>C. Oral-labial HSV infections:</td>
</tr>
<tr>
<td>1. First episode: Oral acyclovir (200 mg) has been used clinically. Oral famciclovir (250 mg bid) or valacyclovir (1 g bid) has been used clinically.</td>
</tr>
<tr>
<td>2. Recurrent episodes: Oral valacyclovir (1 g bid for 1 or 500 mg bid for 3 days) is effective in reducing pain and speeding healing. Self-initiated therapy with 6-times-daily topical penciclovir cream is effective in speeding the healing of oral-labial HSV. Topical acyclovir cream has also been shown to speed healing.</td>
</tr>
<tr>
<td>3. Suppression of reactivation of oral-labial HSV: Oral acyclovir (400 mg bid), if started before exposure and continued for the duration of exposure (usually 5–10 days), will prevent reactivation of recurrent oral-labial HSV infection associated with severe sun exposure.</td>
</tr>
<tr>
<td>D. Herpetic whitlow: Oral acyclovir (200 mg) is given 5 times daily for 7–10 days.</td>

</tbody>
</table>

**PREVENTION** The success of efforts to control HSV disease on a population basis through suppressive antiviral chemotherapy and/or educational programs will be limited. Barrier forms of contraception (especially condoms) decrease the likelihood of transmission of HSV infection, particularly during periods of asymptomatic viral excretion. When lesions are present, HSV infection may be transmitted by skin-to-skin contact despite the use of a condom. Nevertheless, the available data suggest that consistent condom use is an effective means of reducing the risk of genital HSV-2 transmission. Recent studies have shown that chronic daily antiviral therapy with valacyclovir can also be partially effective in reducing acquisition of HSV-2, especially among susceptible women. There are no comparative efficacy studies of valacyclovir versus condom use. Most authorities suggest both approaches. Several candidate HSV vaccines are under investigation.

Prevention of neonatal HSV requires the prevention of acquisition of HSV by women in the third trimester of pregnancy. Identification of <0.5% of HSV-2 isolates show reduced in vitro sensitivity to acyclovir. The lack of appreciable change in the frequency of detection of such isolates in the past 20 years probably reflects the reduced transmission of TK-deficient mutants. Isolation of HSV from lesions persisting despite adequate dosages and blood levels of acyclovir should raise the suspicion of acyclovir resistance. Therapy with the antiviral drug foscarnet is useful (Chap. 162). Because of its toxicity and cost, this drug is usually reserved for patients with extensive mucocutaneous infections. Cidofovir is a nucleotide analogue and exists as a phosphonate or monophosphate form. Most TK-deficient strains of HSV are sensitive to cidofovir. Cidofovir ointment speeds healing as a phosphonate or monophosphate form. Most TK-deficient strains of HSV are sensitive to cidofovir. Cidofovir ointment speeds healing as a phosphonate or monophosphate form.
of women or couples susceptible to acquisition of HSV in pregnancy through serologic screening is receiving increasing attention, and such screening is being used with increasing frequency.

**164 VARICELLA-ZOSTER VIRUS INFECTIONS**

*Richard J. Whitley*

**DEFINITION** Varicella-zoster virus (VZV) causes two distinct clinical entities: varicella (chickenpox) and herpes zoster (shingles). Chickenpox, a ubiquitous and extremely contagious infection, is usually a benign illness of childhood characterized by an exanthematous vesicular rash. With reactivation of latent VZV (which is most common after the sixth decade of life), herpes zoster presents as a dermatomal vesicular rash, usually associated with severe pain.

**ETIOLOGY** A clinical association between varicella and herpes zoster has been recognized for nearly 100 years. Early in the twentieth century, similarities in the histopathologic features of skin lesions resulting from varicella and herpes zoster were demonstrated. Viral isolates from patients with chickenpox and herpes zoster produced similar alterations in tissue culture—specifically, the appearance of eosinophilic intranuclear inclusions and multinucleated giant cells. These results suggested that the viruses were biologically similar. Restriction endonuclease analyses of viral DNA from a patient with chickenpox who subsequently developed herpes zoster verified the molecular identity of the two viruses responsible for these different clinical presentations.

VZV is a member of the family Herpesviridae, sharing with other members such structural characteristics as a lipid envelope surrounding a nucleocapsid with icosahedral symmetry, a total diameter of 180 to 200 nm, and centrally located double-stranded DNA that is 125,000 bp in length.

**PATHOGENESIS AND PATHOLOGY**

### Primary Infection

Transmission is most likely to take place by the respiratory route; the subsequent localized replication of the virus at an undefined site (presumably the nasopharynx) leads to seeding of the reticuloendothelial system and ultimately to the development of viremia. Viremia in patients with chickenpox is reflected in the diffuse and scattered nature of the skin lesions and can be verified in selected cases by the recovery of VZV from the blood or routinely by polymerase chain reaction (PCR). Vesicles involve the corium and dermis, with degenerative changes characterized by ballooning, the presence of multinucleated giant cells, and eosinophilic intranuclear inclusions. Infection may involve localized blood vessels of the skin, resulting in necrosis and epidermal hemorrhage. With the evolution of disease, the vesicular fluid becomes cloudy because of the recruitment of polymorphonuclear leukocytes and the presence of degenerated cells and fibrin. Ultimately, the vesicles either rupture and release their fluid (which includes infectious virus) or are gradually reabsorbed.

### Recurrent Infection

The mechanism of reactivation of VZV that results in herpes zoster is unknown. Presumably, the virus infects the dorsal root ganglia during chickenpox, where it remains latent until reactivated. Histopathologic examination of representative dorsal root ganglia during active herpes zoster demonstrates hemorrhage, edema, and lymphocytic infiltration.

Active replication of VZV in other organs, such as the lung or the brain, can occur during either chickenpox or herpes zoster but is uncommon in the immunocompetent host. Pulmonary involvement is characterized by interstitial pneumonitis, multinucleated giant cell formation, intranuclear inclusions, and pulmonary hemorrhage. Central nervous system (CNS) infection leads to histopathologic evidence of perivascular cuffing similar to that encountered in measles and other viral encephalitides. Focal hemorrhagic necrosis of the brain, characteristic of herpes simplex virus encephalitis, is uncommon in VZV infection.

**EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS**

### Chickenpox

Humans are the only known reservoir for VZV. Chickenpox is highly contagious, with an attack rate of at least 90% among susceptible (seronegative) individuals. Persons of both sexes and all races are infected equally often. The virus is endemic in the population at large; however, it becomes epidemic among susceptible individuals during seasonal peaks—namely, late winter and early spring in the temperate zone. Historically, children between the ages of 5 and 9 are most commonly affected and account for 50% of all cases. Most other cases involve children aged 1 to 4 and those aged 10 to 14. Approximately 10% of the population of the United States over the age of 15 is susceptible to infection. VZV vaccination during the second year of life is dramatically changing the epidemiology of infection.

The incubation period of chickenpox ranges from 10 to 21 days but is usually between 14 and 17 days. Secondary attack rates in susceptible siblings within a household are between 70 and 90%. Patients are infectious ~48 h prior to the onset of the vesicular rash, during the period of vesicle formation (which generally lasts 4 to 5 days), and until all vesicles are crusted.

Clinically, chickenpox presents as a rash, low-grade fever, and malaise, although a few patients develop a prodrome 1 to 2 days before onset of the exanthem. In the immunocompetent patient, this usually a benign illness that is associated with lassitude and with body temperatures of 37.8°C to 39.4°C (100°F to 103°F) of 3 to 5 days’ duration. The skin lesions—the hallmark of the infection—include maculopapules, vesicles, and scabs in various stages of evolution (Fig. 164-1). These lesions, which evolve from maculopapules to vesicles over hours to days, appear on the trunk and face and rapidly spread to involve other areas of the body. Most are small and have an erythematous base with a diameter of 5 to 10 mm. Successive crops appear over a 2- to 4-day period. Lesions can also be found on the mucosa of the pharynx and/or the vagina. Their severity varies from one person to another. Some individuals have very few lesions, while others have...
maternal disease develops within 5 days before delivery or within 48 h thereafter. Because the newborn does not receive protective transplacental antibodies and has an immature immune system, the illness may be unusually severe. The reported mortality rate has been as high as 30% in this group. Congenital varicella, with clinical manifestations of limb hypoplasia, cicatricial skin lesions, and microcephaly at birth, is extremely uncommon.

**Herpes Zoster**  
Herpes zoster, a sporadic disease, is the consequence of reactivation of latent VZV from the dorsal root ganglia. Most patients have no history of recent exposure to other individuals with VZV infection. Herpes zoster occurs at all ages, but its incidence is highest (5 to 10 cases per 1000 persons) among individuals in the sixth decade of life and beyond. Recurrent herpes zoster is exceedingly rare except in immunocompromised hosts, especially those with AIDS.

Herpes zoster, also called shingles, is characterized by a unilateral vesicular eruption within a dermatome, often associated with severe pain. The dermatomes from T3 to L3 are most frequently involved. If the ophthalmic branch of the trigeminal nerve is involved, zoster ophthalmicus results. The factors responsible for the reactivation of VZV are not known. In children reactivation is usually benign, whereas in adults it can be debilitating. The continuum of pain from onset to resolution is known as zoster-associated pain. The onset of disease is heralded by pain within the dermatome that may precede lesions by 48 to 72 h; an erythematous maculopapular rash evolves rapidly into vesicular lesions (Fig. 164-2). In the normal host, these lesions may remain few in number and continue to form only for a period of 3 to 5 days. The duration of disease is generally between 7 and 10 days; however, it may take as long as 2 to 4 weeks for the skin to return to normal. Patients with herpes zoster can transmit infection to seronegative individuals, with consequent chickenpox. In a few patients, characteristic localization of pain to a dermatome with serologic evidence of herpes zoster has been reported in the absence of skin lesions. When branches of the trigeminal nerve are involved, lesions may appear on the face, in the mouth, in the eye, or on the tongue. Zoster ophthalmicus is usually a debilitating condition that can result in blindness in the absence of antiviral therapy. In the Ramsay Hunt syndrome, pain and vesicles appear in the external auditory canal, and patients lose their sense of taste in the anterior two-thirds

![FIGURE 164-1](image1.png) Numerous varicella lesions at various stages of evolution: vesicles on an erythematous base, umbilical vesicles, and crusts.

as many as 2000. Younger children tend to have fewer vesicles than older individuals. Secondary and tertiary cases within families are associated with a relatively large number of vesicles. Immunocompromised patients—both children and adults, particularly those with leukemia—have lesions (often with a hemorrhagic base) that are more numerous and take longer to heal than those of immunocompetent patients. Immunocompromised individuals are also at greater risk for visceral complications, which occur in 30 to 50% of cases and are fatal 15% of the time in the absence of antiviral therapy.

The most common infectious complication of varicella is secondary bacterial superinfection of the skin, which is usually caused by *Streptococcus pyogenes* or *Staphylococcus aureus*. This complication may result from excoriation of skin lesions after scratching. Gram’s staining of skin lesions should help clarify the etiology of unusually erythematous and pustulated lesions.

The most common extracutaneous site of involvement in children is the CNS. The syndrome of acute cerebellar ataxia and meningeal irritation generally appears 7 to 10 days after the onset of the rash and rarely develops in the preeruptive phase. The cerebrospinal fluid (CSF) contains lymphocytes and elevated levels of protein. CNS involvement is a benign complication of VZV infection in children and generally does not require hospitalization. Aseptic meningitis, encephalitis, transverse myelitis, Guillain-Barré syndrome, and Reye’s syndrome can also occur. Encephalitis is reported in 0.1 to 0.2% of children with chickenpox. Other than supportive care, no specific therapy is available for patients with CNS involvement.

**Varicella pneumonia** is the most serious complication following chickenpox, developing more commonly in adults (up to 20% of cases) than in children. It usually has its onset 3 to 5 days into the illness and is associated with tachypnea, cough, dyspnea, and fever. Cyanosis, pleuritic chest pain, and hemoptysis are frequent. Roentgenographic evidence of disease consists of nodular infiltrates and interstitial pneumonitis. Resolution of pneumonitis parallels improvement of the skin rash; however, patients may have persistent fever and compromised pulmonary function for weeks.

Other complications of chickenpox include myocarditis, corneal lesions, nephritis, arthritis, bleeding diatheses, acute glomerulonephritis, and hepatitis. Hepatic involvement, distinct from Reye’s syndrome and usually asymptomatic, is common in chickenpox and is generally characterized by elevated levels of liver enzymes, particularly aspartate and alanine aminotransferases.

**Perinatal varicella** is associated with a high mortality rate when...
of the tongue while developing ipsilateral facial palsy. The geniculate ganglion of the sensory branch of the facial nerve is involved.

The most debilitating complication of herpes zoster, in both the normal and the immunocompromised host, is pain associated with acute neuritis and postherpetic neuralgia. Postherpetic neuralgia is uncommon in young individuals; however, at least 50% of patients over age 50 with zoster report some degree of pain in the involved dermatome months after the resolution of cutaneous disease. Changes in sensation in the dermatome, resulting in either hypo- or hyperesthesia, are common.

CNS involvement may follow localized herpes zoster. Many patients without signs of meningeal irritation have CSF pleocytosis and moderately elevated levels of CSF protein. Symptomatic meningoencephalitis is characterized by headache, fever, photophobia, meningitis, and vomiting. A rare manifestation of CNS involvement is granulomatous angitis with contralateral hemiplegia, which can be diagnosed by cerebral arteriography. Other neurologic manifestations include transverse myelitis with or without motor paralysis.

Like chickenpox, herpes zoster is more severe in the immunocompromised host than in the normal individual. Lesions continue to form for over a week, and scabbing is not complete in most cases until 3 weeks into the illness. Patients with Hodgkin’s disease and non-Hodgkin’s lymphoma are at greatest risk for progressive herpes zoster. Cutaneous dissemination (Fig. 164-3) develops in ~40% of these patients. Among patients with cutaneous dissemination, the risk of pneumonitis, meningoencephalitis, hepatitis, and other serious complications is increased by 5 to 10%. However, even in immunocompromised patients, disseminated zoster is rarely fatal.

Patients who have received a bone marrow transplant are at particularly high risk of VZV infection. Thirty percent of cases of posttransplantation VZV infection occur within 1 year (50% of these within 9 months); 45% of the patients involved have cutaneous or visceral dissemination. The mortality rate in this situation is 10%. Postherpetic neuralgia, scarring, and bacterial superinfection are especially frequent in VZV infections occurring within 9 months of transplantation. Among infected patients, concomitant graft-versus-host disease increases the chance of dissemination and/or death.

DIFFERENTIAL DIAGNOSIS The diagnosis of chickenpox is not difficult. The characteristic rash and a history of recent exposure should lead to a prompt diagnosis. Other viral infections that can mimic chickenpox include disseminated herpes simplex virus infection in patients with atopic dermatitis and the disseminated vesiculopapular lesions sometimes associated with coxsackievirus infection, echovirus infection, or atypical measles. However, these rashes are more commonly morbiliform with a hemorrhagic component rather than vesicular or vesiculopustular. Rickettsialpox (Chap. 158) can be confused with chickenpox; however, it can be distinguished easily by detection of the “herald spot” at the site of the mite bite and the development of a more pronounced headache. Serologic testing is also useful in differentiating rickettsialpox from varicella. Concern about smallpox has recently increased because of the threat of bioterrorism (Chap. 205). The lesions of smallpox are larger than those of chickenpox and are all at the same stage of evolution.

Unilateral vesicular lesions in a dermatomal pattern should lead rapidly to the diagnosis of herpes zoster, although the occurrence of shingles without a rash has been reported. Both herpes simplex virus infections and coxsackievirus infections can cause dermatomal vesicular lesions. Supportive diagnostic virology and fluorescent staining of skin scrapings with monoclonal antibodies are helpful in ensuring the proper diagnosis. In the prodromal stage of herpes zoster, the diagnosis can be exceedingly difficult and may be made only after lesions have appeared or by retrospective serologic assessment.

LABORATORY FINDINGS Unequivocal confirmation of the diagnosis is possible only through the isolation of VZV in susceptible tissue-culture cell lines, the demonstration of either seroconversion or a fourfold or greater rise in antibody titer between convalescent- and acute-phase serum specimens, or the detection of VZV DNA by PCR. A rapid impression can be obtained by a Tzanck smear, with scraping of the base of the lesions in an attempt to demonstrate multinucleated giant cells, although the sensitivity of this method is low (~60%). PCR technology for the detection of viral DNA in vesicular fluid is available in a limited number of diagnostic laboratories. Direct immunofluorescent staining of cells from the lesion base or detection of viral antigens by other assays (such as the immunoperoxidase assay) is also useful, although these tests are not commercially available. The most frequently employed serologic tools for assessing host response are the immunofluorescent detection of antibodies to VZV membrane antigens, the fluorescent antibody to membrane antigen (FAMA) test, immune adherence hemagglutination, and enzyme-linked immunosorbent assay (ELISA). The FAMA test and the ELISA appear to be the most sensitive.

FIGURE 164-3 Herpes zoster is seen in this HIV-infected patient as hemorrhagic vesicles and pustules on an erythematous base grouped in a dermatomal distribution.

TREATMENT Medical management of chickenpox in the immunologically normal host is directed toward the prevention of avoidable complications. Obviously, good hygiene includes daily bathing and soaks. Secondary bacterial infection of the skin can be avoided by meticulous skin care, particularly with close cropping of fingernails. Pruritus can be decreased with topical dressings or the administration of antipruritic drugs. Tepid water baths and wet compresses are better than drying lotions for the relief of itching. Aluminum acetate soaks for the management of herpes zoster can be both soothing and cleansing. Administration of aspirin to children with chickenpox should be avoided because of the association of aspirin derivatives with the development of Reye’s syndrome. Acyclovir therapy (800 mg by mouth five times daily for 5 to 7 days) is recommended for adolescents and adults with chickenpox of ≤24 h duration. Likewise, acyclovir therapy may be of benefit to children <12 years of age if initiated early in the disease (<24 h) at a dose of 20 mg/kg every 6 h.

Patients with herpes zoster benefit from oral antiviral therapy, as evidenced by accelerated healing of lesions and resolution of zoster-associated pain with acyclovir, valacyclovir, or famciclovir. Acyclovir, now off patent, is administered at a dosage of 800 mg five times daily for 7 to 10 days. Famciclovir, the prodrug of penciclovir, is at least as effective as acyclovir and perhaps more so. One study showed twofold faster resolution of postherpetic neuralgia in famciclovir-treated patients with zoster than in recipients of placebo. The dose is 500 mg by mouth three times daily for 7 days. Valacyclovir, the prodrug of acyclovir, accelerates healing and resolution of zoster-associated pain more promptly than acyclovir. The dose is 1 g by mouth three times
Therapy is instituted 7 days after intense exposure. At this time, the
administration of acyclovir is considered. Therapy should be initiated for
in the immunocompromised host, both chickenpox and herpes zoster
including disseminated disease) should be treated with intravenous
acyclovir, which reduces the occurrence of visceral complications but
has no effect on healing of skin lesions or pain. The dose is 10 to 12.5
mg/kg every 8 h for 7 days. Oral acyclovir therapy is not recommended
for the treatment of VZV infections in immunocompromised patients.
Concomitantly with the administration of intravenous acyclovir, it is
desirable to attempt to wean these patients from immunosuppressive
treatment.

Patients with varicella pneumonia may require removal of bron-
chial secretions and ventilatory support. Persons with zoster ophthal-
micus should be referred immediately to an ophthalmologist.

The management of acute neuritis and/or postherpetic neuralgia can
be particularly difficult. In addition to the judicious use of analgesics,
ranging from nonnarcotics to narcotic derivatives, drugs such as ga-
bapentin, amitriptyline hydrochloride, lidocaine patches, and fluphen-
azine hydrochloride have been reported to be beneficial for pain relief.

In one study, glucocorticoid therapy administered early in the course
of localized herpes zoster significantly accelerated such quality-of-life
improvements as a return to usual activity and termination of anal-
gesia. The dose of prednisone administered orally was 60 mg/d on
days 1 through 7, 30 mg/d on days 8 through 14, and 15 mg/d on days
15 through 21. This regimen is appropriate only for relatively healthy
elderly persons who have moderate or severe pain at presentation.

Patients with osteoporosis, diabetes mellitus, glycosuria, or hyperten-
sion may not be appropriate candidates. Glucocorticoids should not be
used without concomitant antiviral therapy.

PREVENTION Three methods are used for the prevention of VZV infec-
tions. First, a live attenuated varicella vaccine (OKA) is recommended
for all children >1 year of age (up to 12 years of age) who have not
had chickenpox and for adults known to be seronegative for VZV. A
single dose of vaccine is administered to children, whereas adults re-
quire two doses. The vaccine is both safe and efficacious. Break-
through cases are mild and may result in spread of the vaccine virus
to susceptible contacts. The universal vaccination of children is re-
sulting in a decreased incidence of chickenpox in sentinel communi-
ties. Furthermore, inactivation of the vaccine virus significantly
decreases the occurrence of herpes zoster after human stem-cell trans-
plantation. A vaccine study is being performed in individuals >60
years of age to determine its impact on the incidence and severity of
shingles.

A second approach is to administer varicella-zoster immune glob-
ulin (VZIG) to individuals who are susceptible, are at high risk for
developing complications of varicella, and have had a significant ex-
posure. This product should be given within 96 h (preferably within
72 h) of the exposure. Indications for administration of VZIG appear
in Table 164-1.

Lastly, antiviral therapy can be given as prophylaxis to individuals
at high risk who are ineligible for vaccine or beyond the 96-h window
after direct contact. While the initial studies have used acyclovir, sim-
lar benefit can be anticipated with either valacyclovir or famciclovir.

Therapy is instituted 7 days after intense exposure. At this time, the

TABLE 164-1 Recommendations for VZIG Administration

Exposure criteria
1. Exposure to person with chickenpox or zoster
   a. Household; residence in the same household
   b. Playmate; face-to-face indoor play
   c. Hospital
      Varicella: same 2- to 4-bed room or adjacent beds in large ward,
      face-to-face contact with infectious staff member or patient, visit
      by a person deemed contagious
      Zoster: intimate contact (e.g., touching or hugging) with a person
d. Newborn infant: onset of varicella in the mother ≤5 days before
delivery or ≤48 h after delivery; VZIG is not indicated if the mother
has zoster
2. Patient should receive VZIG as soon as possible but not >96 h after
   exposure

Candidates (provided they have significant exposure) include:
1. Immunocompromised susceptible children without history of varicella
   or varicella immunization
2. Susceptible pregnant women
3. Newborn infants whose mother had onset of chickenpox within 5 days
   before or within 48 h after delivery
4. Hospitalized premature infant (≥28 weeks of gestation) whose mother
   lacks a reliable history of chickenpox or serologic evidence of protec-
tion against varicella
5. Hospitalized premature infant (<28 weeks of gestation or ≤1000-g birth
   weight), regardless of maternal history of varicella or varicella-zoster
   virus serologic status

DEFINITION Epstein-Barr virus (EBV) is the cause of heterophile-positive infectious mononucleosis (IM), which is characterized by fever, sore throat, lymphadenopathy, and atypical lymphocytosis. EBV is also associated with several human tumors, including nasopharyngeal carcinoma, Burkitt’s lymphoma, Hodgkin’s disease, and (in patients with immunodeficiencies) B cell lymphoma. The virus, a member of the family Herpesviridae, consists of a linear DNA core surrounded by a nucleocapsid and an envelope that contains glycoproteins. The two types of EBV that are widely prevalent in nature are not distinguishable by conventional serologic tests.

EPIDEMIOLOGY EBV infections occur worldwide. These infections are most common in early childhood, with a second peak during late adolescence. By adulthood, more than 90% of individuals have been infected and have antibodies to the virus. IM is usually a disease of young adults. In lower socioeconomic groups and in areas of the world with lower standards of hygiene (e.g., developing countries), EBV tends to infect children at an early age, and symptomatic IM is uncommon. In areas with higher standards of hygiene, infection with EBV is often delayed until adulthood, and IM is more prevalent.

EBV is spread by contact with oral secretions. The virus is frequently transmitted from asymptomatic adults to infants and among young adults by transfer of saliva during kissing. Transmission by less intimate contact is rare. EBV has been transmitted by blood transfusion and by bone marrow transplantation. More than 90% of asymptomatic seropositive individuals shed the virus in oropharyngeal secretions.

PATHOGENESIS EBV is transmitted by salivary secretions. The virus infects the epithelium of the oropharynx and the salivary glands and is shed from these cells. While B cells may become infected after contact with epithelial cells, studies suggest that lymphocytes in the tonsillar crypts can be infected directly. The virus then spreads through the bloodstream. The proliferation and expansion of EBV-infected B cells along with reactive T cells during IM result in enlargement of lymphoid tissue. Polyclonal activation of B cells leads to the production of antibodies to host-cell and viral proteins. During the acute phase of IM, up to 1 in every 100 B cells in the peripheral blood is infected by EBV, while after recovery, about 1 in every million B cells is infected. During IM there is an inverted CD4+/CD8+ T cell ratio. The percentage of CD4+ T cells decreases while there are large clonal expansions of CD8+ T cells; up to 40% of CD8+ T cells are directed against EBV antigens during acute infection. Data suggest that memory B cells, not epithelial cells, are the reservoir for EBV in the body. When patients are treated with acyclovir, shedding of EBV from the oropharynx stops but the virus persists in B cells.

The EBV receptor (CD21), present on the surface of B cells, is also the receptor for the C3d component of complement. EBV infection of epithelial cells results in viral replication and production of virions. When B cells are infected by EBV in vitro, they become transformed and can proliferate indefinitely. During latent infection of B cells, only the EBV nuclear antigens (EBNAs), latent membrane proteins (LMPs), and small EBV RNAs are expressed in vitro. EBV-transformed B cells secrete immunoglobulin; only a small fraction of cells produce virus.

Cellular immunity is more important than humoral immunity in controlling EBV infection. In the initial phase of infection, suppressor T cells, natural killer cells, and nonspecific cytotoxic T cells are important in controlling the proliferation of EBV-infected B cells. Levels of markers of T cell activation and serum interferon γ are elevated. Later in infection, HLA-restricted cytotoxic T cells that recognize EBNA2 and LMPs and destroy EBV-infected cells are generated. Studies have shown that one of the late genes expressed during EBV replication, BCRF1, is a homologue of interleukin 10 and can inhibit the production of interferon γ by mononuclear cells in vitro.

If T cell immunity is compromised, EBV-infected B cells may begin to proliferate. When EBV is associated with lymphoma, virus-induced proliferation is but one step in a multistep process of neoplastic transformation. In many EBV-containing tumors, LMP-1 mimics members of the tumor necrosis factor receptor family (e.g., CD40), transmitting growth-proliferating signals.

CLINICAL MANIFESTATIONS Most EBV infections in infants and young children are either asymptomatic or present as mild pharyngitis with or without tonsillitis. In contrast, up to 75% of infections in adolescents present as IM.

Signs and Symptoms The incubation period for IM in young adults is ~4 to 6 weeks. A prodrome of fatigue, malaise, and myalgia may last for 1 to 2 weeks before the onset of fever, sore throat, and lymphadenopathy. Fever is usually low-grade and is most common in the first 2 weeks of the illness; however, it may persist for >1 month. Common signs and symptoms are listed along with their frequencies in Table 165-1. Lymphadenopathy and pharyngitis are most prominent during the first 2 weeks of the illness, while splenomegaly is more prominent during the second and third weeks. Lymphadenopathy most often affects the posterior cervical nodes but may be generalized. Enlarged lymph nodes are frequently tender and symmetric but are not fixed in place. Pharyngitis, often the most prominent sign, can be accompanied by enlargement of the tonsils with an exudate resembling that of streptococcal pharyngitis. A morbilliform or papular rash, usually on the arms or trunk, develops in ~5% of cases. Most patients treated with ampicillin develop a macular rash; this rash is not predictive of future adverse reactions to penicillins. Erythema nodosum and erythema multiforme have also been described (Chap. 48). Most patients have symptoms for 2 to 4 weeks, but malaise and difficulty concentrating can persist for months.

Symptomatic IM is uncommon in infants and young children. IM in the elderly presents relatively often as nonspecific symptoms, including prolonged fever, fatigue, myalgia, and malaise; in contrast, pharyngitis, lymphadenopathy, splenomegaly, and atypical lymphocytes are relatively rare in elderly patients.

Laboratory Findings The white blood cell count is usually elevated and peaks at 10,000 to 20,000/μL during the second or third week of illness. Lymphocytosis is usually demonstrable, with >10% atypical lymphocytes. The latter cells are enlarged lymphocytes that have abundant cytoplasm, vacuoles, and indentations of the cell membrane. CD8+ cells predominate among the atypical lymphocytes. Low-grade neutropenia and thrombocytopenia are common during the first month of clinical symptoms.

of illness. Liver function is abnormal in more than 90% of cases. Serum levels of aminotransferases and alkaline phosphatase are usually mildly elevated; the serum concentration of bilirubin is elevated in ~40% of cases.

**Complications** Most cases of IM are self-limited. Deaths are very rare and most often are due to central nervous system (CNS) complications, splenic rupture, upper airway obstruction, or bacterial superinfection.

When CNS complications develop, they usually do so during the first 2 weeks of EBV infection; in some patients, especially children, they are the only clinical manifestations of IM. Heterophile antibodies and atypical lymphocytes may be absent. Meningitis and encephalitis are the most common neurologic abnormalities, and patients may present with headache, meningismus, or cerebellar ataxia; acute hemiplegia and psychosis have also been described. The cerebrospinal fluid (CSF) contains mainly lymphocytes, with occasional atypical lymphocytes. Most cases resolve without neurologic sequelae. Acute EBV infection has also been associated with lymphocytes, with occasional atypical lymphocytes. Most cases resolve without neurologic sequelae. Acute EBV infection has also been associated with cranial nerve palsies (especially ones involving cranial nerve VII), Guillain-Barré syndrome, acute transverse myelitis, and peripheral neuritis.

Autoimmune hemolytic anemia occurs in ~2% of cases during the first 2 weeks. In most cases the anemia is Coombs’ test-positive, with cold agglutinins directed against the i red blood cell antigen. Most patients with hemolysis have mild anemia that lasts for 1 or 2 months, but some patients have severe disease with hemoglobinuria and jaundice. Nonspecific antibody responses may also include rheumatoid factor, antinuclear antibodies, anti-smooth muscle antibodies, antiplatelet antibodies, and cryoglobulins. IM has been associated with red-cell aplasia, severe granulocytopenia, thrombocytopenia, pancytopenia, and hemophagocytic syndrome. The spleen ruptures in fewer than 0.5% of cases. Splenic rupture is more common among males than among females and may be manifest as abdominal pain, referred shoulder pain, or hemodynamic compromise.

Hypertrophy of lymphoid tissue in the tonsils or adenoids can result in upper airway obstruction, as can inflammation and edema of the epiglottis, pharynx, or uvula. About 10% of patients with IM develop streptococcal pharyngitis after their initial sore throat resolves.

Other rare complications associated with acute EBV infection include hepatitis (which can be fulminant), myocarditis or pericarditis with electrocardiographic changes, pneumonia with pleural effusion, interstitial nephritis, genital ulcerations, and vasculitis.

**OTHER DISEASES ASSOCIATED WITH EBV INFECTION** EBV-associated lymphoproliferative disease has been described in patients with congenital or acquired immunodeficiency, including those with severe combined immunodeficiency, AIDS, and recipients of bone marrow or organ transplants who are receiving immunosuppressive drugs (especially cyclosporine). Proliferating EBV-infected B cells infiltrate lymph nodes and multiple organs, and patients present with fever and lymphadenopathy or gastrointestinal symptoms. Pathologic studies show B cell hyperplasia or poly- or monoclonal lymphoma. The X-linked lymphoproliferative disorder (Duncan’s disease) is a recessive disorder of young boys who have a normal response to childhood infections but develop fatal lymphoproliferative disorders after infection with EBV. The gene mutated in this syndrome, SAP or SH2D1A, has been identified; its product binds to a protein that mediates interactions of B and T cells. Most patients with this syndrome die of acute IM; others develop hypogammaglobulinemia, malignant B cell lymphomas, aplastic anemia, or agranulocytosis. IM has also proved fatal to some patients with no obvious preexisting immune abnormality.

Oral hairy leukoplakia (Fig. 165-1) is an early manifestation of infection with HIV in adults (Chap. 173). Most patients present with raised, white corrugated lesions on the tongue (and occasionally on the buccal mucosa) that contain EBV DNA. Children infected with HIV can develop lymphoid interstitial pneumonitis; EBV DNA is often found in lung tissue from these patients.

Patients with the chronic fatigue syndrome may have titers of antibody to EBV that are elevated but are not significantly different from those in healthy EBV-seropositive adults. While some patients have malaise and fatigue that persist for weeks or months after IM, persistent EBV infection is not a cause of the chronic fatigue syndrome. Chronic active EBV infection is very rare and is distinct from the chronic fatigue syndrome. The affected patients have an illness lasting >6 months with markedly elevated titers of antibody to EBV and evidence of organ involvement, including hepatosplenomegaly, lymphadenopathy, and pneumonitis, uveitis, or neurologic disease.

EBV is associated with several malignancies. About 15% of cases of Burkitt’s lymphoma in the United States and ~90% of those in Africa are associated with EBV (Chap. 97). African patients with Burkitt’s lymphoma have high levels of antibody to EBV, and their tumor tissue usually contains viral DNA. EBV-containing Burkitt’s lymphoma also occurs in patients with AIDS. Anaplastic nasopharyngeal carcinoma is uniformly associated with EBV; the affected tissues contain viral DNA and antigens. Patients with nasopharyngeal carcinoma often have elevated titers of antibody to EBV (Chap. 74).

EBV has been associated with Hodgkin’s disease, especially the mixed-cellularity type (Chap. 97). Patients with Hodgkin’s disease often have elevated titers of antibody to EBV, and in about half of cases viral DNA and antigens are found in Reed-Sternberg cells. In some cases, EBV DNA has been detected in tonsillar carcinoma, angioimmunoblastic lymphadenopathy, angiocentric nasal NK/T cell immunoproliferative lesions, T cell lymphoma, thymoma, gastric carcinoma, and CNS lymphoma from patients with no underlying immunodeficiency. Studies have demonstrated viral DNA in leiomysarcomas from AIDS patients and in smooth-muscle tumors from organ transplant recipients. Virtually all CNS lymphomas in AIDS patients are associated with EBV. While serologic studies have shown higher levels of antibodies to EBV before the onset of multiple sclerosis, other studies (including measurement of EBV antibody titers in the CSF) are needed to ascertain a possible causal relationship.

**DIAGNOSIS**  ■ **Serologic Testing** The heterophile test is used for the diagnosis of IM in children and adults (Table 165-2). In the test for this antibody, human serum is absorbed with guinea pig kidney, and the heterophile titer is defined as the greatest serum dilution that agglutinates sheep, horse, or cow erythrocytes. Although heterophile antibody binds to certain animal erythrocytes, it does not interact with EBV proteins. A titer of 40-fold or greater is diagnostic of acute EBV infection in a patient who has symptoms compatible with IM and atypical lymphocytes. Tests for heterophile antibodies are positive in 40% of patients with IM during the first week of illness and in 80 to 90% during the third week. Therefore, repeated testing may be necessary, especially if the initial test is performed early. Tests usually remain positive for 3 months after the onset of illness, but heterophile antibodies can persist for up to 1 year. These antibodies usually are not detectable in children <5 years of age, in the elderly, or in patients presenting with symptoms not typical of IM. The commercially available monospot test for heterophile antibodies is somewhat more sensitive than the classic heterophile test. The monospot test is ~75%
sensitive and ~90% specific compared with EBV-specific serologies. False-positive monospot results are more common in persons with connective tissue disease, lymphoma, viral hepatitis, and malaria.

EBV-specific antibody testing is used for patients with suspected acute EBV infection who lack heterophile antibodies and for patients with atypical infections (Table 165-2). Serologic tests are particularly useful in young children, who often do not develop heterophile antibodies. Titers of IgM and IgG antibodies to viral capsid antigen (VCA) are elevated in the serum of more than 90% of patients at the onset of disease. IgM antibody to VCA is most useful for the diagnosis of acute IM because it is present at elevated titers only during the first 2 to 3 months of the disease; in contrast, IgG antibody to VCA is usually not useful for diagnosis of IM but is often used to assess exposure to EBV in the past because it persists for life. Seroconversion to EBNA positivity is also useful for the diagnosis of acute infection with EBV. Antibodies to EBNA are detectable relatively late (3 to 6 weeks after the onset of symptoms) in nearly all cases of acute EBV infection and persist for the lifetime of the patient. These antibodies may be lacking in immunodeficient patients and in those with chronic active EBV infection.

Titers of other antibodies may also be elevated in IM; however, these elevations are less useful for diagnosis. Antibodies to early antigens (EAs) are found either in a diffuse pattern in the nucleus and cytoplasm of infected cells (EA-D antibody) or restricted to the cytoplasm (EA-R antibody). These antibodies are detectable 3 to 4 weeks after the onset of symptoms in patients with IM. About 70% of individuals with IM have EA-D antibodies during the course of illness; the presence of EA-D antibodies is especially likely in those with relatively severe disease. These antibodies usually persist for only 3 to 6 months. Levels of EA-D antibodies are also elevated in patients with nasopharyngeal carcinoma or chronic active EBV infection. EA-R antibodies are only occasionally detected in patients with IM but are often found at elevated titers in patients with African Burkitt’s lymphoma or chronic active EBV infection. IgA antibodies to EBV antigens have proved useful for the identification of patients with nasopharyngeal carcinoma and of persons at high risk for the disease.

**TABLE 165-3 Treatment Options for Posttransplantation EBV Lymphoproliferative Disease**

1. Reduction of immunosuppression, when possible
2. Excision of localized lesions
3. Interferon α
4. Monoclonal antibody to CD20 (rituximab)
5. Radiation therapy (especially for CNS lesions)
6. For stem cell transplant recipients: donor lymphocyte infusions or donor EBV-specific cytotoxic T cell infusions
7. For solid organ transplant recipients: autologous or HLA-matched, EBV-specific, cytotoxic T cell infusions
8. Cytotoxic chemotherapy

* Infused T cells must be HLA matched; lymphoproliferative lesions are usually of donor origin for stem cell transplant recipients and of recipient origin for solid organ transplant recipients.

AUWAERTER PG: Infectious mononucleosis in middle age. JAMA 281:454, 1999
PAPADOPOULOS EB et al: Infusions of donor leukocytes to treat Epstein-Barr

**Other Studies**

Detection of EBV DNA, RNA, or proteins has been valuable in demonstrating the association of the virus with various malignancies. The polymerase chain reaction has been used to detect EBV DNA in the CSF of some AIDS patients with lymphomas and to monitor the amount of EBV DNA in the blood of patients with lymphoproliferative disease. Culture of EBV from throat washings or blood is not helpful in the diagnosis of acute infection, since EBV commonly persists in the oropharynx and in B cells for the lifetime of the infected individual.

**Differential Diagnosis**

The differential diagnosis of IM and atypical lymphoproliferative disease (Chap. 117) generally does not respond to antiviral therapy. When possible, therapy should be directed toward reduction of immunosuppression (Table 165-3). Interferon α or antibody to CD20 has been effective in some cases. Infusions of donor lymphocytes are often effective for stem cell transplant recipients, although graft-versus-host disease can occur. Infusions of EBV-specific cytotoxic T cells have been used to prevent EBV lymphoproliferative disease in high-risk settings as well as to treat the disease.

The isolation of patients with IM is unnecessary. Vaccines directed against the major EBV glycoprotein have been effective in animal studies and are undergoing small-scale clinical trials.

166 Cytomegalovirus and Human Herpesvirus Types 6, 7, and 8

Martin S. Hirsch

CYTOMEGALOVIRUS

DEFINITION Cytomegalovirus (CMV), which was initially isolated from patients with congenital cytomegalic inclusion disease, is now recognized as an important pathogen in all age groups. In addition to inducing severe birth defects, CMV causes a wide spectrum of disorders in older children and adults, ranging from an asymptomatic, subclinical infection to a mononucleosis syndrome in healthy individuals to disseminated disease in immunocompromised patients. Human CMV is one of several related species-specific viruses that cause similar diseases in various animals. All are associated with the production of characteristic enlarged cells—hence the name cytomegalovirus.

CMV is a member of the β-herpesvirus group and has double-strand DNA, four species of mRNA, a protein capsid, and a lipoprotein envelope. Like other herpesviruses, CMV demonstrates icosahedral symmetry, replicates in the cell nucleus, and can cause either a lytic and productive or a latent infection. CMV can be distinguished from other herpesviruses by certain biologic properties, such as host range and type of cytopathology induced. Viral replication is associated with the production of large intranuclear inclusions and smaller cytoplasmic inclusions. The virus appears to replicate in a variety of cell types in vivo; in tissue culture it grows preferentially in fibroblasts. Although there is little evidence that CMV is oncogenic in vivo, the virus does transform fibroblasts in rare instances, and genomic transforming fragments have been identified.

EPIDEMIOLOGY CMV has a worldwide distribution. Approximately 1% of newborns in the United States are infected with CMV, and the percentage is higher in many less-developed countries. Communal living and poor personal hygiene facilitate early spread. Perinatal and early childhood infections are common. Virus may be present in breast milk, saliva, feces, and urine. Transmission of CMV has been identified among young children in day-care centers and has been traced from infected toddler to pregnant mother to developing fetus. When an infected child introduces CMV into a household, 50% of susceptible family members seroconvert within 6 months.

The virus is not readily spread by casual contact but requires repeated or prolonged intimate exposure for transmission. In late adolescence and young adulthood, CMV is often transmitted sexually, and asymptomatic viral carriage in semen or cervical secretions is common. CMV antibody is present in detectable levels in nearly 100% of female prostitutes and sexually active homosexual men. Sexually active adults may harbor several strains of CMV simultaneously. Transfusion of whole blood or certain blood products containing viable leukocytes may also transmit CMV, with a frequency of 0.14 to 10% per unit transfused.

Once infected, an individual probably carries CMV for life. The infection usually remains latent. However, CMV reactivation syndromes develop frequently when T lymphocyte–mediated immunity is compromised—for example, after organ transplantation or in association with lymphoid neoplasms and certain acquired immunodeficiencies (in particular, infection with HIV; Chap. 173). Most primary CMV infections in organ transplant recipients (Chap. 117) result from transmission of the virus in the graft itself. In CMV-seropositive transplant recipients, infection results from reactivation of latent virus or, less commonly, from reinfection by a new strain of CMV. CMV infection may be associated with coronary artery stenosis following heart transplantation or coronary angioplasty, but this association requires further validation.

PATHOGENESIS Congenital CMV infection can result from either primary or reactivation infection of the mother. However, clinical disease in the fetus or newborn is almost exclusively related to primary maternal infection (Table 166–1). The factors determining the severity of congenital infection are unknown; a deficient capacity to produce precipitating antibodies and to mount T cell responses to CMV is associated with relatively severe disease.

Primary infection in late childhood or adulthood is often associated with a vigorous T lymphocyte response that may contribute to the development of a mononucleosis syndrome similar to that observed following Epstein-Barr virus (EBV) infection (Chap. 165). The hallmark of such infection is the appearance of atypical lymphocytes in the peripheral blood; these cells are predominantly activated CD8+ T lymphocytes. Polyclonal activation of B cells by the virus contributes to the development of rheumatoid factors and other autoantibodies during CMV mononucleosis.

Once acquired by symptomatic or asymptomatic primary infection,
CMV persists indefinitely in tissues of the host. The sites of persistent or latent infection probably include multiple cell types and various organs. Transmission following blood transfusion or organ transplantation is due to silent infections in these tissues. Autopsy studies suggest that salivary glands and bowel may be areas of latent infection.

If the host’s T cell responses become compromised by disease or by iatrogenic immunosuppression, latent virus can be reactivated to cause a variety of syndromes. Chronic antigenic stimulation in the presence of immunosuppression (for example, following tissue transplantation) appears to be an ideal setting for CMV activation and CMV-induced disease. Certain particularly potent suppressants of T cell immunity, such as antithymocyte globulin, are associated with a high rate of clinical CMV syndromes, which may follow either primary or reactivation infection. CMV may itself contribute to further T lymphocyte hyporesponsiveness, which often precedes superinfection with other opportunistic pathogens, such as Pneumocystis. CMV and Pneumocystis are frequently found together in immunosuppressed patients with severe interstitial pneumonia.

PATHOLOGY Cytomegalic cells in vivo (presumed to be infected epithelial cells) are two to four times larger than surrounding cells and often contain an 8- to 10-μm intranuclear inclusion that is eccentrically placed and is surrounded by a clear halo, producing an “owl’s eye” appearance. Smaller granular cytoplasmic inclusions are demonstrated occasionally. Cytomegalic cells are found in a wide variety of organs, including salivary gland, lung, liver, kidney, intestine, pancreas, adrenal gland, and the central nervous system.

The cellular inflammatory response to infection consists of plasma cells, lymphocytes, and monocyte-macrophages. Granulomatous reactions occasionally develop, particularly in the liver. Immunopathologic reactions may contribute to CMV disease. Immune complexes have been detected in infected infants, sometimes in association with CMV-related glomerulopathies. Immune-complex glomerulopathy has been observed in some CMV-infected patients after renal transplantation.

CLINICAL MANIFESTATIONS ■ Congenital CMV Infection Fetal infections range from inapparent to severe and disseminated. Cytomegalic inclusion disease develops in ~5% of infected fetuses and is seen almost exclusively in infants born to mothers who develop primary infections during pregnancy. Petechiae, hepatosplenomegaly, and jaundice are the most common presenting features (60 to 80% of cases). Microcephaly with or without cerebral calcifications, intrauterine growth retardation, and prematurity are reported in 30 to 50% of cases. Inguinal hernias and chorioretinitis are less common. Laboratory abnormalities include elevated alanine aminotransferase levels, thrombocytopenia, conjugated hyperbilirubinemia, hemolysis, and elevated cerebrospinal fluid protein levels. The prognosis for severely infected infants is poor; the mortality rate is 20 to 30%, and fewer of the patients who survive escape intellectual or hearing difficulties later in childhood. The differential diagnosis of cytomegalic inclusion disease in infants includes syphilis, rubella, toxoplasmosis, infection with herpes simplex virus or enterovirus, and bacterial sepsis.

Most congenital CMV infections are clinically inapparent at birth. Between 5 and 25% of asymptptomatically infected infants develop significant psychomotor, hearing, ocular, or dental abnormalities over the next several years.

Perinatal CMV Infection The newborn may acquire CMV at the time of delivery by passage through an infected birth canal or by postnatal contact with breast milk or other maternal secretions. Approximately 40 to 60% of infants who are breast-fed for >1 month by seropositive mothers become infected. Iatrogenic transmission can also result from neonatal blood transfusion. Screening of blood products before they are transfused into low-birth-weight seronegative infants or into seronegative pregnant women decreases the risk of infection.

The great majority of infants infected at or after delivery remain asymptomatic. However, protracted interstitial pneumonitis has been associated with perinatally acquired CMV infection, particularly in premature infants, and occasionally has been accompanied by infection with Chlamydia trachomatis, Pneumocystis, or Ureaplasma urealyticum. Poor weight gain, adenopathy, rash, hepatitis, anemia, and atypical lymphocytosis may also be found, and CMV excretion often persists for months or years.

CMV Mononucleosis The most common clinical manifestation of CMV infection in normal hosts beyond the neonatal period is a heterophil antibody–negative mononucleosis syndrome. This manifestation may develop spontaneously or may follow the transfusion of leukocyte-containing blood products. Although the syndrome occurs at all ages, it most often involves sexually active young adults. Incubation periods range from 20 to 60 days, and the illness generally lasts for 2 to 6 weeks. Prolonged high fevers, sometimes accompanied by chills, profound fatigue, and malaise, characterize this disorder. Myalgia, headache, and splenomegaly are frequent, but in CMV mononucleosis (as opposed to infectious mononucleosis caused by EBV), exudative pharyngotonsillitis and cervical lymphadenopathy are rare. Occasional patients develop rubelliform rashes, often after exposure to ampicillin. Less commonly observed are interstitial or segmental pneumonia, myocarditis, pleuritis, arthritis, and encephalitis. In rare cases, Guillain-Barré syndrome complicates CMV mononucleosis. The characteristic laboratory abnormality is relative lymphocytosis in peripheral blood, with more than 10% atypical lymphocytes. Total leukocyte counts may be low, normal, or markedly elevated. Although significant jaundice is uncommon, serum aminotransferase and alkaline phosphatase levels are often moderately elevated. Heterophil antibodies are absent; however, transient immunologic abnormalities are common and may include the presence of cryoglobulins, rheumatoid factors, cold agglutinins, and antinuclear antibodies. Hemolytic anemia, thrombocytopenia, and granulocytopenia complicate recovery in rare instances.

Most patients recover without sequelae, although postviral asthenia may persist for months. The excretion of CMV in urine, genital secretions, and/or saliva often continues for months or years. Rarely, CMV infection is fatal in immunocompetent hosts; even when such patients survive, they can have recurrent episodes of fever and malaise that are sometimes associated with autonomic nervous system dysfunction (e.g., attacks of sweating or flushing).

CMV Infection in the Immunocompromised Host (See also Table 166-1) CMV appears to be the most common and important viral pathogen complicating organ transplantation (Chap. 117). In recipients of kidney, heart, lung, and liver transplants, CMV induces a variety of syndromes, including fever and leukopenia, hepatitis, pneumonitis, esophagitis, gastritis, colitis, and retinitis. CMV disease may be an independent risk factor for both graft loss and death. The period of maximal risk is between 1 and 4 months after transplantation, although retinitis may be a later complication. Disease likelihood and levels of viral replication generally are greater after primary infection than after reactivation. In addition, molecular studies indicate that seropositive transplant recipients are susceptible to reinfection with donor-derived, genotypically variant CMV, and such infection often results in disease. Reactivation infection, although frequent, is less likely than primary infection to be important clinically. The risk of clinical disease is related to various factors, such as the degree of immunosuppression; the use of antibodies to T cell receptors; and co-infection with other pathogens, such as human herpesvirus type 6. The transplanted organ is particularly vulnerable as a target for CMV infection; thus, there is a tendency for CMV hepatitis to follow liver transplantation and for CMV pneumonitis to follow lung transplantation.

CMV pneumonia occurs in 15 to 20% of bone marrow transplant recipients, with a case-fatality rate of 84 to 88%. The risk is greatest between 5 and 13 weeks after transplantation, and the several risk factors identified include certain types of immunosuppressive therapy, acute graft-versus-host disease, older age, viremia, and seropositivity before transplantation.
CMV is recognized as an important pathogen in patients with advanced HIV infection (Chap. 173), in whom it often causes retinitis or disseminated disease, particularly when peripheral-blood CD4+ cell counts fall below 50 to 100/μL. As treatment for underlying HIV infection has improved, the incidence of serious CMV infections (e.g., retinitis) has decreased. However, institution of highly active antiretroviral regimens sometimes leads to acute flare-ups of CMV retinitis during the first few weeks of therapy.

Syndromes produced by CMV in the immunocompromised host often begin with prolonged fever, malaise, anorexia, fatigue, night sweats, and arthralgias or myalgias. Liver function abnormalities, leukopenia, thrombocytopenia, and atypical lymphocytosis may be observed during these episodes. The development of tachypnea, hypoxia, and unproductive cough signals respiratory involvement. Radiologic examination of the lung often reveals bilateral interstitial or reticulonodular infiltrates, which begin in the periphery of the lower lobes and spread centrally and superiorly; localized segmental, nodular, or alveolar patterns are also common. The differential diagnosis includes infection with Pneumocystis; infections due to other viral, bacterial, or fungal pathogens; pulmonary hemorrhage; and injury secondary to irradiation or to treatment with cytotoxic drugs.

Gastrointestinal CMV involvement may be localized or extensive and almost exclusively affects compromised hosts. Ulcers of the esophagus, stomach, small intestine, or colon may result in bleeding or perforation. CMV infection may lead to exacerbations of underlying ulcerative colitis. Hepatitis occurs frequently, particularly following liver transplantation, and CMV-associated acalculous cholecystitis and adenitis have been described.

CMV rarely causes meningoencephalitis in otherwise-healthy individuals. Two forms of CMV encephalitis are seen in patients with AIDS. One resembles HIV encephalitis and presents as progressive dementia; the other is a ventriculonecrotizing, bulbous neuritis characterized by cranial-nerve deficits, nystagmus, disorientation, lethargy, and ventriculomegaly. In immunocompromised patients, CMV can also cause subacute progressive polyradiculopathy, which is often reversible if recognized and treated promptly.

CMV retinitis is an important cause of blindness in immunocompromised patients, particularly patients with advanced AIDS (Chap. 173). Early lesions consist of small, opaque, white areas of granular retinal necrosis that spread in a centrifugal manner and are later accompanied by hemorrhages, vessel sheathing, and retinal edema (Fig. 166-1). CMV retinopathy must be distinguished from that due to other conditions, including toxoplasmosis, candidiasis, and herpes simplex virus infection.

Fatal CMV infections are often associated with persistent viremia and the involvement of multiple organ systems. Progressive pulmonary infiltrates, pancytopenia, hyperamylasemia, and hypotension are characteristic features that are frequently found in conjunction with a terminal bacterial, fungal, or protozoan superinfection. Extensive ad-

**FIGURE 166-1** Cytomegalovirus in a patient with AIDS appears as an arcuate zone of retinitis with hemorrhages and optic disk swelling. Often CMV is confined to the retinal periphery, beyond view of the direct ophthalmoscope.
lactic or suppressive ganciclovir may be useful in high-risk bone marrow or organ transplant recipients (e.g., those who are CMV-seropositive before transplantation or who are CMV culture–positive afterward). In many patients with AIDS, persistently low CD4+ cell counts, and CMV disease, clinical and virologic relapses occur promptly if treatment with ganciclovir is discontinued. Therefore, prolonged maintenance regimens are recommended for such patients. Resistance to ganciclovir is common among patients treated for $>3$ months and is usually related to mutations in the CMV UL97 gene.

Valganciclovir is an orally bioavailable produg that is rapidly metabolized to ganciclovir in intestinal tissues and the liver. Approximately 60% of an oral dose of valganciclovir is absorbed. An oral valganciclovir dose of 900 mg results in ganciclovir blood levels similar to those obtained with an intravenous ganciclovir dose of 5 mg/kg. Oral valganciclovir appears to be as effective as intravenous ganciclovir for both CMV retinitis induction and maintenance regimens. Furthermore, the adverse-event profiles and rates of resistance development for the two drugs are similar.

Ganciclovir or valganciclovir therapy for CMV retinitis consists of a 14- to 21-day induction course (5 mg/kg intravenously twice daily for ganciclovir or 900 mg twice daily for valganciclovir) followed by a prolonged maintenance regimen. For parenteral maintenance, the ganciclovir dose is 5 mg/kg daily or 6 mg/kg 5 days per week; for oral maintenance, 900 mg of valganciclovir once daily is recommended. Peripheral-blood neutropenia develops in 16 to 29% of treated patients but may be ameliorated by granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor. Discontinuation of maintenance therapy should be considered in patients with AIDS who, while receiving antiretroviral therapy, have a sustained (>6-month) increase in CD4 cell counts to $>100–150/\muL$. Foscarnet (sodium phosphonoformate) also acts against CMV infection by inhibiting viral DNA polymerase. Because this agent does not require phosphorylation to be active, it is also effective against most ganciclovir-resistant CMV isolates. Foscarnet is less well tolerated than ganciclovir and causes considerable toxicity, including renal dysfunction, hypomagnesemia, hypokalemia, hypocalcemia, genital ulcers, dysuria, nausea, and paresthesia. Moreover, foscarnet administration requires the use of an infusion pump and close clinical monitoring. With aggressive hydration and dose adjustments for renal dysfunction, the toxicity of foscarnet can be reduced. The use of foscarnet should be avoided when a saline load cannot be tolerated (e.g., in cardiomyopathy). The approved induction regimen is 60 mg/kg every 8 h for 2 weeks, although 90 mg/kg every 12 h is equally effective and no more toxic. Maintenance infusions should deliver 90 to 120 mg/kg once daily; no oral preparation is available. Foscarnet-resistant viruses may emerge during extended therapy.

Ganciclovir may also be administered via a slow-release pellet sutured into the eye. Although this intraocular device provides good local protection, contralateral eye disease and disseminated disease are not affected, and early retinal detachment is possible. A combination of intraocular and systemic therapy may be better than the intraocular implant alone.

Cidofovir is a nucleotide analogue with a long intracellular half-life that allows intermittent intravenous administration. Induction regimens of 5 mg/kg weekly for 2 weeks are followed by maintenance regimens of 3 to 5 mg/kg every 2 weeks. Cidofovir can cause severe nephrotoxicity through dose-dependent proximal tubular cell injury; however, this adverse effect can be ameliorated somewhat by saline hydration and probencid.

It is not still clear whether universal prophylaxis or preemptive therapy in immunocompromised hosts with CMV seropositivity is the preferable approach. For patients with advanced HIV infection (CD4 cell counts of $<50/\muL$), some authorities have advocated prophylaxis with oral ganciclovir or valganciclovir. However, side effects, lack of proven benefit, possible induction of viral resistance, and cost have precluded the wide acceptance of this practice. Similar questions have arisen concerning prophylaxis in organ transplant recipients. As techniques for identifying individuals at risk improve (e.g., quantification of CMV DNA by PCR), it may become possible to preemptively treat those at highest risk to prevent end-organ disease.

**Human Herpesvirus Types 6, 7, and 8**

Human herpesvirus (HHV) type 6 was first isolated in 1986 from peripheral-blood leukocytes of six persons with various lymphoproliferative disorders. The virus has a worldwide distribution, and two genetically distinct variants (HHV-6A and HHV-6B) are now recognized.

Infection with HHV-6 frequently develops during infancy as maternal antibody wanes. Congenital infections have also been described. HHV-6 (mostly variant B) can cause exanthem subitum (roseola infantum), a common illness characterized by fever with subsequent rash. This virus is also a major cause of febrile seizures without rash during infancy. In older age groups, HHV-6 has been associated with mononucleosis syndromes, focal encephalitis, and (in immunocompromised hosts) pneumonitis and disseminated disease. In transplant recipients, HHV-6 infection may be associated with graft dysfunction. As many as 80% of adults are seropositive for HHV-6. The virus may be transmitted by saliva and possibly by genital secretions. Like many other viruses, HHV-6 has been implicated in the pathogenesis of multiple sclerosis, although further study is needed to distinguish association and etiology.

HHV-7 was isolated in 1990 from T lymphocytes from the peripheral blood of a healthy 26-year-old man. Other isolates have since been obtained. It appears that the virus is frequently acquired during childhood and is commonly present in the saliva of healthy adults. No human disease has yet been definitively linked to HHV-7, although some cases of exanthem subitum, other childhood febrile illnesses, and neurologic syndromes (encephalitis, flaccid paralysis) have been associated with HHV-7 infection. An association has been made between HHV-7 and pityriasis rosea, but further studies must confirm this relationship.

HHV-6, HHV-7, and CMV infections may cluster in transplant recipients, making it difficult to sort out the roles of the various agents in individual clinical syndromes. HHV-6 and HHV-7 appear to be susceptible to ganciclovir and foscarnet, although definitive evidence of clinical responses is lacking.

Unique herpesvirus-like DNA sequences were reported during 1994 and 1995 in tissues derived from Kaposi’s sarcoma (KS) and body cavity–based lymphoma occurring in patients with AIDS. The virus from which these sequences were derived has now been cultured and is designated HHV-8 or Kaposi’s sarcoma–associated herpesvirus (KSHV). HHV-8, which infects certain B lymphocytes and endothelium-derived spindle cells, appears to be causally related not only to KS but also to a subgroup of AIDS-related B-cell body-cavity-based lymphomas and to multicentric Castleman’s disease, a lymphoproliferative disorder of B cells.

Unlike other herpesvirus infections, HHV-8 infection is more common in some geographic areas (e.g., central and southern Africa) than in others (North America, Asia, northern Europe). Concurrent epidemics of HIV-1 and HHV-8 infections among certain populations (e.g., homosexual and bisexual men) in the late 1970s and early 1980s appear to have resulted in the frequent association of AIDS and KS. Both viruses appear to be sexually transmitted, and HHV-8 may be transmitted in saliva as well. Transmission of HHV-8 may also be associated with organ transplantation and injection drug use. Among individuals with intact immunity, asymptomatic infection is the rule, and neoplastic disorders develop only after immunocompromise. Effective antiretroviral therapy for HIV-infected individuals has led to a marked reduction in rates of KS among individuals dually infected with HHV-8 and HIV in resource-rich areas. HHV-8 itself is susceptible in vitro to ganciclovir, foscarnet, and cidofovir, although clinical evidence for benefit of these agents is lacking.
MOLLUSCUM CONTAGIOSUM AND OTHER POXVIRUSES, EXCLUDING SMALLPOX VIRUS
Fred Wang

The poxviruses include a large number of related DNA viruses that infect various vertebrate hosts. The poxviruses responsible for infections in humans, along with the main manifestations of these infections, are listed in Table 167-1. Systemic human disease can result from infection with smallpox (variola major) virus, a poxvirus that infects only humans (Chap. 205), or from zoonotic infection with monkeypox virus. Other poxvirus infections cause primarily localized skin disease in humans. Molluscum contagiosum virus (MCV) is an obligate human pathogen that causes distinctive proliferative skin lesions; molluscum contagiosum is the most frequent human disease resulting from poxvirus infection. Exposure to animals infected with other poxviruses can also cause localized skin disease in humans.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is generally a benign disease consisting of pearly, flesh-colored, umbilicated skin lesions 2 to 5 mm in diameter with a characteristic dimple at the center (Fig. 167-1). A relative lack of inflammation and necrosis distinguishes these proliferative lesions from other poxvirus lesions. The lesions occur singly or in clusters. MCV is a human poxvirus that is transmitted by close contact, including sexual intercourse. Swimming pools are a common vector for transmission. Atopy and compromise of skin integrity increase the risk of infection. Lesions may be found anywhere on the body except the palms and soles and may be associated with an eczematous rash. The incubation period ranges from 2 weeks to 6 months, with an average of 2 to 7 weeks. In most cases, the disease is self-limited and regresses spontaneously after 3 to 4 months in immunocompetent hosts. There are no systemic complications, but skin lesions may persist for 3 to 5 years. Molluscum contagiosum develops especially often in association with the advanced stages of HIV infection, with a prevalence of 5 to 18% among HIV-infected patients (Chap. 173). The disease is often more generalized, severe, and persistent in AIDS patients than in other groups, frequently involving the face and upper body. Extensive molluscum contagiosum has also been reported in conjunction with other types of immunodeficiency.

The diagnosis of molluscum contagiosum is typically made by its clinical presentation and can be confirmed by histologic demonstration of the cytoplasmic eosinophilic inclusions, or molluscum bodies, that are characteristic of poxvirus replication. MCV cannot be propagated in vitro, but electron microscopy and molecular studies can be used for its identification.

There is no specific systemic treatment for molluscum contagiosum, but a variety of techniques for physical ablation have been used. Molluscum contagiosum may respond to effective control of HIV infection with highly active antiretroviral therapy. Cidofovir may have some efficacy in the treatment of recalcitrant molluscum contagiosum in immunosuppressed hosts.

ZOONOTIC POXVIRUS INFECTIONS

Monkeypox virus naturally infects nonhuman primates in the tropical rain forests of western and central Africa and can infect humans who come into direct contact with infected animals. Human disease is rare and is characterized by a systemic illness and vesicular rash similar to those of variola. A large outbreak of monkeypox occurred between February 1996 and October 1997 in central Africa, with a case-fatality ratio of 3%. The prolonged period of active cases suggested a potential
for sustained person-to-person transmission, and the higher proportion of younger case-patients suggested the possible consequences of discontinued smallpox vaccination. Clinical presentations were occasionally confused with the more common varicella-zoster virus infection. Compared with the lesions of this herpesvirus infection, monkeypox lesions tend to be more uniform (i.e., in the same stage of development at the same time), diffuse, and peripheral in distribution.

The first outbreak of monkeypox infection in the Western Hemisphere occurred in the midwestern United States during May and June 2003. Monkeypox virus infections were diagnosed in several people who had close contact with ill prairie dogs, a Gambian rat, and a rabbit purchased as pets from a common animal distributor. Patients presented most frequently with fever, respiratory symptoms, and lymphadenopathy—12 days after exposure. The typical vescicular rash developed with or shortly (1 to 3 days) after the fever. The Centers for Disease Control and Prevention recommended smallpox vaccination for persons having close or intimate contact with a documented case of human or animal monkeypox infection in order to reduce the risk of spread. Vaccination can be given up to 14 days after exposure.

Orf virus and pseudocowpox virus are parapoxviruses that naturally infect sheep and cattle. Direct contact with infected animals can result in infections in humans, typically on the hands, with the development of a nodular, highly vascular proliferative lesion that may ulcerate. Human orf virus infection is also called 'ecthyma contagiosum,' and human pseudocowpox virus infection causes "milker’s nodules." Zoonotic infection with cowpox virus, an orthopoxvirus, causes painful hemorrhagic lesions, mostly on the hands or face, with fever or flu-like symptoms and lymphadenitis. Lesions generally resolve in 6 to 8 weeks. Human infection with tanapox virus occurs after contact with infected monkeys. In most cases, a febrile prodrome is followed by eruption of a single nodular lesion on the exposed area, but multiple lesions have also been reported. The lesions are relatively large, often break down to form an ulcer, and resolve in 5 to 6 weeks.

**PARVOVIRUS**

**Neil R. Blacklow**

DEFINITION The parvovirus group includes several species-specific viruses of animals. One parvovirus, designated B19, is known to be a human pathogen. B19 is a small (diameter, 20 to 25 nm), isosahedral, nonveloped, single-stranded DNA virus with an outer capsid formed by two structural proteins. Individual virus particles contain DNA strands of positive or negative polarity. The virus is stable and retains infectivity after incubation at 60°C for 16 h. It has failed to grow in conventional cell culture lines and animal model systems but does replicate in vitro in erythroid progenitor cells derived from human bone marrow, umbilical cord, peripheral blood, or fetal liver sources.

During the 1980s, it was discovered that B19 causes a variety of disorders ranging from erythema infectiousum and acute arthropathy in otherwise healthy hosts to transient aplastic crisis and chronic anemia in compromised patients to fetal infection manifested by death or hydrops fetalis. Many of the severe manifestations of B19 viremia relate to the propensity of the virus to infect and lyse erythroid precursor cells in the bone marrow. The name B19 is derived from the code number of the human serum in which the virus was discovered.

PATHOGENESIS Two studies of adult volunteers have provided a basis for understanding the pathogenesis of B19 infection, which has two phases. The first phase is characterized by viremia that develops approximately 6 days after intranasal inoculation of B19 into susceptible individuals who lack serum antibodies to the virus (Fig. 168-1). The viremia lasts about 1 week; its clearance is correlated with the development of IgM antibodies to B19, which remain detectable for up to a few months. IgG antibodies develop several days later and persist indefinitely. Nonspecific systemic symptoms lasting 2 or 3 days occur early during the viremic phase; these symptoms include headache, malaise, myalgia, fever, chills, and pruritus and are accompanied by reticulocytopenia and excretion of the virus from the respiratory tract. Several days after the onset of symptoms, a clinically insignificant decline in hemoglobin concentration is noted; the decreased level is maintained for 7 to 10 days, during which time examination of bone marrow samples reveals a marked depletion of erythroid precursor cells. Transient mild lymphopenia, neutropenia, and a drop in platelet count also may be found. A second phase of illness begins around 17 or 18 days after virus inoculation (after the clearance of viremia, the cessation of viral shedding in throat secretions, and the resolution of reticulocytopenia). This illness mimics erythema infectiousum in adults, with 2 or 3 days of fine maculopapular rash accompanied by arthralgias and arthritis that last another 1 or 2 days. This phase occurs in the presence of rising serum titers of antibody to B19.

The studies just described indicate that B19 disease in the otherwise healthy host, manifested by self-limited erythema infectiousum and/or arthropathy, is almost certainly an immune-complex disorder. This concept is supported by the induction of erythema infectiousum through the infusion of immunoglobulins into chronically viremic patients. In contrast, B19 disease in the compromised host (chronic hemolytic disease or immunodeficiency syndromes) is often serious, resulting from the destruction by B19 of erythroid precursor cells. Normal hosts can tolerate 7 to 10 days of shutoff of erythropoiesis; however, patients with hemolytic disease who require increased production of erythrocytes do not tolerate erythroid cell destruction and usually develop severe transient aplastic crisis. Patients who are immunodeficient may fail to clear B19 viremia, the results being persistent infection of red blood cells and chronic severe anemia. The fetus requires a higher level of red cell production than do adults and has an immature immune system; both these factors could explain B19-induced hydrops fetalis.

B19 binds specifically to a cellular receptor, erythrocyte P antigen; this specific binding explains the tropism of B19 for erythroid progenitor cells, particularly pronormoblasts and normoblasts. The few persons who lack P antigen cannot be infected with B19.

**EPIDEMIOLOGY** Although B19 infections occur year-round, they appear most commonly as outbreaks of erythema infectiousum in schools during winter and spring months. Between 20 and 60% of children in outbreaks are symptomatic, and many are asymptomatically infected. Seroepidemiologic studies indicate that approximately half of adults possess serum antibodies to B19. Antibody prevalence (reflecting prior exposure and probable immunity to the virus) rises rapidly between the ages of 5 and 18 years and continues to increase with age—a pattern probably indicating ongoing exposure during adulthood. B19 can be detected in throat swabblings, respiratory tract secretions, and serum, and its detection at these sites probably correlates with infectiousness. Patients with transient aplastic crisis have viremia and shed virus and therefore are highly infectious. Their infectivity has been firmly documented as the source of one well-defined nosocomial outbreak of erythema infectiousum among nurses. In contrast, individuals with erythema infectiousum are much less infectious. The usual route of viral transmission under natural conditions is unknown but may be
respiratory or through direct contact. B19 can be transmitted during therapy with clotting factor concentrate and other plasma derivatives, even after exposure to detergent, steam, or dry heat. It has been recommended that polymerase chain reaction (PCR) testing for B19 be used for screening and that potentially infectious material be discarded.

**CLINICAL MANIFESTATIONS**

**Erythema Infectiosum**

Erythema infectiosum is the most common manifestation of B19 infection and occurs predominantly in children. This entity is also called fifth disease because it was classified in the late nineteenth century as the fifth in a series of six exanthems of childhood. Normally a mild illness, erythema infectiosum typically presents as a facial rash with a “slapped-cheek” appearance that is sometimes preceded by low-grade fever. The rash may develop quickly on the arms and legs and usually has a lacy, reticular, erythematous appearance (Fig. 168-2). The trunk, palms, and soles are less commonly involved. Occasionally, the rash appears with maculopapular, morbilliform, vesicular, purpuric, or pruritic characteristics. The typical rash resolves in about a week but can recur intermittently for several weeks, particularly after stress, exercise, exposure to sunlight, bathing, or change in environmental temperature. Arthralgia and arthritis are uncommon among children but are frequent among adults, in whom the rash is often absent or nonspecific, with a lack of the characteristic facial erythema.

**Arthropathy**

B19 infection in adults most commonly presents as acute arthralgias and arthritis, sometimes accompanied by rash. The arthritis is characteristically symmetric and peripheral, involving the wrists, hands, and knees most frequently. It normally resolves in about 3 weeks and is nondestructive. However, a small percentage of patients have arthritis persisting for months or even (in rare cases) for years. It is not known whether these individuals have persistent infection or an abnormal immune response to the virus.

**Transient Aplastic Crisis**

B19 infection is the cause in most instances of transient aplastic crisis developing suddenly in patients with chronic hemolytic disease. Nearly all hemolytic conditions can be affected by B19 infection, including sickle cell disease, erythocyte enzyme deficiencies, hereditary spherocytosis, thalassemias, paroxysmal nocturnal hemoglobinuria, and autoimmune hemolysis. B19-induced aplastic crisis can also occur in the setting of acute blood loss. Patients present with weakness, lethargy, pallor, and severe anemia, a syndrome often preceded by a few days of nonspecific symptoms. These patients have intense reticulocytopenia lasting 7 to 10 days, and their bone marrow contains no erythroid precursor cells despite a normal myeloid series. Transient aplastic crisis can produce life-threatening anemia and may require urgent transfusion therapy. Unlike patients with erythema infectiosum or arthropathy, those with transient aplastic crisis are viremic and can readily transmit B19 infection to other people.

**Chronic Anemia in Immunodeficient Patients**

Immunodeficient patients may be unable to eliminate B19 infection, probably because they cannot produce adequate levels of virus-specific IgM antibodies. The result is persistent infection with destruction of erythroid precursor cells in the bone marrow and chronic transfusion-dependent anemia. This condition has been described occasionally in patients with immunodeficiency related to infection with HIV, congenital immunodeficiencies, and acute lymphoblastic leukemia during maintenance chemotherapy as well as in recipients of bone marrow, heart, liver, lung, and kidney transplants. In addition, some cases of idiopathic pure red-cell aplasia probably are caused by persistent B19 infection. B19-induced chronic anemia may be the presenting finding of an otherwise unrecognized immunodeficiency. Chronic anemia may fluctuate in intensity over time and may be cured or controlled by immunoglobulin therapy. Both the spectrum of immunodeficiencies associated with B19-induced chronic anemia and the frequency of the association remain to be determined.

**Fetal and Congenital Infection**

Maternal B19 infections usually do not adversely affect the fetus. More often than not, in fact, the fetus remains uninfected. Therefore, couples in which the pregnant woman is infected should be counseled as to the relatively low risk of fetal infection. It is estimated that fewer than 10% of maternal B19 infections in the first 20 weeks of pregnancy lead to fetal death; when fetal death does occur, it is usually attributable to the development of nonimmune hydrops fetalis, wherein the fetus succumbs to severe anemia and congestive heart failure. In these instances, B19 can be detected in fetal tissues, with predominant infection of erythroblasts. One unconfirmed report suggests that B19 causes late second-trimester and third-trimester nonhydropic fetal deaths. Pregnant women with known exposure to B19 should have their serum monitored for IgM antibodies to the virus and for elevated levels of ß-fetoprotein and human chorionic gonadotropin; ultrasonic examinations of the fetus for hydrops should...
Human papillomavirus infections

Richard C. Reichman

Definition
Human papillomaviruses (HPVs) selectively infect the epithelium of skin and mucous membranes. These infections may be asymptomatic, produce warts, or be associated with a variety of both benign and malignant neoplasms.

Etiologic agent
Papillomaviruses are members of the family Papillomaviridae. They are nonenveloped, measure 50 to 55 nm in diameter, have icosahedral capsids composed of 72 capsomeres, and contain a double-stranded circular DNA genome of ~7900 base pairs. The genomic organization of all papillomaviruses is similar and consists of an early (E) region, a late (L) region, and a noncoding upstream regulatory region (URR). Oncogenic HPV types can immortalize human keratinocytes, and this activity has been mapped to products of early genes E6 and E7. E6 protein facilitates the degradation of the p53 tumor-suppressor protein, and E7 protein binds the retinoblastoma gene product and related proteins. The E1 and E2 proteins modulate viral DNA replication and regulate gene expression. The L1 gene codes for the major capsid protein, which makes up 80% of the virion mass. L2 codes for a minor capsid protein. Type-specific conformational antigenic determinants are located on the virion surface. Papillomavirus types are distinguished from one another by the degree of nucleic acid sequence homology. Distinct types share <90% of their DNA sequences in L1. More than 100 HPV types are recognized, and individual types are associated with specific clinical manifestations. For example, HPV-1 causes plantar warts, HPV-6 causes anogenital warts, and HPV-16 infection can produce cervical dysplasia and invasive cervical cancer. HPVs are species-specific and have not been

TREATMENT
Erythema infectiosum usually requires no treatment; the same is true for many cases of arthropathy. More severe cases of arthropathy, particularly those involving chronic symptoms, can be treated with nonsteroidal anti-inflammatory agents. Transient aplastic crisis is usually treated with erythrocyte transfusions. In immunodeficient anemic patients, B19 infection should be treated with commercial intravenous immunoglobulin, which is known to contain IgG antibodies to B19. This therapy controls and may cure B19 infection.

PROPHYLAXIS
Prophylaxis of B19 infection with immunoglobulin should be considered for patients with chronic hemolysis or immunodeficiency and for pregnant women. The risk of infection for these persons may be reduced by hand washing before eating or after contact with respiratory or other secretions when B19 is known to be present in a community. Patients with transient aplastic crisis or chronic B19 infection (but not those with erythema infectiosum or arthropathy) pose a serious risk for nosocomial transmission of infection. They should be hospitalized in a private room with contact and respiratory isolation precautions. It is not known whether pre- or postexposure administration of immunoglobulin prevents infection. No vaccine for B19 is currently available; however, noninfectious B19 capsid proteins have been given safely to healthy volunteers, who developed high levels of B19-specific neutralizing antibodies.

FURTHER READING
There are few good studies of the incidence or prevalence of human warts in well-defined populations. Common warts (verruca vulgaris) are found in as many as 25% of some groups and are most prevalent among young children. Plantar warts (verruca plantaris) are also widely prevalent; they occur most often among adolescents and young adults. Condyloma acuminatum (anogenital warts) is one of the most common sexually transmitted diseases in the United States. HPV infection of the uterine cervix produces the squamous cell abnormalities most frequently detected on Papanicolaou smears. Most anogenital HPV infections are transmitted through direct contact with infectious lesions. However, characteristics of infectious lesions, including appearance, have not been defined, and individuals without obvious disease may transmit infection. Close personal contact is also assumed to play a role in the transmission of most cutaneous warts; the importance of fomites in this setting is not clear. Minor trauma at the site of inoculation may facilitate transmission. Recurrent respiratory papillomatosis in young children is an uncommon disease that is acquired from maternal genital tract infection; in adults, orogenital sexual contact may transmit the disease.

According to a consensus panel gathered by the World Health Organization, a large body of epidemiologic and biologic data has established that some HPV infections cause cervical cancer. For example, >95% of cervical cancers contain HPV DNA of oncogenic (high-risk) types, such as 16, 18, 31, 33, and 45. HPV DNA is also present in the precursor lesions of cervical cancer (cervical intraepithelial neoplasias). Such lesions containing DNA of oncogenic types are more likely to progress than those associated with low-risk HPV types, such as 6 and 11. HPV DNA is transcribed in tumor tissues, and many epidemiologic studies have confirmed a strong relationship between HPV infection (with or without cofactors) and the development of cervical cancer. However, it is important to realize that most cervical HPV infections, including those caused by high-risk types, are self-limited. Infection with specific HPV types has also been associated with squamous cell carcinomas and dysplasias of the penis, anus, vagina, and vulva. In patients with epidermodysplasia verruciformis, squamous cell cancers develop frequently at sites infected with specific HPV types, including 5 and 8.

Serologic studies employing virus-like particles as antigens have demonstrated type-specific antibodies in most patients with HPV genital tract infections.

**CLINICAL MANIFESTATIONS** The clinical manifestations of HPV infection depend on the location of lesions and the type of virus. Common warts usually occur on the hands as flesh-colored to brown, exophytic, and hyperkeratotic papules. Plantar warts may be quite painful; they can be differentiated from calluses by paring of the surface to reveal thorn- or papilla-like capillaries. Flat warts (verruca plana) are most common among children and occur on the face, neck, chest, and flexor surfaces of the forearms and legs.

Anogenital warts develop on the skin and mucosal surfaces of external genitalia and perianal areas (Fig. 169-1). Among circumcised men, warts are most commonly found on the penile shaft. Lesions frequently occur at the urethral meatus and may extend proximally. Receptive anal intercourse predisposes both men and women to the development of perianal warts, but such lesions occasionally develop without such a history. In women, warts appear first at the posterior introitus and adjacent labia. They then spread to other parts of the vulva and commonly involve the vagina and cervix. External warts in both sexes are suggestive of the presence of internal lesions, although internal lesions may be present without external warts, particularly among women. The differential diagnosis of anogenital warts includes condylomata lata of secondary syphilis, molluscum contagiosum, human papillomavirus (pearly penile papules), fibroepitheliomas, and a variety of benign and malignant mucocutaneous neoplasms. Respiratory papillomatosis in young children, which may be life-threatening, presents as hoarseness, stridor, or respiratory distress. The disease in adults is usually milder.

Immunosuppressed patients, particularly those undergoing organ transplantation, often develop pityriasis versicolor—like lesions, from which DNA of several HPV types has been extracted. Occasionally, such lesions appear to undergo malignant transformation. Patients infected with HIV frequently have severe clinical manifestations of HPV infection and appear to be at unusually high risk for cervical and anal dysplasia as well as for potentially invasive cancer. HPV disease in patients with HIV infection is difficult to treat and often recurs.

Epidermodysplasia verruciformis is a rare autosomal recessive disease characterized by an inability to control HPV infection. Patients are often infected with unusual HPV types and frequently develop cutaneous squamous cell malignancies, particularly in sun-exposed areas. The lesions resemble flat warts or macules similar to those of pityriasis versicolor.

The complications of warts include itching and occasionally bleeding. In rare cases warts become secondarily infected with bacteria or fungi. Large masses of warts may cause mechanical problems, such as obstruction of the birth canal. Dysplasias of the uterine cervix are generally asymptomatic until frank carcinoma develops. Patients with anogenital HPV disease may develop serious psychological symptoms due to anxiety and depression over this condition.

**PATHOGENESIS** The incubation period of HPV disease is usually 3 to 4 months (range, 1 month to 2 years). All types of squamous epithelium can be infected by HPV, and the gross and histologic appearances of individual lesions vary with the site of infection and the type of virus. The replication of HPV begins with the infection of basal cells. As cellular differentiation proceeds, HPV DNA replicates and is transcribed. Ultimately, virions are assembled in the nucleus and released when keratinocytes are shed. This process is associated with proliferation of all epidermal layers except the basal layer and produces acanthosis, parakeratosis, and hyperkeratosis. Koilocytes—large round cells with pyknotic nuclei—appear in the granular layer. Histologically normal epithelium may contain HPV DNA, and residual DNA after treatment can be associated with recurrent disease.

Epithelial HPV DNA is present in the nuclei of infected cells in benign lesions caused by HPV. However, in severe dysplasias and cancers, HPV DNA is generally integrated, with disruption of the E1/E2 open reading frames. This disruption leads to upregulation of E6 and E7 and subsequent interference with cellular tumor-suppressor proteins.

Host defense responses to HPV infection are incompletely under-
stood, and immune correlates of protection from infection and resolution of disease have not been established. Because patients with defects in cell-mediated immune responses, including transplant recipients and patients with HIV infection, frequently develop severe HPV disease, such responses are probably important for the control of virus replication. Histologic studies demonstrating an epidermal lymphomonomocytic infiltrate in resolving warts suggest that local immunity may be of particular importance in the resolution of disease. HPV infection can also elicit a serologic response; antibodies to the viral capsid have been found in sera of patients with anogenital warts, cutaneous warts, and respiratory papillomatosis. Antibodies to E-region proteins, most notably E7, have been detected among patients with cervical carcinoma. In one prophylactic vaccine study, induction of a serologic response was associated with protection from cervical HPV infection in a group of immunocompetent young women.

**DIAGNOSIS**  Most warts that are visible to the naked eye can be diagnosed correctly by history and physical examination alone. The use of a colposcope is invaluable in assessing vaginal and cervical lesions and is helpful in the diagnosis of oral and cutaneous HPV disease as well. Application of 3 to 5% solutions of acetic acid may aid in the visualization of lesions, although the sensitivity and specificity of this procedure are unknown. Papanicolaou smears prepared from cervical or anal scrapings often show cytologic evidence of HPV infection. Persistent or atypical lesions should be biopsied and examined by routine histologic methods. The most sensitive and specific methods of virologic diagnosis entail the use of techniques such as the polymerase chain reaction or the hybrid capture assay to detect HPV nucleic acids and to identify specific virus types. Such tests may be useful in the diagnosis and management of cervical HPV disease, although their utility may vary according to the prevalence of disease and the availability of traditional cytologic and histologic testing. Serologic techniques to diagnose HPV infection are not helpful in individual cases and are not widely available.

**TREATMENT**  (Table 169-1)

Decisions regarding the initiation of therapy should be made with the knowledge that currently available modes of treatment are not completely effective and some have significant side effects. In addition, treatment may be expensive, and many HPV lesions resolve spontaneously. Frequently used therapies include cryosurgery, application of caustic agents, electrodesiccation, surgical excision, and ablation with a laser. Topical antimitabolites such as 5-fluorouracil have also been used. Both failure and recurrence have been well documented with all of these methods of treatment. Cryosurgery is the initial treatment of choice for condyloma acuminatum. Topically applied podophyllin preparations as well as podoflox may also be used. Various interferon preparations have been employed with modest success in the treatment of respiratory papillomatosis and condyloma acuminatum. A topically applied interferon inducer, imiquimod, is also of benefit in the treatment of condyloma acuminatum. The diagnosis and management of anogenital dysplasias and of internal anogenital warts require special skills and resources, and patients with such lesions should be referred to a qualified specialist.

**PREVENTION**  Apart from the avoidance of contact with infectious lesions, no effective methods for the prevention of HPV infections are available at present. Barrier methods of contraception may be helpful in preventing transmission of condyloma acuminatum and other anogenital HPV-associated diseases. Vaccines consisting of virus-like particles (VLPs) can prevent papillomavirus disease in animal models. One study of an HPV-16 VLP vaccine in uninfected women has shown protection from cervical infection with the homologous virus. More extensive clinical trials of these preparations are likely to demonstrate reductions in rates of cervical HPV disease.

GENERAL CONSIDERATIONS  Acute viral respiratory illnesses are among the most common of human diseases, accounting for one-half or more of all acute illnesses. The incidence of acute respiratory disease in the United States is from 3 to 5.6 cases per person per year. The rates are highest among children <1 year old (6.1 to 8.3 cases per year) and remain high until age 6, when a progressive decrease begins. Adults have 3 to 4 cases per person per year. Morbidity from acute respiratory illnesses accounts for 30 to 50% of time lost from work by adults and for 60 to 80% of time lost from school by children. The use of antibacterial agents to treat viral respiratory infections represents a major source of abuse of that category of drugs.

It has been estimated that two-thirds to three-fourths of cases of acute respiratory illnesses are caused by viruses. More than 200 antigenically distinct viruses from 9 different genera have been reported to cause acute respiratory illness, and it is likely that additional agents will be described in the future. The vast majority of these viral infections involve the upper respiratory tract, but lower respiratory tract disease can also develop, particularly in younger age groups and in certain epidemiologic settings.

The illnesses caused by respiratory viruses traditionally have been divided into multiple distinct syndromes, such as the “common cold,” pharyngitis, croup (laryngotracheobronchitis), tracheitis, bronchiolitis, bronchitis, and pneumonia. Each of these general categories of illness has a certain epidemiologic and clinical profile; for example, croup occurs exclusively in very young children and has a characteristic clinical course. Some types of respiratory illness are more likely to be associated with certain viruses (e.g., the common cold with rhinoviruses), while others occupy characteristic epidemiologic niches (e.g., adenovirus infections in military recruits). The syndromes most commonly associated with infections with the major respiratory virus groups are summarized in Table 170-1. Most respiratory viruses clearly have the potential to cause more than one type of respiratory illness, and frequently features of several types of illness are found in the same patient. Moreover, the clinical illnesses induced by these viruses are rarely sufficiently distinctive to permit an etiologic diagnosis on clinical grounds alone, although the epidemiologic setting increases the likelihood that one group of viruses rather than another is involved. In general, laboratory methods must be relied on to establish a specific viral diagnosis.

This chapter reviews viral infections caused by six of the major groups of respiratory viruses: rhinoviruses, coronaviruses, respiratory syncytial viruses, metapneumoviruses, parainfluenza viruses, and adenoviruses. The recent extraordinary outbreaks of lower respiratory tract disease associated with coronaviruses (severe acute respiratory syndrome, or SARS) are also discussed. Influenza viruses, which are a major cause of mortality as well as morbidity, are reviewed in Chap. 171. Herpesviruses, which occasionally cause pharyngitis and which also cause lower respiratory tract disease in immunosuppressed patients, are reviewed in Chap. 163. Enteroviruses, which account for occasional respiratory illnesses during the summer months, are reviewed in Chap. 175.

RHINOVIRUS INFECTIONS

ETIOLOGIC AGENT  Rhinoviruses are members of the Picornaviridae family, small (15 to 30 nm) nonenveloped viruses that contain a single-stranded RNA genome. In contrast to other members of the picornavirus family, such as enteroviruses, rhinoviruses are acid-labile and are almost completely inactivated at pH ≤ 3. Rhinoviruses grow preferentially at 33° to 34°C—the temperature of the human nasal passages—rather than at the higher temperature (37°C) of the lower respiratory tract. A total of 102 distinct serotypes of rhinovirus are recognized. Of these serotypes, 91 use intercellular adhesion molecule 1 (ICAM-1) as a cellular receptor and comprise the “major” receptor

*SARS-associated coronavirus (SARS-CoV) caused epidemics of pneumonia from November 2002 to July 2003 (see text).

Serotypes 4 and 7.

Fever, cough, myalgia, malaise.

May or may not have a respiratory component.

Newly recognized human metapneumoviruses that cause upper and lower respiratory tract illnesses; their relative frequency has not yet been established.
group, 10 use the low-density lipoprotein receptor and comprise the “minor” receptor group, and 1 uses a sialoprotein cellular receptor.

**EPIDEMIOLOGY** Rhinoviruses are a major cause of the common cold and have been isolated from 15 to 40% of adults with common cold-like illnesses. Overall rates of infection with rhinoviruses are higher among infants and young children and decrease with increasing age. Rhinovirus infections occur throughout the year, with seasonal peaks in early fall and spring in temperate climates. These infections are most often introduced into families by preschool or grade-school children <6 years old. Between 25 and 70% of initial illnesses in family settings are followed by secondary cases, with the highest attack rates among the youngest siblings at home. Attack rates also increase with family size.

Rhinoviruses appear to spread through direct contact with infected secretions, usually respiratory droplets. In some studies of volunteers, transmission was most efficient by hand-to-hand contact, with subsequent self-inoculation of the conjunctival or nasal mucosa. In other studies, transmission by large- or small-particle aerosol was demonstrated. Virus can also be recovered from plastic surfaces inoculated 1 to 3 h previously; this observation suggests that environmental surfaces contribute to transmission. In studies of married couples in which neither partner had detectable serum antibody, transmission was associated with prolonged contact (>122 h) during a 7-day period. Transmission was inefficient unless virus was recoverable from the donor’s hands and nasal mucosa, at least 1000 TCID50 of virus was present in nasal washes from the donor, and the donor was at least moderately symptomatic with the “cold.” Despite anecdotal observations, exposure to cold temperatures, fatigue, or sleep deprivation has not been associated with increased rates of rhinovirus-induced illness in volunteers, although some studies have suggested that psychologically defined “stress” may contribute to development of symptoms.

Infection with rhinoviruses is worldwide in distribution. By the time they reach adulthood, nearly all individuals have neutralizing antibodies to multiple serotypes, although the prevalence of antibody to any one serotype varies widely. Multiple serotypes circulate simultaneously, and generally no single serotype or group of serotypes has been more prevalent than the others.

**PATHOGENESIS** Rhinoviruses infect cells through attachment to specific cellular receptors; as mentioned above, most serotypes attach to ICAM-1, while a few use the low-density lipoprotein receptor. Relatively limited information is available on the histopathology and pathogenesis of acute rhinovirus infections in humans. Examination of biopsy specimens obtained during experimentally induced and naturally occurring illness indicates that the nasal mucosa is edematous, is often hyperemic, and—during acute illness—is covered by a mucoid discharge. There is a mild infiltrate with inflammatory cells, including neutrophils, lymphocytes, plasma cells, and eosinophils. Mucus-secreting glands in the submucosa appear hyperactive; the nasal turbinates are engorged, a condition that may lead to obstruction of nearby openings of sinus cavities. Several mediators, such as bradykinin, lysylbradykinin, prostaglandins, histamine, and interleukins 1, 6, and 8, have been linked to the development of signs and symptoms in rhinovirus-induced colds.

The incubation period for rhinovirus illness is short, generally 1 or 2 days. Virus shedding coincides with the onset of illness or may begin shortly before symptoms develop. The mechanisms of immunity to rhinovirus are not well worked out. In some studies, the presence of homotypic antibody has been associated with significantly reduced rates of subsequent infection and illness, but data conflict regarding the relative importance of serum and local antibody in protection from rhinovirus infection.

**CLINICAL MANIFESTATIONS** The most common clinical manifestations of rhinovirus infections are those of the common cold. Illness usually begins with rhinorrhea and sneezing accompanied by nasal congestion. The throat is frequently sore, and in some cases sore throat is the initial complaint. Systemic signs and symptoms, such as malaise and headache, are mild or absent, and fever is unusual. Illness generally lasts for 4 to 9 days and resolves spontaneously without sequelae. In children, bronchitis, bronchiolitis, and bronchopneumonia have been reported; nevertheless, it appears that rhinoviruses are not major causes of lower respiratory tract disease in children. Rhinoviruses may cause exacerbations of asthma and chronic pulmonary disease in adults. The vast majority of rhinovirus infections resolve without sequelae, but complications related to obstruction of the eustachian tubes or sinus ostia, including otitis media or acute sinusitis, can develop. In immunosuppressed patients, particularly bone marrow transplant recipients, severe and even fatal pneumonias have been associated with rhinovirus infections.

**DIAGNOSIS** Although rhinoviruses are the most frequently recognized cause of the common cold, similar illnesses are caused by a variety of other viruses, and the etiologic diagnosis cannot be made on clinical grounds alone. Rather, rhinovirus infection is diagnosed by isolation of the virus from nasal washes or nasal secretions in tissue culture. In practice, this procedure is rarely undertaken because of the benign, self-limited nature of the illness. In most settings, detection of rhinovirus RNA by polymerase chain reaction (PCR) is more sensitive than that by tissue culture; however, this PCR is largely a research procedure. Given the many serotypes of rhinovirus, diagnosis by serum antibody tests is currently impractical. Likewise, common laboratory tests, such as white cell count and sedimentation rate, are not helpful.

**TREATMENT** Rhinovirus infections are generally mild and self-limited, so treatment is not usually necessary. Therapy in the form of first-generation antihistamines and nonsteroidal anti-inflammatory drugs may be beneficial in patients with particularly pronounced symptoms, and an oral decongestant may be added if nasal obstruction is particularly troublesome. Reduction of activity is prudent in instances of significant discomfort or fatigability. Antibacterial agents should be used only if bacterial complications such as otitis media or sinusitis develop. Specific antiviral therapy is not available.

**PREVENTION** Application of interferon sprays intranasally has been effective in the prophylaxis of rhinovirus infections but is also associated with local irritation of the nasal mucosa. Studies of the prevention of rhinovirus infection by administration of antibodies to ICAM-1 or by the soluble purified receptors themselves have yielded disappointing results. Experimental vaccines to certain rhinovirus serotypes have been generated, but their usefulness is questionable because of the myriad serotypes and the uncertainty about mechanisms of immunity. Thorough hand washing, environmental decontamination, and protection against autoinoculation may help to reduce rates of transmission of infection.

**CORONAVIRUS INFECTIONS, INCLUDING SARS**

**ETIOLOGIC AGENT** Coronaviruses are pleomorphic, single-strand RNA viruses that measure 100 to 150 nm in diameter. The name derives from the crownlike appearance produced by the club-shaped projections that stud the viral envelope. Coronaviruses infect a wide variety of animal species and have been divided into three antigenic groups. Previously recognized coronaviruses that infect humans fell into two of these groups (I and II), which are represented by prototype isolates HCoV-229E and HCoV-OC43, respectively. The coronavirus associated with SARS (SARS-CoV) appears to be of a novel and distinct group (Fig. 170-1). To date, the SARS-CoV strains that have been fully sequenced have shown only minimal variation.

In general, human coronaviruses have been difficult to cultivate in vitro, and some strains grow only in human tracheal organ cultures rather than in tissue culture. SARS-CoV is an exception whose ready growth in African green monkey kidney (Vero E6) cells greatly facilitates its study.
Epidemiology

Generally, human coronavirus infections are present throughout the world. Seroprevalence studies of strains HCoV-229E and HCoV-OC43 have demonstrated that serum antibodies are acquired early in life and increase in prevalence with advancing age, so that >80% of adult populations have antibodies as measured by enzyme-linked immunosorbent assay (ELISA). Overall, coronaviruses account for 10 to 35% of common colds, depending on the season. Coronavirus infections appear to be particularly prevalent in late fall, winter, and early spring—times when rhinovirus infections are less common.

The epidemic of the coronavirus-associated illness known as SARS apparently began in Guangdong Province of China in November 2002 and possibly originated from contact with semidomesticated animals such as the palm civet or the dog raccoon. These animals are prized as edible delicacies in the area and harbor infections with coronaviruses related to SARS-CoV. Between November 16, 2002, and February 28, 2003, 792 cases of apparent SARS were noted in Guangdong, and it was recognized that health care workers and their contacts accounted for many of the cases. A physician from Guangdong who traveled to Hong Kong to visit his family 5 days after the onset of his illness may represent the index case that introduced SARS into Hong Kong. In March 2003, a large number of cases of severe respiratory disease were reported to the World Health Organization (WHO) from Hong Kong. Many of the patients had had contact with the putative index case, had stayed at the hotel where he resided, or had had contact with secondary cases. At nearly the same time, similar cases were noted in Singapore, Thailand, Vietnam, Taiwan, and Toronto (Canada), initially in travelers from Hong Kong or Guangdong. Ultimately, 8422 cases were identified by WHO in 28 countries of Asia, Europe, and North America, although ~90% of cases occurred in China and Hong Kong. Case-fatality rates varied among the outbreaks, with an overall figure of ~11%. The disease appeared to be somewhat milder in cases in the United States and was clearly less severe among children (see below).

The mechanisms of transmission of SARS are incompletely understood. Clusters of cases suggest that spread may occur by both large and small aerosols and perhaps by the fecal-oral route as well. The outbreak of illness in a large apartment complex in Hong Kong suggested that environmental sources, such as sewage or water, may also play a role in transmission. Some ill individuals appeared to be hyperinfectious (“super-spreaders”) and were capable of transmitting infection to 10 to 40 contacts, although most infections resulted in spread either to no one or to up to three individuals.

Pathogenesis

Coronaviruses that cause the common cold (e.g., strains HCoV-229E and HCoV-OC43) infect ciliated epithelial cells in the nasopharynx. Viral replication leads to damage of ciliated cells and induction of chemokines and interleukins, which result in common-cold symptoms similar to those induced by rhinoviruses.

The pathogenesis of SARS is that of a systemic illness in which virus likely enters and infects cells of the respiratory tract but is also found in the bloodstream, in the urine, and (for up to 2 months) in the stool. Virus persists in the respiratory tract for 2 to 3 weeks, and titers peak ~7 days after the onset of systemic illness. Pulmonary pathology consists of hyaline membrane formation, desquamation of pneumocytes in alveolar spaces, and an interstitial infiltrate consisting of lymphocytes and mononuclear cells. Giant cells are frequently seen, and coronavirus particles have been detected in type II pneumocytes.

Clinical Manifestations

After an incubation period that generally lasts 2 to 7 days (range, 1 to 10 days), SARS usually begins as a systemic illness marked by the onset of fever, which is often accompanied by malaise, headache, and myalgias and is followed in 1 to 2 days by a nonproductive cough and dyspnea. Approximately 25% of patients have diarrhea. Chest x-rays can show a variety of infiltrates, including patchy areas of consolidation—most frequently in peripheral and lower lung fields—or interstitial infiltrates, which can progress to diffuse involvement (Fig. 170-2).

In severe cases, respiratory function may worsen during the second week of illness and progress to frank adult respiratory distress syndrome (ARDS) accompanied by multiorgan dysfunction. Risk factors for severity of disease include an age of >50 and comorbidities such as cardiovascular disease, diabetes, or hepatitis. Illness in pregnant women may be particularly severe, but SARS-CoV infection appears to be milder in children than in adults.

The clinical features of common colds caused by human coronaviruses are similar to those of illness caused by rhinoviruses. In studies of volunteers, the mean incubation period of colds induced by coronaviruses (3 days) is somewhat longer than that of illness caused by rhinoviruses, and the duration of illness is somewhat shorter (mean, 6 to 7 days). In some studies, the amount of nasal discharge was somewhat greater in colds induced by coronaviruses than in those induced by rhinoviruses. Coronavirus other than SARS-CoV have been recovered occasionally from infants with pneumonia and from military recruits with lower respiratory tract disease and have been associated with worsening of chronic bronchitis.

Laboratory Findings and Diagnosis

Laboratory abnormalities in SARS include lymphopenia, which is present in ~50% of cases and which mostly affects CD4+ T cells but also involves CD8+ T cells and NK cells. Total white blood cell counts are normal or slightly low, and thrombocytopenia may develop as the illness progresses. Elevated serum levels of aminotransferases, creatine kinase, and lactate dehydrogenase have been reported.

The WHO and the Centers for Disease Control and Prevention have developed case definitions for diagnosis of SARS. These definitions include clinical, epidemiologic, and laboratory features, which are being refined as additional information on SARS is gathered. SARS-CoV can be grown from respiratory tract samples by inoculation into Vero E6 tissue culture cells, in which a cytopathic effect can be seen within days. A rapid diagnosis can be made by reverse-transcriptase PCR (RT-PCR) of respiratory tract samples and plasma early in illness and of urine and stool later on. RT-PCR appears to be more sensitive than tissue culture, but only around one-third of cases are positive by PCR at initial presentation. Serum antibodies can be detected by ELISA or immunofluorescence, and nearly all patients develop detectable serum antibodies within 28 days after the onset of illness.

Laboratory diagnosis of coronavirus-induced colds is rarely required. Coronaviruses that cause those illnesses are frequently difficult to cultivate in vitro but can be detected in clinical samples by ELISA or immunofluorescence assays or by RT-PCR for viral RNA. These research procedures can be used to detect coronaviruses in unusual clinical settings.
RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

**ETIOLOGIC AGENT**  
Respiratory syncytial virus (RSV) is a member of the Paramyxoviridae family (genus *Pneumovirus*). RSV, an enveloped virus ~150 to 300 nm in diameter, is so named because its replication in vitro leads to the fusion of neighboring cells into large multinucleated syncyta. The single-stranded RNA genome codes for 11 virus-specific proteins. Viral RNA is contained in a helical nucleocapsid surrounded by a lipid envelope bearing two glycoproteins: the G protein, by which the virus attaches to cells, and the F (fusion) protein, which facilitates entry of the virus into the cell by fusing host and viral membranes. RSV was once considered to be of a single antigenic type, but two distinct groups (A and B) and multiple subtypes within each group have now been described. Antigenic diversity is reflected by differences in the G protein, while the F protein is highly conserved. Both antigenic groups can circulate simultaneously in outbreaks, although the relative proportions of each vary. Infections with group B viruses may be somewhat milder than those with group A viruses.

**EPIDEMIOLOGY**  
RSV is the major respiratory pathogen of young children and the foremost cause of lower respiratory disease in infants. Infection with RSV is evident throughout the world in annual epidemics that occur in late fall, winter, or spring and last up to 5 months. The virus is rarely encountered during the summer. Rates of illness are highest among infants 1 to 6 months of age, peaking between 2 and 3 months of age. The attack rates among susceptible infants and children are extraordinarily high, approaching 100% in settings such as day-care centers where large numbers of susceptible infants are present. By age 2, virtually all children will have been infected with RSV. RSV accounts for 20 to 25% of hospital admissions of young infants and children for pneumonia and for up to 75% of cases of bronchiolitis in this age group. It has been estimated that more than half of infants who are at risk will become infected during an RSV epidemic.

In older children and adults, reinfection with RSV is frequent but disease is milder than in infancy. A common cold–like syndrome is the illness most commonly associated with RSV infection in adults. Severe lower respiratory tract disease with pneumonitis can occur in elderly (often institutionalized) adults and in patients with immunocompromising disorders or treatment, including recipients of bone marrow and solid-organ transplants. RSV is also an important nosocomial pathogen; during an outbreak, it can infect pediatric patients and up to 25 to 50% of the staff on pediatric wards. The spread of virus among families is efficient; up to 40% of siblings may become infected when RSV is introduced into the family setting.

RSV is transmitted primarily by close contact with contaminated fingers or fomites and by self-inoculation of the conjunctiva or anterior nares. Virus may also be spread by coarse aerosols produced by coughing or sneezing, but it is inefficiently spread by fine-particle aerosols. The incubation period is ~4 to 6 days, and virus shedding may last for ≥2 weeks in children and for shorter periods in adults. In immunosuppressed patients, shedding can be prolonged for multiple weeks.

**PATHOGENESIS**  
Little is known about the histopathology of minor RSV infection. Severe bronchiolitis or pneumonia is characterized by necrosis of the bronchial epithelium and a peribronchial infiltrate of lymphocytes and mononuclear cells. Interalveolar thickening and filling of alveolar spaces with fluid can also be found. The correlates of protective immunity to RSV are incompletely understood. Because reinfection occurs frequently and is often associated with illness, the immunity that develops after single episodes of infection clearly is not complete or long-lasting. However, the cumulative effect of multiple reinfections is to temper subsequent disease and to provide some temporary measure of protection against infection. Studies of experimentally induced disease in healthy volunteers indicate that the presence of nasal IgA neutralizing antibody correlates more closely with protection than does the presence of serum antibody. Studies in infants, however, suggest that maternally acquired antibody provides some protection from lower respiratory tract disease, although illness can be severe even in infants who have moderate levels of maternally derived
CLINICAL MANIFESTATIONS RSV infection leads to a wide spectrum of respiratory illnesses. In infants, 25 to 40% of infections result in lower respiratory tract involvement, including pneumonia, bronchiolitis, and tracheobronchitis. In this age group, illness begins most frequently with rhinorrhea, low-grade fever, and mild systemic symptoms, often accompanied by cough and wheezing. Most patients recover gradually over 1 to 2 weeks. In more severe illness, tachypnea and dyspnea develop, and eventually frank hypoxia, cyanosis, and apnea can ensue. Physical examination may reveal diffuse wheezing, rhonchi, and rales. Chest radiography shows hyperexpansion, peribronchial thickening, and variable infiltrates ranging from diffuse interstitial infiltrates to segmental or lobar consolidation. Illness may be particularly severe in children born prematurely and in those with congenital cardiac disease, bronchopulmonary dysplasia, nephrotic syndrome, or immunosuppression. One study documented a 37% mortality rate for infants with RSV pneumonia and congenital cardiac disease.

In adults, the most common symptoms of RSV infection are those of the common cold, with rhinorrhea, sore throat, and cough. Illness is occasionally associated with moderate systemic symptoms such as malaise, headache, and fever. RSV has also been reported to cause lower respiratory tract disease with fever in adults, including severe pneumonia in the elderly—particularly in nursing-home residents, among whom its impact can rival that of influenza. RSV pneumonia can be a significant cause of morbidity and mortality in patients undergoing bone-marrow and solid-organ transplantation, where case-fatality rates of 20 to 80% have been reported. Sinusitis, otitis media, and worsening of chronic obstructive and reactive airway disease have also been associated with RSV infection.

LABORATORY FINDINGS AND DIAGNOSIS The diagnosis of RSV infection can be suspected on the basis of a suggestive epidemiologic setting—that is, severe illness among infants during an outbreak of RSV in the community. Infections in older children and adults cannot be differentiated with certainty from those caused by other respiratory viruses. The specific diagnosis is established by isolation of RSV from respiratory secretions, such as sputum, throat swabs, or nasopharyngeal washes. Virus is isolated in tissue culture and is identified specifically by neutralization, or complement-fixation tests. The testsmaybe useful in reducing the spread of virus.

Rapid viral diagnosis is available by immunofluorescence techniques or ELISA, or other immunologic techniques. HMPV can be detected in nasal aspirates and respiratory secretions, such as sputum, throat swabs, or nasopharyngeal washes. In children, these techniques have sensitivities and specificities of 80 to 95%; they are somewhat less sensitive in specimens from adults. Serologic diagnosis may be made by comparison of acute- and convalescent-phase serum specimens by ELISA, neutralization, or complement-fixation tests. These tests may be useful in older children and adults but are less sensitive in children <4 months of age.

TREATMENT Treatment of upper respiratory tract RSV infection is aimed primarily at the alleviation of symptoms and is similar to that for other viral infections of the upper respiratory tract. For lower respiratory tract infections, respiratory therapy, including hydration, suctioning of secretions, and administration of humidified oxygen and anticholinergic agents, is given as needed. In severe hypoxia, intubation and ventilatory assistance may be required. Studies of infants with RSV infection who were given aerosolized ribavirin, a nucleoside analogue active in vitro against RSV, have demonstrated a beneficial effect on the resolution of lower respiratory tract illness, including alleviation of blood-gas abnormalities. Treatment with aerosolized ribavirin is recommended for infants who are severely ill or who are at high risk for complications of RSV infection; included are premature infants and those with bronchopulmonary dysplasia, congenital heart disease, or immunosuppression. The efficacy of ribavirin in older children and adults with RSV pneumonia, including those with immunosuppression, has not been established. Administration of standard immunoglobulin, immunoglobulin with high antibody titers to RSV (RSV Ig), or chimeric mouse-human monoclonal IgG against RSV (palivizumab) has not been found to be beneficial in the treatment of RSV pneumonia. Combined therapy with aerosolized ribavirin and palivizumab is being evaluated in the treatment of immunosuppressed patients with RSV pneumonia.

PREVENTION Monthly administration of RSV Ig or palivizumab has been approved as prophylaxis against RSV for children <2 years of age who have bronchopulmonary dysplasia or were born prematurely. Considerable interest exists in the development of vaccines against RSV. Inactivated whole-virus vaccines have been ineffective; in one study, they actually potentiated the disease in infants. Other approaches include immunization with purified F and G surface glycoproteins of RSV or generation of stable, live attenuated virus vaccines. In settings such as pediatric wards where rates of transmission are high, barrier methods for the protection of hands and conjunctivae may be useful.

METAPNEUMOVIRUS INFECTIONS Human metapneumovirus (HMPV) is a newly described viral respiratory pathogen that has been assigned to the Paramyxoviridae family (genus Metapneumovirus). Its morphology and genomic organization are similar to those of avian metapneumoviruses, which are recognized respiratory pathogens of turkeys. HMPV particles may be spherical, filamentous, or pleomorphic in shape and measure 60 to 280 nm in diameter. Particles contain 15-nm projections from the surface that are similar in appearance to those of other Paramyxoviridae. Studies of the RNA genome indicate that there are at least two genetic subgroups or genotypes of HMPV. HMPV was initially detected in nasal aspirates from 28 children hospitalized with lower respiratory tract illnesses over a 20-year period (1981–2001) in the Netherlands. HMPV infections have since been reported in a wide variety of age groups, including elderly adults, and in both immunocompetent and immunosuppressed hosts. Initial seroepidemiologic studies suggest that HMPV infections are worldwide in distribution, are most frequent during the winter, and occur early in life, so that serum antibodies to the virus are present in nearly all children by the age of 5. The spectrum of clinical illnesses associated with HMPV is similar to that associated with RSV and includes both upper and lower respiratory tract illnesses, such as bronchiolitis, cough, and pneumonia. HMPV can be detected in nasal aspirates and respiratory secretions by PCR or by growth in rhesus monkey kidney (LLC-MK2) tissue cultures. Serologic diagnosis can be made by ELISA, which utilizes HMPV-infected tissue culture lysates as sources of antigens. Preliminary studies indicate that HMPV infections account for 4% of respiratory tract illnesses requiring hospitalization of children and for 2 to 4% of acute respiratory illnesses in ambulatory adults and elderly patients. HMPV has been detected in a few cases of SARS, but its role (if any) in these illnesses has not been established. Assessment of the overall significance of HMPV infections awaits the conduct of large-scale epidemiologic studies.

PARAINFLUENZA VIRUS INFECTIONS ETOLOGIC AGENT Parainfluenza viruses belong to the Paramyxoviridae family (genera Respirovirus andRubulavirus). They are 150 to 200 nm in diameter, are enveloped, and contain a single-stranded RNA genome. The envelope is studded with two glycoproteins: one possesses both hemagglutinin and neuraminidase activity and the other
contains fusion activity. The viral RNA genome is enclosed in a helical nucleocapsid and codes for six structural and several accessory proteins. All four distinct serotypes of parainfluenza viruses share certain antigens with other members of the Paramyxoviridae family, including mumps and Newcastle disease viruses.

**Epidemiology**  Parainfluenza viruses are distributed throughout the world; infection with type 4 (subtypes 4A and 4B) has been reported less widely, probably because type 4 is more difficult to grow in tissue culture. Infection is acquired in early childhood, so that by 5 years of age most children have antibodies to serotypes 1, 2, and 3. Types 1 and 2 cause epidemics during the fall, often occurring in an alternate-year pattern. Type 3 infection has been detected during all seasons of the year, but epidemics have occurred annually in the spring.

The contribution of parainfluenza infections to respiratory disease varies with both the location and the year. In studies conducted in the United States, parainfluenza virus infections have accounted for 4.3 to 22% of respiratory illnesses in children. In adults, parainfluenza infections are generally mild and account for <10% of respiratory illnesses. The major importance of parainfluenza viruses is as a cause of respiratory illness in young children, in whom they rank second only to RSV as causes of lower respiratory tract illness. Parainfluenza virus type 1 is the most frequent cause of croup (laryngotracheobronchitis) in children, while serotype 2 causes similar, although generally less severe, disease. Type 3 is an important cause of bronchiolitis and pneumonia in infants, while illnesses associated with type 4 have generally been mild. Unlike types 1 and 2, type 3 frequently causes illness during the first month of life, when passively acquired maternal antibody is still present. Parainfluenza viruses are spread through infected respiratory secretions, primarily by person-to-person contact and/or by large droplets. The incubation period has varied from 3 to 6 days in experimental infections but may be somewhat shorter for naturally occurring disease in children.

**Pathogenesis**  Immunity to parainfluenza viruses is incompletely understood, but evidence suggests that immunity to infections with serotypes 1 and 2 is mediated by local IgA antibodies in the respiratory tract. Passively acquired serum neutralizing antibodies also confer some protection against infection with types 1, 2, and—to a lesser degree—3. Studies in experimental animal models and in immunosuppressed patients suggest that T-cell–mediated immunity may also be important in parainfluenza virus infections.

**Clinical Manifestations**  Parainfluenza virus infections occur most frequently among children, in whom initial infection with serotype 1, 2, or 3 is associated with an acute febrile illness 50 to 80% of the time. Children may present with coryza, sore throat, hoarseness, and cough that may or may not be croupy. In severe croup, fever persists, with worsening coryza and sore throat. A brassy or barking cough may progress to frank stridor. Most children recover over the next 1 or 2 days, although progressive airway obstruction and hypoxia ensue occasionally. If bronchiolitis or pneumonia develops, progressive cough accompanied by wheezing, tachypnea, and intercostal retractions may occur. In this setting, sputum production increases modestly. Physical examination shows nasopharyngeal discharge and oropharyngeal infection, along with rhonchi, wheezes, or coarse breath sounds. Chest x-rays can show air trapping and occasionally interstitial infiltrates.

In older children and adults, parainfluenza infections tend to be milder, presenting most frequently as a common cold or as hoarseness, with or without cough. Lower respiratory tract involvement in older children and adults is uncommon, but tracheobronchitis in adults has been reported. Severe, prolonged, and even fatal parainfluenza infection has been reported in children and adults with severe immunosuppression, including bone-marrow and solid-organ transplant recipients.

**Laboratory Findings and Diagnosis**  The clinical syndromes caused by parainfluenza viruses (with the possible exception of croup in young children) are not sufficiently distinctive to be diagnosed on clinical grounds alone. A specific diagnosis is established by detection of virus in respiratory tract secretions, throat swabs, or nasopharyngeal washings. Viral growth in tissue culture is detected either by hemagglutination or by a cytopathic effect. Rapid viral diagnosis may be made by identification of parainfluenza antigens in exfoliated cells from the respiratory tract with immunofluorescence or ELISA, although these techniques appear to be less sensitive than tissue culture. Highly specific and sensitive PCR assays have also been described. Serologic diagnosis can be established by hemagglutination inhibition, complement-fixation, or neutralization tests of acute- and convalescent-phase specimens. However, as frequent heterotypic responses occur among the parainfluenza serotypes, the serotype causing illness often cannot be identified by serologic techniques alone.

Acute epiglottitis caused by *Haemophilus influenzae* type b must be differentiated from viral croup. Influenza A virus is also a common cause of croup during epidemic periods.

**Treatment**  For upper respiratory tract illness, symptoms can be treated as discussed for other viral respiratory tract illnesses. If complications such as sinusitis, otitis, or superimposed bacterial bronchitis develop, appropriate antibiotics should be administered. Mild cases of croup should be treated with bed rest and moist air generated by vaporizers. More severe cases require hospitalization and close observation for the development of respiratory distress. If acute respiratory distress develops, humidified oxygen and intermittent racemic epinephrine are usually administered. Aerosolized or systemically administered glucocorticoids are beneficial; the latter have a more profound effect. No specific antiviral therapy is available, although ribavirin is active against parainfluenza viruses in vitro and anecdotal reports describe its use clinically, particularly in immunosuppressed patients. Effective vaccines against parainfluenza viruses have not been developed.

**Adenovirus Infections**

**Etiologic Agent**  Adenoviruses are complex DNA viruses that measure 70 to 80 nm in diameter. Human adenoviruses belong to the genus *Mastadenovirus*, which includes 51 serotypes. Adenoviruses have a characteristic morphology consisting of an icosahedral shell composed of 20 equilateral triangular faces and 12 vertices. The protein coat (capsid) consists of hexon subunits with group-specific and type-specific antigenic determinants and penton subunits at each vertex primarily containing group-specific antigens. A fiber with a knob at the end projects from each penton; this fiber contains type-specific and some group-specific antigens. Human adenoviruses have been divided into six subgenera (A through F) on the basis of the homology of DNA genomes and other properties. The adenovirus genome is a linear double-stranded DNA that codes for structural and nonstructural polypeptides. The replicative cycle of adenovirus may result either in lytic infection of cells or in the establishment of a latent infection (primarily involving lymphoid cells). Some adenovirus types can induce oncogenic transformation, and tumor formation has been observed in rodents; however, despite intensive investigation, adenoviruses have not been associated with tumors in humans.

**Epidemiology**  Adenovirus infections most frequently affect infants and children. Infections occur throughout the year but are most common from fall to spring. Adenoviruses account for ~10% of acute respiratory infections in children but for <2% of respiratory illnesses in civilian adults. Nearly 100% of all adults have serum antibody to multiple serotypes—a finding indicating that infection is common in childhood. Types 1, 2, 3, and 5 are the most frequent isolates from children. Certain adenovirus serotypes—particularly 4 and 7 but also 3, 14, and 21—are associated with outbreaks of acute respiratory disease in military recruits in winter and spring. Adenovirus infection can
be transmitted by inhalation of aerosolized virus, by inoculation of virus into conjunctival sacs, and probably by the fecal-oral route as well. Type-specific antibody generally develops after infection and is associated with protection, albeit incomplete, against infection with the same serotype.

**CLINICAL MANIFESTATIONS** In children, adenoviruses cause a variety of clinical syndromes. The most common is an acute upper respiratory tract infection, with prominent rhinitis. On occasion, lower respiratory tract disease, including bronchiolitis and pneumonia, also develops. Adenoviruses, particularly types 3 and 7, cause pharyngoconjunctival fever, a characteristic acute febrile illness of children that occurs in outbreaks, most often in summer camps. The syndrome is marked by bilateral conjunctivitis in which the bulbar and palpebral conjunctivae have a granular appearance. Low-grade fever is frequently present for the first 3 to 5 days, and rhinitis, sore throat, and cervical adenopathy develop. The illness generally lasts for 1 to 2 weeks and resolves spontaneously. Febrile pharyngitis without conjunctivitis has also been associated with adenovirus infection. Adenoviruses have been isolated from cases of whooping cough with or without *Bordetella pertussis;* the significance of adenovirus in that disease is unknown.

In adults, the most frequently reported illness has been acute respiratory disease caused by adenovirus types 4 and 7 in military recruits. This illness is marked by a prominent sore throat and the gradual onset of fever, which often reaches 39°C (102.2°F) on the second or third day of illness. Cough is almost always present, and coryza and regional lymphadenopathy are frequently seen. Physical examination may show pharyngeal edema, injection, and tonsillar enlargement with little or no exudate. If pneumonia has developed, auscultation and x-ray of the chest may indicate areas of patchy infiltration.

Adenoviruses have been associated with a number of non–respiratory tract diseases, including acute diarrheal illness caused by types 40 and 41 in young children and hemorrhagic cystitis caused by types 11 and 21. Epidemic keratoconjunctivitis, caused most frequently by types 8, 19, and 37, has been associated with contaminated common sources such as ophthalmic solutions and roller towels. Adenoviruses have also been implicated in disseminated disease and pneumonia in immunosuppressed patients, including recipients of solid-organ or bone-marrow transplants. In bone-marrow transplant recipients, adenovirus infections have manifested as pneumonia, hepatitis, nephritis, colitis, encephalitis, and hemorrhagic cystitis. In solid-organ transplant recipients, adenovirus infection may involve the organ transplanted (e.g., hepatitis in liver transplants, nephritis in renal transplants) but can disseminate to other organs as well. In patients with AIDS, high-numbered and intermediate adenovirus serotypes have been isolated, usually in the setting of low CD4+ cell counts, but their isolation frequently has not been clearly linked to disease manifestations. Adenovirus nucleic acids have been detected in myocardial cells from patients with “idiopathic” myocardopathies, and adenoviruses have been suggested as causative agents in some cases.

**LABORATORY FINDINGS AND DIAGNOSIS** Adenovirus infection should be suspected in the epidemiologic setting of acute respiratory disease in military recruits and in certain of the clinical syndromes (such as pharyngoconjunctival fever or epidemic keratoconjunctivitis) in which outbreaks of characteristic illnesses occur. In most cases, however, illnesses caused by adenovirus infection cannot be differentiated from those caused by a number of other viral respiratory agents and *Mycoplasma pneumoniae.* A definitive diagnosis of adenovirus infection is established by detection of the virus in tissue culture (as evidenced by cytopathic changes) and by specific identification with immunofluorescence or other immunologic techniques. Rapid viral diagnosis can be established by immunofluorescence or ELISA of nasopharyngeal aspirates, conjunctival or respiratory secretions, urine, or stool. Highly sensitive and specific PCR assays or nucleic acid hybridization is also available. Adenovirus types 40 and 41, which have been associated with diarrheal disease in children, require special tissue-culture cells for isolation, and these serotypes are most commonly detected by direct ELISA of stool. Serum antibody rises can be demonstrated by complement-fixation or neutralization tests, ELISA, radioimmunoassay, or (for those adenoviruses that hemagglutinate red cells) hemagglutination inhibition tests.

### TREATMENT

Only symptom-based treatment and supportive therapy are available for adenovirus infections, and no clinically useful antiviral compounds have been identified. Ribavirin and cidofovir have activity in vitro against adenoviruses, and anecdotes of their use in disseminated infection have been reported.

**PREVENTION** Live vaccines have been developed against adenovirus types 4 and 7 and have been used to control illness in military recruits. These vaccines consist of live, unattenuated virus administered in enteric-coated capsules. Infection of the gastrointestinal tract with types 4 and 7 does not cause disease but stimulates local and systemic antibodies that are protective against subsequent acute respiratory disease due to those serotypes. This vaccine has not been produced since 1999, and outbreaks of acute respiratory illness caused by adenovirus types 4 and 7 have emerged again among military recruits. Vaccines prepared from purified subunits of adenovirus are being investigated. Adenoviruses are also being studied as live-virus vectors for the delivery of vaccine antigens and for gene therapy.

Influenza is an acute respiratory illness caused by infection with influenza viruses. The illness affects the upper and/or lower respiratory tract and is often accompanied by systemic signs and symptoms such as fever, headache, myalgia, and weakness. Outbreaks of illness of variable extent and severity occur nearly every winter. Such outbreaks result in significant morbidity in the general population and in increased mortality rates among certain high-risk patients, mainly as a result of pulmonary complications.

**ETIOLOGIC AGENT** Influenza viruses are members of the Orthomyxoviridae family, of which influenza A, B, and C viruses constitute three separate genera. The designation of influenza viruses as type A, B, or C is based on antigenic characteristics of the nucleoprotein (NP) and matrix (M) protein antigens. Influenza A viruses are further subdivided (subtyped) on the basis of the surface hemagglutinin (H) and neuraminidase (N) antigens (see below); individual strains are designated according to the site of origin, isolate number, year of isolation, and subtype—for example, influenza A/Moscow/10/99 (H3N2). Influenza A has 15 distinct H and 9 distinct N subtypes, of which only H1, H2, H3, N1, and N2 have been associated with extensive outbreaks of disease in humans. Influenza B and C viruses are similarly designated, but H and N antigens from these viruses do not receive subtype designations, since intratypic variations in influenza B antigens are less extensive than those in influenza A viruses and may not occur with influenza C virus.

Influenza A and B viruses are major human pathogens and the most extensively studied of the Orthomyxoviridae. The type A and type B viruses are morphologically similar. The virions are irregularly shaped spherical particles, 80 to 120 nm in diameter, and have a lipid envelope from the surface of which the H and N glycoproteins project (Fig. 171-1). The hemagglutinin is the site by which virus binds to cell receptors, whereas the neuraminidase degrades the receptor and plays a role in the release of virus from infected cells after replication has taken place. Influenza viruses enter cells by receptor-mediated endocytosis, forming a virus-containing endosome. The viral hemagglutinin mediates fusion of the endosomal membrane with the virus envelope, and viral nucleocapsids are subsequently released into the cytoplasm. Antibodies to the H antigen are the major determinants of immunity to influenza virus, while those to the N antigen limit viral spread and contribute to reduction of the infection. The inner surface of the lipid envelope contains the M proteins M1 and M2, which are involved in stabilization of the lipid envelope and in virus assembly. The virion also contains the NP antigen, which is associated with the viral genome, as well as three polymerase (P) proteins that are essential for transcription and synthesis of viral RNA. Two nonstructural proteins function as an interferon antagonist and posttranscriptional regulator (NS1) and a nuclear export factor (NS2 or NEP).

The genomes of influenza A and B viruses consist of eight single-stranded RNA segments, which code for the structural and nonstructural proteins. Because the genome is segmented, the opportunity for gene reassortment during infection is high; reassortment often occurs during infection of cells with more than one influenza A virus.

**EPIDEMIOLOGY** Influenza outbreaks are recorded virtually every year, although their extent and severity vary widely. Localized outbreaks take place at variable intervals, usually every 1 to 3 years. Except in the past 25 years, global epidemics or pandemics have occurred approximately every 10 to 15 years since the 1918–1919 pandemic (Table 171-1).

The most extensive and severe outbreaks are caused by influenza A viruses, in part because of the remarkable propensity of the H and N antigens of these viruses to undergo periodic antigenic variation. Major antigenic variations, called *antigenic shifts*, may be associated with pandemics and are restricted to influenza A viruses. Minor variations are called *antigenic drifts*. These types of antigenic variation may involve the hemagglutinin alone or both the hemagglutinin and the neuraminidase. An example of an antigenic shift involving both the hemagglutinin and the neuraminidase is that of 1957, when the predominant influenza A virus subtype shifted from H1N1 to H2N2; this shift resulted in a severe pandemic, with an estimated 70,000 excess deaths (i.e., deaths in excess of the number expected without an influenza epidemic) in the United States alone. In 1968, an antigenic shift involving only the hemagglutinin occurred (H2N2 to H3N2); the subsequent pandemic was less severe than that of 1957. In 1977, an H1N1 virus emerged and caused a pandemic that primarily affected younger individuals (i.e., those born after 1957). As can be seen in Table 171-1, H1N1 viruses circulated from 1918 to 1956; thus, individuals born prior to 1957 would be expected to have some degree of immunity to H1N1 viruses. During most outbreaks of influenza A, a single subtype has circulated at a time. However, since 1977, H1N1 and H3N2 viruses have circulated simultaneously, resulting in outbreaks of varying severity. In some outbreaks, influenza B viruses have also circulated simultaneously with influenza A viruses.

The origin of pandemic strains is unknown. Given the marked differences between the primary structures of the hemagglutinins of different subtypes of influenza A viruses (H1, H2, and H3), it seems unlikely that antigenic shifts result from spontaneous mutations in the hemagglutinin gene. Because the segmented genome of influenza viruses may result in high rates of reassortment, it has been suggested that pandemic strains may emerge by reassortment of genes between human and animal influenza A viruses that are known to have a broad host range of infection. There was concern that such reassortment might have occurred in 1997 in Hong Kong, where cases of infection caused by influenza virus A/H5N1 were detected in humans during an extensive outbreak of avian influenza A/H5N1 in poultry. However, only a few cases of A/H5N1 influenza in humans were documented, and the infection did not spread into the community. Recently, H9N2 viruses, which circulate in poultry and swine, have also been associated with limited infections in humans. Influenza B viruses have a much more restricted host range and do not undergo antigenic shifts, although they do undergo antigenic drift.

<sup>a</sup> As determined by retrospective serologic survey of individuals alive during those years (“seroepidemiology”).

<sup>b</sup> Hemagglutinins formerly designated as Hsw and H0 are now classified as variants of H1.

<sup>c</sup> From this time until the present (2002–2003), viruses of the H1N1 and H3N2 subtypes have circulated either in alternating years or concurrently.

**FIGURE 171-1** An electron micrograph of influenza A virus (×140,000).
Pandemics provide the most dramatic evidence of the impact of influenza. However, illnesses that occur between pandemics account for greater total mortality and morbidity, albeit over a longer period. From 1972 through the present, influenza has been associated with at least 20,000 excess deaths during more than half of the interpandemic epidemics in the United States; >40,000 influenza-associated deaths occurred in each of six of these epidemics. Influenza A viruses that circulate between pandemics demonstrate antigenic drifts in the hemagglutinin, which occurs most frequently in five hypervariable regions. Epidemiologically significant strains—that is, those with the potential to cause widespread outbreaks—exhibit changes in amino acids in at least two of these antigenic sites in the hemagglutinin molecule. These point mutations are unlikely to occur simultaneously, it is believed that antigenic drifts result from point mutations occurring sequentially during the spread of virus from person to person. Antigenic drifts have been reported nearly annually since 1977 for H1N1 viruses and since 1968 for H3N2 viruses.

Influenza A epidemics begin abruptly, peak over a 2- to 3-week period, generally last for 2 to 3 months, and often subside almost as rapidly as they began. The first indication of influenza activity in a community is an increase in the number of children with febrile respiratory illnesses who present for medical attention. This increase is followed by increases in rates of influenza-like illnesses among adults and eventually by an increase in hospital admissions for patients with pneumonia, worsening of congestive heart failure, and exacerbations of chronic pulmonary disease. Rates of absence from work and school also rise at this time. An increase in the number of deaths caused by pneumonia and influenza is generally a late observation in an outbreak. Attack rates have been highly variable from outbreak to outbreak but most commonly are in the range of 10 to 20% of the general population. During the pandemic of 1957, it was estimated that the attack rate of clinical influenza exceeded 50% in urban populations and that an additional 25% or more of individuals in these populations may have been subclinically infected with influenza A virus. Among institutionalized populations and in semiclosed settings with many susceptible individuals, even higher attack rates have been reported.

Epidemics of influenza occur almost exclusively during the winter months in the temperate zones of the northern and southern hemispheres. In those locations, it is highly unusual to detect influenza A virus at other times, although serologic rises or even outbreaks have been noted rarely during warm-weather months. In contrast, influenza virus infections occur throughout the year in the tropics. Where or how influenza A virus persists between outbreaks in temperate zones is unknown. It is possible that influenza A viruses are maintained in the human population on a worldwide basis by person-to-person transmission and that large population clusters support a low level of interepidemic transmission. Alternatively, human strains may persist in animal reservoirs. Convincing evidence to support either explanation is not available. In the modern era, rapid transportation may contribute to the transmission of viruses among widespread geographic locales.

The factors that result in the inception and termination of outbreaks of influenza are incompletely understood. A major determinant of the extent and severity of an outbreak is the level of immunity in the population at risk. With the emergence of an antigenically novel influenza virus to which little or no antibody is present in a community, extensive outbreaks may occur. When the absence of antibody is worldwide, epidemic disease may spread around the globe, resulting in a pandemic. Such pandemic waves can continue for several years, until immunity in the population reaches a high level. In the years following pandemic influenza, antigenic drifts among influenza viruses result in outbreaks of variable severity in populations with high levels of immunity to the pandemic strain that circulated earlier. This situation persists until another antigenically novel pandemic strain emerges. Occasionally, the emergence of a significantly different antigenic variant will result only in a localized outbreak. The swine influenza outbreak of 1976 in the United States, caused by an A/H1N1 virus antigenically similar to the virus that circulated in 1918–1919, may be an example, although this outbreak may have represented simply the introduction of a swine influenza virus into a crowded human population without spread beyond that setting. The cluster of human infections with influenza A/H5N1 in Hong Kong in 1997 may also be an example of this phenomenon. It has been suggested that certain viruses, such as recently circulating A/H1N1 strains, may be intrinsically less virulent and cause less severe disease than other variants, even in immunologically virgin subjects. If so, then other (undefined) factors besides the preexisting immunity must play a role in the epidemiology of influenza.

Influenza B virus causes outbreaks that are generally less extensive and are associated with less severe disease than those caused by influenza A virus. The hemagglutinin and neuraminidase of influenza B virus undergo less frequent and less extensive variation than those of influenza A viruses; this characteristic may account, in part, for the lesser extent of disease. Influenza B outbreaks are seen most frequently in schools and military camps, although outbreaks in institutions in which elderly individuals reside have also been noted on occasion. The most serious complication of influenza B virus infection is Reye’s syndrome (Chap. 290). In contrast to influenza A and B viruses, influenza C virus appears to be a relatively minor cause of disease in humans. It has been associated with common cold–like symptoms and occasionally with lower respiratory tract illness. The wide prevalence of serum antibody to this virus indicates that asymptomatic infection may be common.

The morbidity and mortality caused by influenza outbreaks continue to be substantial. Most individuals who die in this setting have underlying diseases that place them at high risk for complications of influenza. Excess hospitalizations for adults and children with high-risk medical conditions have ranged from 56 to 1900 per 100,000 during recent outbreaks of influenza. The most prominent high-risk conditions are chronic cardiac and pulmonary diseases and old age. Mortality among individuals with chronic metabolic, renal, and certain immunosuppressive diseases has also been elevated, although lower than that among patients with chronic cardiopulmonary diseases. The morbidity attributable to influenza in the general population is considerable. It is estimated that interepidemic outbreaks of influenza currently incur annual costs of $12 billion in the United States. If a pandemic were to occur, it is estimated that annual costs would range from $71 to $167 billion for attack rates of 15 to 35%.

**PATHOGENESIS AND IMMUNITY** The initial event in influenza is infection of the respiratory epithelium with influenza virus acquired from respiratory secretions of acutely infected individuals. In all likelihood, transmission occurs via aerosols generated by coughs and sneezes, although hand-to-hand contact, other personal contact, and even fomite transmission may take place. Experimental evidence suggests that infection by a small-particle aerosol (particle diameter <10 μm) is more efficient than that by larger droplets. Initially, viral infection involves the ciliated columnar epithelial cells, but it may also involve other respiratory tract cells, including alveolar cells, mucous gland cells, and macrophages. In infected cells, virus replicates within 4 to 6 h, after which infectious virus is released to infect adjacent or nearby cells. In this way, infection spreads from a few foci to a large number of respiratory cells over several hours. In experimentally induced infection, the incubation period of illness has ranged from 18 to 72 h, depending on the size of the viral inoculum. Histopathologic study reveals degenerative changes, including granularity, vacuolization, swelling, and pyknotic nuclei, in infected ciliated cells. The cells eventually become necrotic and desquamate; in some areas, previously columnar epithelium is replaced by flattened and metaplastic epithelial cells. The severity of illness is correlated with the quantity of virus shed in secretions; thus, the degree of viral replication itself may be an important
factor in pathogenesis. Despite the frequent development of systemic signs and symptoms such as fever, headache, and myalgias, influenza virus has only rarely been detected in extrapulmonary sites (including the bloodstream). Evidence suggests that the pathogenesis of systemic symptoms in influenza may be related to the induction of certain cytokines, particularly tumor necrosis factor α, interferon α, and interleukin 6, in respiratory secretions and in the bloodstream.

The host response to influenza infections involves a complex interplay of humoral antibody, local antibody, cell-mediated immunity, interferon, and other host defenses. Serum antibody responses, which can be detected by the second week after primary infection, are measured by a variety of techniques: hemagglutination inhibition (HI), complement fixation (CF), neutralization, enzyme-linked immunosorbent assay (ELISA), and antineuraminidase antibody assay. Antibodies directed against the hemagglutinin appear to be the most important mediators of immunity; in several studies, HI titers of ≥40 have been associated with protection from infection. Secretory antibodies produced in the respiratory tract are predominantly of the IgA class and also play a major role in protection against infection. Secretory antibody neutralization titers of ≥4 have also been associated with protection. A variety of cell-mediated immune responses, both antigen-specific and antigen-nonspecific, can be detected early after infection and depend on the prior immune status of the host. These responses include T-cell proliferative, T-cell cytotoxic, and natural killer cell activity. In humans, CD8+, HLA class I–restricted cytotoxic T cells (CTLs) are directed at conserved regions of internal proteins (NP, M, and polymerases) as well as against the surface proteins (H and N). Interferons can be detected in respiratory secretions shortly after the shedding of virus has begun, and rises in interferon titers coincide with decreases in virus shedding.

The host defense factors responsible for cessation of virus shedding and resolution of illness have not been defined specifically. Virus shedding generally stops within 2 to 5 days after symptoms first appear, at a time when serum and local antibody responses often are not detectable by conventional techniques (although antibody rises may be detected earlier by use of highly sensitive techniques, particularly in individuals with previous immunity to the virus). It has been suggested that interferon, cell-mediated immune responses, and/or nonspecific inflammatory responses all contribute to the resolution of illness. CTL responses may be particularly important in that regard.

**MANIFESTATIONS** Influenza has most frequently been described as an illness characterized by the abrupt onset of systemic symptoms, such as headache, feverishness, chills, myalgia, or malaise, and accompanying respiratory tract signs, particularly cough and sore throat. In many cases, the onset is so abrupt that patients can recall the precise time they became ill. However, the spectrum of clinical presentations is wide, ranging from a mild, afebrile respiratory illness similar to the common cold (with either a gradual or an abrupt onset) to severe prostration with relatively few respiratory signs and symptoms. In most of the cases that come to a physician’s attention, the patient has a fever, with temperatures of 38° to 41°C (100.4° to 105.8°F). A rapid temperature rise within the first 24 h of illness is generally followed by a gradual defervescence over a 2- to 3-day period, although, on occasion, fever may last for as long as a week. Patients report a feverish feeling and chilliness, but true rigors are rare. Headache, either generalized or frontal, is often particularly troublesome. Myalgias may involve any part of the body but are most common in the legs and lumbosacral area. Arthralgias may also develop.

Respiratory complaints often become more prominent as systemic symptoms subside. Many patients have a sore throat or persistent cough, which may last for a week or more and which is often accompanied by subternal discomfort. Ocular signs and symptoms include pain on moving the eyes, photophobia, and burning of the eyes.

Physical findings are usually minimal in cases of uncomplicated influenza. Early in the illness, the patient appears flushed and the skin is hot and dry, although diaphoresis and mottled extremities are sometimes evident, particularly in older patients. Examination of the pharynx may yield surprisingly unremarkable results despite a severe sore throat, but injection of the mucous membranes and postnasal discharge are apparent in some cases. Mild cervical lymphadenopathy may be noted, especially in younger individuals. The results of chest examination are largely negative in uncomplicated influenza, although ronchi, wheezes, and scattered rales have been reported with variable frequency in different outbreaks. Frank dyspnea, hyperpnea, cyanosis, diffuse rales, and signs of consolidation are indicative of pulmonary complications. Patients with apparently uncomplicated influenza have been reported to have a variety of mild ventilatory defects and increased alveolar-capillary diffusion gradients; thus, subclinical pulmonary involvement may be more frequent than is appreciated.

In uncomplicated influenza, the acute illness generally resolves over a 2- to 5-day period, and most patients have largely recovered in 1 week, although cough may persist for 1 to 2 weeks longer. In a significant minority (particularly the elderly), however, symptoms of weakness or lassitude (postinfluenza asthenia) may persist for several weeks and may prove troublesome for persons who wish to resume their full level of activity promptly. The pathogenetic basis for this asthenia is unknown, although pulmonary function abnormalities may persist for several weeks after uncomplicated influenza.

**COMPLICATIONS** Complications of influenza occur most frequently in patients >64 years old and in those with certain chronic disorders, including cardiac or pulmonary diseases, diabetes mellitus, hemoglobinopathies, renal dysfunction, and immunosuppression. Pregnancy in the second or third trimester also predisposes to complications with influenza. The most significant complication of influenza is pneumonia: “primary” influenza viral pneumonia, secondary bacterial pneumonia, or mixed viral and bacterial pneumonia. Primary influenza viral pneumonia is the least common but most severe of the pulmonary complications. It presents as acute influenza that does not resolve but instead progresses relentlessly, with persistent fever, dyspnea, and eventual cyanosis. Sputum production is generally scanty, but the sputum can contain blood. Few physical signs may be evident early in the illness. In more advanced cases, diffuse rales may be noted, and chest x-ray findings consistent with diffuse interstitial infiltrates and/or acute respiratory distress syndrome may be present. In such cases, arterial blood-gas determinations show marked hypoxia. Viral cultures of respiratory secretions and lung parenchyma, especially if samples are taken early in illness, yield high titers of virus. In fatal cases of primary viral pneumonia, histopathologic examination reveals a marked inflammatory reaction in the alveolar septa, with edema and infiltration by lymphocytes, macrophages, occasional plasma cells, and variable numbers of neutrophils. Fibrin thrombi in alveolar capillaries, along with necrosis and hemorrhage, have also been noted. Eosinophilic hyaline membranes can be found lining alveoli and alveolar ducts.

Primary influenza viral pneumonia has a predilection for individuals with cardiac disease, particularly those with mitral stenosis, but has also been reported in otherwise-healthy young adults as well as in older individuals with chronic pulmonary disorders. In some epidemics of influenza (notably those of 1918 and 1957), pregnancy increased the risk of primary influenza pneumonia. Subsequent epidemics of influenza have been associated with increased rates of hospitalization among pregnant women.

Secondary bacterial pneumonia follows acute influenza. Improvement of the patient’s condition over 2 to 3 days is followed by a reappearance of fever along with clinical signs and symptoms of bacterial pneumonia, including cough, production of purulent sputum, and physical and x-ray signs of consolidation. The most common bacterial pathogens in this setting are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*—organisms that can colonize the nasopharynx and that cause infection in the wake of changes in the pulmonary defense mechanisms. The etiology can often be determined by Gram’s staining and culture of an appropriately obtained sputum specimen. Secondary bacterial pneumonia occurs most frequently in
high-risk individuals with chronic pulmonary and cardiac disease and in elderly individuals. Patients with secondary bacterial pneumonia often respond to antibiotic therapy when it is instituted promptly.

Perhaps the most common pneumonic complications during outbreaks of influenza have mixed features of viral and bacterial pneumonia. Patients may experience a gradual progression of their acute illness or may show transient improvement followed by clinical exacerbation, with eventual manifestation of the clinical features of bacterial pneumonia. Sputum cultures may contain both influenza A virus and one of the bacterial pathogens described above. Patchy infiltrates or areas of consolidation may be detected by physical examination and chest x-ray. Patients with mixed viral and bacterial pneumonia generally have less widespread involvement of the lung than those with primary viral pneumonia, and their hemoglobin may not fall until some time after the administration of appropriate antibiotics. Mixed viral and bacterial pneumonia occurs primarily in patients with chronic cardiovascular and pulmonary diseases.

Other pulmonary complications associated with influenza include worsening of chronic obstructive pulmonary disease and exacerbation of chronic bronchitis and asthma. In children, influenza infection may present as croup. Sinusitis as well as otitis media (the latter occurring of chronic bronchitis and asthma. In children, influenza infection may primarily in patients with chronic cardiovascular and pulmonary diseases may present as group A streptococcal infection following acute illness or may show transient improvement followed by clinical exacerbation, with eventual manifestation of the clinical features of bacterial pneumonia. Sputum cultures may contain both influenza A virus and one of the bacterial pathogens described above. Patchy infiltrates or areas of consolidation may be detected by physical examination and chest x-ray. Patients with mixed viral and bacterial pneumonia generally have less widespread involvement of the lung than those with primary viral pneumonia, and their hemoglobin may not fall until some time after the administration of appropriate antibiotics. Mixed viral and bacterial pneumonia occurs primarily in patients with chronic cardiovascular and pulmonary diseases.

has been associated with nausea and vomiting, whose frequency can be reduced by drug administration with food. Resistant viruses emerge frequently during treatment with amantadine or rimantadine and can be transmitted among family members. The development of resistance appears to be infrequent with zanamivir or oseltamivir. Treatment of children is approved for amantadine and oseltamivir (≥1 year of age) and for zanamivir (≥7 years of age). Ribavirin is a nucleoside analogue with activity against influenza A and B viruses in vitro. It has been reported to be variably effective against influenza when administered as an aerosol but ineffective when administered orally. Its efficacy in the treatment of influenza A or B is unestablished.

Studies demonstrating the therapeutic efficacy of antiviral compounds in influenza have primarily involved young adults with uncomplicated disease; it is not known whether such compounds are effective in the treatment of influenza pneumonia or of other complications of influenza. Therapy for primary influenza pneumonia is directed at maintaining oxygenation and is most appropriately undertaken in an intensive care unit, with aggressive respiratory and hemodynamic support as needed. Bypass membrane oxygenators have been employed in this setting with variable results. When an acute respiratory distress syndrome develops, fluids must be administered cautiously, with close monitoring of blood gases and hemodynamic function. Antibacterial drugs should be reserved for the treatment of bacterial complications of acute influenza, such as secondary bacterial pneumonia. The choice of antibiotics should be guided by Gram’s staining and culture of appropriate specimens of respiratory secretions, such as sputum or transtracheal aspirates. If the etiology of a case of bacterial pneumonia is unclear from an examination of respiratory secretions, empirical antibiotics effective against the most common bacterial pathogens in this setting (S. pneumoniae, S. aureus, and H. influenzae) should be selected (Chaps. 119, 120, and 130).

**PROPHYLAXIS** The major public health measure for prevention of influenza has been the use of inactivated influenza vaccines derived from influenza A and B viruses that circulated during the previous influenza season. If the vaccine virus and the currently circulating viruses are closely related, 50 to 80% protection against influenza would be expected. Presently available inactivated vaccines have been highly purified and are associated with few reactions. Up to 5% of individuals experience low-grade fever and mild systemic symptoms 8 to 24 h after vaccination, and up to one-third develop mild redness or tenderness at the vaccination site. Since the vaccine is produced in eggs, individuals with true hypersensitivity to egg products either should be desensitized or should not be vaccinated. Although the 1976 swine influenza vaccine appears to have been associated with an increased frequency of Guillain-Barré syndrome, influenza vaccines administered since 1976 generally have not been. Possible exceptions were noted during the 1992–1993 and 1993–1994 influenza seasons, when there may have been an excess risk of Guillain-Barré syndrome of slightly more than one case per million among vaccine recipients. However, the overall health risk following influenza outweighs the potential risk associated with vaccination.

The U.S. Public Health Service recommends influenza vaccination for any individual >6 months of age who is at an increased risk for complications of influenza, as noted earlier (Table 171-2). Since commercially available vaccines are inactivated (“killed”), they may be administered safely to immunocompromised patients. Influenza vaccination is not associated with exacerbations of chronic nervous-system diseases such as multiple sclerosis. Vaccine should be administered early in the autumn before influenza outbreaks occur and should then be given annually to maintain immunity against the most current influenza virus strains.

Recently, an advisory committee of the U.S. Food and Drug Administration recommended approval of a live attenuated influenza vaccine that is administered by intranasal spray. The vaccine is generated by reassortment of currently circulating strains of influenza A and B virus with a cold-adapted, attenuated master strain. The cold-adapted vaccine is well tolerated and highly efficacious (92% protective) in young children; in one study, it provided protection against a circulating influenza virus that had drifted antigenically away from the vaccine strain. The committee recommended approval of the cold-adapted vaccine for use in healthy children and adults from 5 to 49 years of age.

Chemoprophylaxis with amantadine or rimantadine, at dosages of 100 to 200 mg/d, has efficacy rates of 70 to 100% against illness associated with influenza A infection. Chemoprophylaxis with oseltamivir (75 mg/d by mouth) or zanamivir (10 mg/d inhaled) has resulted in efficacy rates of 84 to 89% against influenza A and B. Chemoprophylaxis is most likely to be used for high-risk individuals who have not received influenza vaccine or in a situation where the vaccines previously administered are relatively ineffective because of antigenic changes in the circulating virus. During an outbreak, antiviral chemoprophylaxis can be administered simultaneously with inactivated vaccine, since the drugs do not interfere with an immune response to the vaccine. In fact, there is evidence that the protective effects of chemoprophylaxis and vaccine may be additive. However, concurrent administration of chemoprophylaxis and the live attenuated vaccine may interfere with the immune response to the latter. Chemoprophylaxis may also be employed to control nosocomial outbreaks of influenza. For prophylaxis, administration should be instituted promptly when influenza activity is detected and must be continued daily for the duration of the outbreak. Amantadine and rimantadine are approved for prophylaxis in adults and in children ≥1 year old; oseltamivir is approved for prophylaxis in adults and in children ≥13 years old.

The retroviruses, which make up a large family (Retroviridae), infect mainly vertebrates. They have a unique replication cycle whereby their genetic information is encoded by RNA rather than DNA. Retroviruses contain an RNA-dependent DNA polymerase (a reverse transcriptase) that directs the synthesis of a DNA form of the viral genome after infection of a host cell. The designation retrovirus denotes that information in the form of RNA is transcribed into DNA in the host cell—a sequence that overturned a central dogma of molecular biology: that information passes unidirectionally from DNA to RNA to protein. The observation that RNA was the source of genetic information in the causative agents of certain animal tumors led to a number of paradigm-shifting biologic insights regarding not only the direction of genetic-information passage but also the viral etiology of certain cancers and the concept of oncogenes as normal host genes scavenged and altered by a viral vector.

The family Retroviridae includes three subfamilies (Table 172-1): Oncovirinae, of which human T-cell lymphotropic virus (HTLV) type I is the most important in humans; Lentivirinae, of which HIV is the most important in humans; and Spumavirinae, the “foamy” viruses, named for the pathologic appearance of infected cells. A number of spumaviruses have been isolated from humans; however, they are not associated with any known disease and therefore are not discussed further in this chapter.

The wide variety of interactions of a retrovirus with its host range from completely benign events (e.g., silent carriage of endogenous retroviral sequences in the germ-line genome of many animal species) to rapidly fatal infections (e.g., exogenous infection with an oncogenic virus such as Rous sarcoma virus in chickens). The ability of retroviruses to acquire and alter the structure and function of host cell sequences has revolutionized our understanding of molecular carcinogenesis. The viruses can insert into the germ-line genome of the host cell and behave as a transposable or movable genetic element. They can activate or inactivate genes near the site of integration into the genome. They can rapidly alter their own genome by recombination and mutation under selective environmental stimuli.

Most human viral diseases occur as a consequence of either tissue destruction by the virus itself or the host’s response to the virus. Although these mechanisms are operative in retroviral infections, retroviruses have additional mechanisms of inducing disease, including the malignant transformation of an infected cell and the induction of an immunodeficiency state that leads to opportunistic diseases (infections and neoplasms; Chap. 173).

### Structure and Life Cycle

Despite the wide range of biologic consequences of retroviral infection, all retroviruses are similar in structure, genome organization, and mode of replication. Retroviruses are 70 to 130 nm in diameter and have a lipid-containing envelope surrounding an icosahedral capsid with a dense inner core. The core contains two identical copies of the single-strand RNA genome. The RNA molecules are 8 to 10 kb long and are complexed with reverse transcriptase and tRNA. Other viral proteins, such as integrase, are also components of the virion particle. The RNA has features usually found in mRNA: a cap site at the 5′ end of the molecule, which is important in the initiation of mRNA translation, and a polyadenylation site at the 3′ end, which influences mRNA turnover (i.e., messages with shorter polyA tails turn over faster than messages with longer polyA tails). However, the retroviral RNA is not translated; instead it is transcribed into DNA. The DNA form of the retroviral genome is called a provirus.

The replication cycle of retroviruses proceeds in two phases (Fig. 172-1). In the first phase, the virus enters the cytoplasm after binding to a specific cell-surface receptor (with HIV, a cell-surface co-receptor is also utilized for binding and entry); the viral RNA and reverse transcriptase synthesize a double-strand DNA version of the RNA template; and the provirus moves into the nucleus and integrates into the host cell genome. This proviral integration is permanent. Although some animal retroviruses integrate into a single specific site of the host genome, the integration of the provirus does not, in general, lead to the malignant transformation of the cell. The integration of the provirus into the germ-line genome of the host cell is important in the pathogenesis of retroviral diseases.

* The Oncovirinae were originally grouped into types A–D on the basis of morphologic features (size, core location, budding) under electron microscopy; however, this system has been replaced by groupings based on relationships of genome structure and sequence.

**Note:** HTLV, human T-lymphotropic virus; BLV, bovine leukemia virus.
In the latter, the LTR sequences are repeated in both the 5′ and the 3′ terminus of the virus. The LTRs contain sequences involved in initiating the expression of the viral proteins, the integration of the provirus, and the polyadenylation of viral RNAs. The primer binding site, which is critical for the initiation of reverse transcription, and the viral packaging sequences are located outside the LTR sequences. The coding regions include the gag (group-specific antigen, core protein), pol (RNA-dependent DNA polymerase), and env (envelope) genes. The gag gene encodes a precursor polyprotein that is cleaved to form three to five capsid proteins; a fraction of the Gag precursor proteins also contain a protease responsible for cleaving the Gag and Pol polyproteins. A Gag-Pol polyprotein gives rise to the protease that is responsible for cleaving the Gag-Pol polyprotein. The pol gene encodes three proteins: reverse transcriptase, integrase, and the protease. The reverse transcriptase functions to copy the viral RNA into the double-strand DNA provirus, which can attach to the host cell DNA via the action of integrase. The protease functions to cleave the Gag-Pol polyprotein into smaller protein products. The env gene encodes the envelope glycoproteins: one protein that binds to specific surface receptors and determines what cell types can be infected and a smaller transmembrane protein that anchors the complex to the envelope. The cartoon in Fig. 172-3 shows how the retroviral gene products make up the virus structure.

HTLVs have a region between env and the 3′ LTR that encodes at least two proteins in overlapping reading frames: Tax, a 40-kDa protein that does not bind to DNA but induces the expression of host cell transcription factors that alter host cell gene expression; and Rex, a 27-kDa protein that regulates the expression of viral mRNAs. These two proteins are produced from messages that are similar but that are spliced differently from overlapping but distinct exons.

The lentiviruses in general, and HIV-1 and -2 in particular, contain a larger genome than other pathogenic retroviruses. They contain an untranslated region between pol and env that encodes portions of several proteins, varying with the reading frame into which the mRNAs are spliced. Tat is a 14-kDa protein that augments the expression of the viral RNAs. The Nef protein is necessary for the proper assembly of the HIV nucleoprotein core in many types of cells; without Nef, proviral DNA is not efficiently produced in these infected cells. Vpr, Vpu (HIV-1 only), and Vpx (HIV-2 only) are viral proteins encoded by translation of the same message in different reading frames. As noted above, oncogenic retroviruses depend on cell proliferation for their replication; lentiviruses can infect nondividing cells, largely owing to effects mediated by Vpr. Vpr facilitates transport of the provirus into the nucleus and can induce other cellular changes, such as G1 growth arrest and differentiation of some target cells. Vpxp is structurally related to Vpr, but its functions are not fully defined. Vpu promotes the degradation of CD4 in the endoplasmic reticulum and stimulates the release of virions from infected cells.

Retroviruses can be either exogenously acquired by infection with a virion capable of replication or transmitted in the germ line as endogenous virus. Endogenous retroviruses are often replication-defective. The human genome contains endogenous retroviral sequences, but there are no known replication-competent endogenous retroviruses in humans.

In general, viruses that contain only the gag, pol, and env genes either are not pathogenic or take a long time to induce disease; these observations indicate the importance of the other regulatory genes in viral disease pathogenesis. The pathogenesis of neoplastic transformation by retroviruses relies on the chance integration of the provirus at a spot in the genome that will result in the expression of a cellular gene (proto-oncogene) that becomes transforming by virtue of its unregulated expression. For example, avian leukemia virus causes B cell leukemia by inducing the expression of myc. Some retroviruses possess several integrated endogenous retroviruses, and these viral oncogenes are capable of transforming the infected host cell. Viruses that have oncogenes often have lost a portion of their
genome that is required for replication. Such viruses need helper viruses to reproduce, a feature that may explain why these acute transforming retroviruses are rare in nature. All human retroviruses identified to date are exogenous and are not acutely transforming (i.e., they lack a transforming oncogene).

These remarkable properties of retroviruses have led to experimental efforts to use them as vectors to insert specific genes into particular cell types, a process known as gene therapy or gene transfer. The process could be used to repair a genetic defect or to introduce a new property that could be used therapeutically; for example, a gene (e.g., thymidine kinase) that would make a tumor cell susceptible to killing by a drug (e.g., ganciclovir) could be inserted. One source of concern about the use of retroviral vectors in humans is that replication-competent viruses might rescue endogenous retroviral replication, with unpredictable results. This concern is not merely hypothetical: The detection of proteins encoded by endogenous retroviral sequences on the surface of cancer cells implies that the genetic events leading to the cancer were able to activate the synthesis of these usually silent genes.

**HUMAN T-CELL LYMPHOTROPIC VIRUS**

HTLV-I was isolated in 1980 from a T-cell lymphoma cell line from a patient originally thought to have cutaneous T cell lymphoma. Later it became clear that the patient had a distinct form of lymphoma (originally reported in Japan) called adult T-cell leukemia/lymphoma (ATL). Serologic data have determined that HTLV-I is the cause of at least two important diseases: ATL and tropical spastic paraparesis, also called HTLV-I-associated myelopathy (HAM). HTLV-I may also play a role in infective dermatitis and uveitis syndromes.

Two years after the isolation of HTLV-I, HTLV-II was isolated from a patient with an unusual form of hairy cell leukemia that affected T cells. Although early epidemiologic studies of HTLV-II failed to reveal a consistent disease association, more recent studies suggest an association of HTLV-II with human disease (see “Associated Diseases” under “Features of HTLV-II Infection,” below), particularly among injection drug users.

**BIOLOGY AND MOLECULAR BIOLOGY**

Because the biology of HTLV-I and that of HTLV-II are similar, the following discussion will focus on HTLV-I.

The cellular receptor for HTLV-I has not yet been identified, but it maps to chromosome 17. Generally, only T cells are productively infected, but infection of B cells and other cell types is occasionally detected. The most common outcome of HTLV-I infection is latent carriage of randomly integrated provirus in CD4+ T cells. HTLV-I does not contain an oncogene and does not insert into a unique site in the genome. Indeed, most infected cells express no viral gene products. The only viral gene product that is routinely expressed in tumor cells transformed by HTLV-I is tax, and even tax is not expressed in the tumor cells of many ATL patients. Cells transformed in vitro, by contrast, actively transcribe HTLV-I RNA and produce infectious virions. Most HTLV-I-transformed cell lines are the result of the infection of a normal host T cell in vitro. It is difficult to establish cell lines derived from authentic ATL cells.

Although tax does not itself bind to DNA, it does induce the expression of a wide range of host cell gene products, including transcription factors (especially c-rel, ets-1 and -2, and members of the fos/jun family), cytokines (e.g., interleukin (IL) 2, granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor (TNF)), and membrane proteins and receptors [major histocompatibility (MHC) molecules and IL-2 receptor α]. The genes activated by tax are generally controlled by transcription factors of the c-rel and cyclic AMP response element binding (CREB) protein families. It is unclear how this induction of host gene expression leads to neoplastic transformation: tax can interfere with G1 and mitotic cell-cycle checkpoints, block apoptosis, and promote antigen-independent T cell proliferation. Induction of a cytokine-autocrine loop has been proposed; however, IL-2 is not the crucial cytokine. The involvement of IL-4, IL-7, and IL-15 has been proposed.

In light of the irregular expression of tax in ATL cells, it has been suggested that tax is important in the early phases of transformation.
but is not essential for the maintenance of the transformed state. As is clear from the epidemiology of HTLV-I infection, transformation of an infected cell is a rare event and may depend on heterogeneous second, third, or fourth genetic hits. No consistent chromosomal abnormalities have been described in ATL; however, individual cases with p53 mutations and translocations involving the T cell receptor genes on chromosome 14 have been reported. Tax may repress certain DNA repair enzymes, permitting the accumulation of genetic damage that would normally be repaired. However, the molecular pathogenesis of HTLV-I-induced neoplasia is not fully understood.

FEATURES OF HTLV-I INFECTION

**Epidemiology**

HTLV-I infection is transmitted in at least three ways: from mother to child, especially in breast milk; through sexual activity, more commonly from men to women; and through the blood—via contaminated transfusions or contaminated needles. The virus is most commonly transmitted perinatally. Compared with HIV, which can be transmitted in cell-free form, HTLV-I is less infectious, and its transmission usually requires cell-to-cell contact.

HTLV-I is endemic in southwestern Japan and Okinawa, where >1 million persons are infected. Antibodies to HTLV-I are present in the serum of up to 35% of Okinawans, 10% of residents of the Japanese island of Kyushu, and <1% of persons in nonendemic regions of Japan. Despite this high prevalence of infection, only ~500 cases of ATL are diagnosed in this area each year. Clusters of infection have been noted in other areas of the Orient, such as Taiwan; in the Caribbean basin, including northeastern South America; in central Africa; in Italy; in Israel; in the Arctic; and in the southeastern part of the United States.

A progressive spastic or ataxic myelopathy that develops in an individual who is HTLV-I positive (i.e., who has serum antibodies to HTLV-I) is likely to be due to direct nervous system infection with the virus; a similar disorder may result from infection with HIV or HTLV-II. In rare instances, patients with HAM have a stronger immune response to the virus. Among patients with HAM, 20% of patients acquire HTLV-I from contaminated blood products.

The cumulative lifetime risk of developing ATL is 3% among HTLV-I-infected patients (the risk is three times greater in men than in women); a similar cumulative risk is projected for HAM. The distribution of the two diseases overlaps the distribution of HTLV-I, with >95% of affected patients showing serologic evidence of HTLV-I infection. The latent period between infection and the emergence of disease is 20 to 30 years for ATL. For HAM, the median latency period is ~3.3 years (range, 4 months to 30 years). The development of ATL is rare among persons infected by blood products; however, ~20% of patients with HAM acquire HTLV-I from contaminated blood.

**Associated Diseases**

**ATL**

Four clinical types of ATL are described: acute, lymphomatous, chronic, and smoldering. All of these tumors are monoclonal proliferations of CD4+ post-thymic T cells with clonal proviral integrations and clonal T cell receptor gene rearrangements.

About 60% of patients who develop malignancy have classic acute ATL, which is characterized by a short clinical prodrome (~2 weeks between the first symptoms and the diagnosis) and an aggressive natural history (median survival period, 6 months). The clinical picture is dominated by rapidly progressive skin lesions, pulmonary involvement, hypercalcemia, and lymphocytosis with cells containing lobulated or “flower-shaped” nuclei (see Fig. 97-10). The malignant cells have monoclonal proviral integrations and express CD4, CD3, and CD25 (low-affinity IL-2 receptors) on their surface. Serum levels of CD25 can be used as a tumor marker. Anemia and thrombocytopenia are rare. The skin lesions may be difficult to distinguish from those in mycosis fungoides. Lytic bone lesions, which are common, do not contain tumor cells but rather are composed of osteolytic cells, usually without osteoblastic activity. Despite the leukemic picture, bone marrow involvement is patchy in most cases.

The hypercalcemia of ATL is multifactorial; the tumor cells produce osteoclast-activating factors (TNF-α, IL-1, lymphotxin) and can also produce a parathyroid hormone—like molecule. Affected patients have an underlying immunodeficiency that makes them susceptible to opportunistic infections similar to those seen in patients with AIDS (Chap. 173). The pathogenesis of the immunodeficiency is unclear. Pulmonary infiltrates in ATL patients reflect leukemic infiltration half the time and opportunistic infections with organisms such as *Pneumocystis* and other fungi the other half. Gastrointestinal symptoms are nearly always related to opportunistic infection. *Strongyloides stercoralis* is a gastrointestinal parasitic infection that has a pattern of exacerbation and regression similar to that of HTLV-I. HTLV-I-infected persons also infected with the parasite may develop ATL more often or more rapidly than those without *Strongyloides* infections. Serum concentrations of lactate dehydrogenase (LDH) and alkaline phosphatase are often elevated. About 10% of patients have leptomeningeal involvement leading to weakness, altered mental status, paresthesia, and/or headache. Unlike other forms of central nervous system (CNS) lymphoma, ATL may be accompanied by normal CSF protein levels. The diagnosis depends on finding ATL cells in the CSF (Chap. 97).

Patients with the chronic form of ATL generally have normal serum levels of calcium and LDH and no involvement of the CNS, bone, or gastrointestinal tract. The median duration of survival for these patients is 2 years. In some cases, chronic ATL progresses to the acute form of the disease.

Fewer than 5% of patients have the smoldering form of ATL. In this form, the malignant cells have monoclonal proviral integration; <5% of peripheral blood cells exhibit typical morphologic abnormalities; hypercalcemia, adenopathy, and hepatosplenomegaly do not develop; the CNS, the bones, and the gastrointestinal tract are not involved; and skin and pulmonary lesions may be present. The median survival period of this small subset of patients appears to be ≥5 years.

**HAM (TROPICAL SPASTIC PARAPARESIS)**

In contrast to ATL, in which there is a slight predominance of male patients, HAM affects females disproportionately. HAM resembles multiple sclerosis in certain ways (Chap. 359). The onset is insidious. Symptoms include weakness or stiffness in one or both legs, back pain, and urinary incontinence. Sensory changes are usually mild, but peripheral neuropathy may develop. The disease generally takes the form of slowly progressive and unremitting thoracic myelopathy; one-third of patients are bedridden within 10 years of diagnosis, and one-half are unable to walk unassisted by this point. Patients display spastic paraparesis or paraplegia with hyperreflexia, ankle clonus, and extensor planter responses. Cognitive function is usually spared; cranial nerve abnormalities are unusual.

Magnetic resonance imaging (MRI) reveals lesions in both the white matter and the paraventricular regions of the brain as well as in the spinal cord. Pathologic examination of the spinal cord shows symmetric degeneration of the lateral columns, including the corticospinal tracts; some cases involve the posterior columns as well. The spinal meninges and cord parenchyma contain an inflammatory infiltrate with myelin destruction.

HTLV-I is not usually found in cells of the CNS but may be detected in a small population of lymphocytes present in the CSF. In endemic HTLV-I receptor is greater in HAM than in ATL, and patients with HAM have a stronger immune response to the virus. Antibodies to HTLV-I are present in the serum and appear to be produced...
in the CSF of HAM patients, where titers are often higher than in the serum. The pathophysiology of HAM may involve the induction of autoimmune destruction of neural cells by T cells with specificity for viral components such as Tax or Env proteins. One theory is that susceptibility to HAM may be related to the presence of human leukocyte antigen (HLA) alleles capable of presenting viral antigens in a fashion that leads to autoimmunity. Insufficient data are available to confirm an HLA association.

It is unclear what factors influence whether HTLV-I infection will cause disease and, if it does, whether it will induce a neoplasm (ATL) or an autoimmune disorder (HAM). Differences in viral strains, in the susceptibility of particular MHC haplotypes, and in the route of HTLV-I infection, in the viral load, and in the nature of the HTLV-I-related immune response are putative factors, but few definitive data are available.

**OTHER PUTATIVE HTLV-I-RELATED DISEASES** In areas where HTLV-I is endemic, diverse inflammatory and autoimmune diseases have been attributed to the virus, including uveitis, dermatitis, pneumonitis, rheumatoid arthritis, and polymyositis. However, a causal relationship between HTLV-I and these illnesses has not been rigorously established.

**Prevention** Women in endemic areas should not breast-feed their children, and blood donors should be screened for serum antibodies to HTLV-I. As in the prevention of HIV infection, the practice of safe sex and the avoidance of needle sharing are important.

**TREATMENT**

For the small number of patients who develop HTLV-I-related disease, therapies are not curative. In patients with the acute and lymphomatous types of ATL, the disease progresses rapidly. Hypercalcemia is generally controlled by glucocorticoid administration and cytotoxic therapy directed against the neoplasm. The tumor is highly responsive to combination chemotherapy that is employed against other forms of lymphoma; however, patients are susceptible to overwhelming bacterial and opportunistic infections, and ATL relapses within 4 to 10 months after remission in most patients. The combination of interferon α and zidovudine may extend survival. Because viral replication is not clearly associated with ATL progression, zidovudine is probably effective through its cytotoxic effects (as a chain-terminating thymidine analogue) rather than its antiviral effects. An experimental approach using an yttrium 90–labeled or toxin-conjugated antibody to the IL-2 receptor appears promising but is not widely available. Patients with the chronic or smoldering form of ATL may be managed with an expectant approach: Treat any infections, and watch and wait for signs of progression to acute disease.

Patients with HAM may obtain some benefit from the use of glucocorticoids to reduce inflammation. Antiretroviral regimens have not been effective. In one study, danazol (200 mg three times daily) produced significant neurologic improvement in five of six treated patients, with resolution of urinary incontinence in two cases, decreased spasticity in three, and restoration of the ability to walk after confinement to a wheelchair in two. Physical therapy and rehabilitation are important components of management.

**FEATURES OF HTLV-II INFECTION**

**Epidemiology** HTLV-II is endemic in certain Native American tribes and in Africa. It is generally considered to be a New World virus that was brought from Asia to the Americas 10,000 to 40,000 years ago during the migration of infected populations across the Bering land bridge.

The mode of transmission of HTLV-II is probably the same as that of HTLV-I (see above). HTLV-II may be less readily transmitted sexually than HTLV-I.

Studies of large cohorts of injection drug users with serologic assays that reliably distinguish HTLV-I from HTLV-II indicate that the vast majority of HTLV-positive subjects are infected with HTLV-II. The seroprevalence of HTLV in a cohort of 7841 injection drug users from drug treatment centers in Baltimore, Chicago, Los Angeles, New Jersey (Asbury Park and Trenton), New York City (Brooklyn and Harlem), Philadelphia, and San Antonio was 20.9%, with >97% of cases due to HTLV-II. The seroprevalence of HTLV-II was higher in the Southwest and the Midwest than in the Northeast. In contrast, the seroprevalence of HIV-I was higher in the Northeast than in the Southwest or the Midwest. Approximately 3% of the cohort members were infected with both HTLV-II and HIV-I. The seroprevalence of HTLV-II increased linearly with age. Women were significantly more likely to be infected with HTLV-II than were men; the virus is thought to be more efficiently transmitted from male to female than from female to male.

**Associated Diseases** Although HTLV-II was isolated from a patient with a T cell variant of hairy cell leukemia, this virus has not been consistently associated with a particular disease and in fact has been thought of as “a virus searching for a disease.” However, evidence is accumulating that HTLV-II may play a role in certain neurologic, hematologic, and dermatologic diseases. These data require confirmation, particularly in light of the previous confusion regarding the relative prevalences of HTLV-I and HTLV-II among injection drug users.

**Prevention** Avoidance of needle sharing, safe-sex practices, screening of blood (by assays for HTLV-I, which also detect HTLV-II), and avoidance of breast-feeding by infected women are important principles in the prevention of spread of HTLV-II.

**HUMAN IMMUNODEFICIENCY VIRUS**

HIV-1 and HIV-2 are members of the lentivirus subfamily of Retroviridae and are the only lentviruses known to infect humans. The lentiviruses are slow-acting by comparison with viruses that cause acute infection (e.g., influenza virus) but not by comparison with other retroviruses. The features of acute primary infection with HIV resemble those of more classic acute infections. The characteristic chronicity of HIV disease is consistent with the designation lentivirus. →For a detailed discussion of HIV, see Chap. 173.

**FURTHER READING**

AIDS was first recognized in the United States in the summer of 1981, when the U.S. Centers for Disease Control and Prevention (CDC) reported the unexplained occurrence of *Pneumocystis carinii* pneumonia in five previously healthy homosexual men in Los Angeles and of Kaposi’s sarcoma (KS) in 26 previously healthy homosexual men in New York and Los Angeles. Within months, the disease became recognized in male and female injection drug users (IDUs) and soon thereafter in recipients of blood transfusions and in hemophiliacs. As the epidemiologic pattern of the disease unfolded, it became clear that a microbe transmissible by sexual (homosexual and heterosexual) contact and blood or blood products was the most likely etiologic agent of the epidemic.

In 1983, human immunodeficiency virus (HIV) was isolated from a patient with lymphadenopathy, and by 1984 it was demonstrated clearly to be the causative agent of AIDS. In 1985, a sensitive enzyme-linked immunosorbent assay (ELISA) was developed, which led to an appreciation of the scope and evolution of the HIV epidemic at first in the United States and other developed nations and ultimately among developing nations throughout the world (see below). The staggering worldwide growth of the HIV pandemic has been matched by an explosion of information in the areas of HIV virology, pathogenesis (both immunologic and virologic) and treatment of HIV disease, treatment and prophylaxis of the opportunistic diseases associated with HIV infection, and vaccine development. The information flow related to HIV disease is enormous and continues to expand, and it has become almost impossible for the health care specialist to stay abreast of the literature. The purpose of this chapter is to present the most current information available on the scope of the epidemic; on its pathogenesis, treatment, and prevention; and on prospects for vaccine development. Above all, the aim is to provide a solid scientific basis and practical clinical guidelines for a state-of-the-art approach to the HIV-infected patient.

**DEFINITION**

With the identification of HIV in 1983 and its proof as the etiologic agent of AIDS in 1984, and with the availability of sensitive and specific diagnostic tests for HIV infection, the case definition of AIDS has undergone several revisions over the years. The current CDC classification system for HIV-infected adolescents and adults categorizes persons on the basis of clinical conditions associated with HIV infection and CD4+ T lymphocyte counts. The system is based on three ranges of CD4+ T lymphocyte counts and three clinical categories and is represented by a matrix of nine mutually exclusive categories (Tables 173-1 and 173-2). Using this system, any HIV-infected individual with a CD4+ T cell count of <200/μL has AIDS by definition, regardless of the presence of symptoms or opportunistic diseases (Table 173-1). Once individuals have had a clinical condition in category B, their disease cannot again be classified as category A, even if the condition resolves; the same holds true for category C in relation to category B.

The definition of AIDS is indeed complex and comprehensive; however, the clinician should not focus on whether AIDS is present but should view HIV disease as a spectrum ranging from primary infection, with or without the acute syndrome, to the asymptomatic stage, to advanced disease (see below). The definition of AIDS was established not for the practical care of patients but for surveillance purposes.

**Etiologic Agent**

The etiologic agent of AIDS is HIV, which belongs to the family of human retroviruses (Retroviridae) and the subfamily of lentiviruses (Chap. 172). Nononcogenic lentiviruses cause disease in other animal species, including sheep, horses, goats, cattle, cats, and monkeys. The four recognized human retroviruses belong to two distinct groups: the human T lymphotropic viruses (HTLV) I and HTLV-II, which are transforming retroviruses; and the human immunodeficiency viruses, HIV-1 and HIV-2, which are cytopathic viruses (Chap. 172). The most common cause of HIV disease throughout the world, and certainly in the United States, is HIV-1, which comprises several subtypes with different geographic distributions (see below). HIV-2 was first identified in 1986 in West African patients and was originally confined to West Africa. However, a number of cases that can be traced to West Africa or to sexual contacts with West Africans have been identified throughout the world. Both HIV-1 and HIV-2 are zoonotic infections. HIV-2 is more closely related phylogenetically to the simian immunodeficiency virus (SIV) found in sooty mangabeys than it is to HIV-1. HIV-1 likely originated from the Pan troglodytes troglodytes species of chimpanzees in whom the virus had co-evolved over centuries. The taxonomic relationship among primate lentiviruses is shown in Fig. 173-1.

**Morphology of HIV**

Electron microscopy shows that the HIV virion is an icosahedral structure (Fig. 173-2A) containing numerous external spikes formed by the two major envelope proteins, the external gp120 and the transmembrane gp41. The virion buds from the surface of the infected cell and incorporates a variety of host proteins, including major histocompatibility complex (MHC) class I and II antigens (Chap. 296), into its lipid bilayer. The structure of HIV-1 is schematically diagrammed in Fig. 173-2B (Chap. 172).

**Replication Cycle of HIV**

HIV is an RNA virus whose hallmark is the reverse transcription of its genomic RNA to DNA by the enzyme reverse transcriptase. The replication cycle of HIV begins with the high-affinity binding of the gp120 envelope protein via a portion of its V1 region near the N terminus to its receptor on the host cell surface, the CD4 molecule (Fig. 173-3). The CD4 molecule is a 55-kDa protein found predominantly on a subset of T lymphocytes that are responsible for helper or inducer function in the immune system (Chap. 295). It is also expressed on the surface of monocytes/macrophages and dendritic/Langerhans cells. Once gp120 binds to CD4, the gp120 undergoes a conformational change that facilitates binding to one of a group of co-receptors. The two major co-receptors for HIV-1 are CCR5 and CXCR4. Both receptors belong to the family of seven-transmembrane-domain G protein–coupled cellular receptors, and the use of one or the other or both receptors by the virus for entry into the cell is an important determinant of the cellular tropism of the virus (see below for details). Certain dendritic cells express a diversity of C-type lectin receptors on their surface, one of which is called DC-SIGN, that bind with high affinity to the HIV gp120 envelope protein, allowing the dendritic cell to facilitate the binding of virus to the CD4 + T cell upon engagement of dendritic cells with CD4 + T cells. Following binding of the envelope protein to the CD4 molecule, the conformation of the viral envelope changes dramatically, and fusion with the host cell membrane occurs via the newly exposed gp41 molecule penetrating the plasma membrane of the target cell and then coiling upon itself to bring the virion and target cell together. Following fusion (Fig. 173-4), the HIV genomic RNA is uncoated and internalized into the target cell (Fig. 173-3). The reverse transcriptase enzyme, which is contained in the infecting virion, then catalyzes the reverse transcription of the genomic RNA into double-strand DNA. The DNA translocates to the nucleus, where it is integrated in a somewhat, but not completely, random fashion into the host cell chromosomes through the action of another viral-encoded enzyme, integrase. Sites of HIV integration into the nuclear DNA are preferential for active genes and regional hotspots. This provirus may remain transcriptionally inactive (latent) or it may manifest varying levels of gene expression, up to active production of virus.

Cellular activation plays an important role in the life cycle of HIV and is critical to the pathogenesis of HIV disease (see below). Following initial binding and internalization of virions into the target cell, incompletely reverse-transcribed DNA intermediates are labile in quiescent cells and will not integrate efficiently into the host cell genome.
unless cellular activation occurs shortly after infection. Furthermore, some degree of activation of the host cell is required for the initiation of transcription of the integrated proviral DNA into either genomic RNA or mRNA. This latter process may not necessarily be associated with the obvious expression of the classic cell surface markers of activation. In this regard, activation of HIV expression from the latent state depends on the interaction of a number of cellular and viral factors. Following transcription, HIV mRNA is translated into proteins that undergo modification through glycosylation, myristylation, phosphorylation, and cleavage. The viral particle is formed by the assembly of HIV proteins, enzymes, and genomic RNA at the plasma membrane of the cells. Budding of the progeny virion occurs through specialized regions in the lipid bilayer of the host cell membrane known as lipid rafts, where the core acquires its external envelope (Chap. 172). The virally encoded protease then catalyzes the cleavage of the gag-pol precursor (see below) to yield the mature virion. Progression through the virus replication cycle is profoundly influenced by a variety of viral regulatory gene products. Likewise, each point in the replication cycle of HIV is a real or potential target for therapeutic intervention (see below). Thus far, the reverse transcriptase and protease enzymes have proven clinically to be susceptible to pharmacologic disruption (see below). Recently, inhibitors of virus–target cell fusion have shown therapeutic promise, and inhibitors of the viral enzyme integrase are in clinical trials.

**HIV GENOME**  Figure 173-5 illustrates the arrangement of the HIV genome schematically. Like other retroviruses, HIV-1 has genes that encode the structural proteins of the virus: *gag* encodes the proteins that form the core of the virion (including p24 antigen); *pol* encodes the enzymes responsible for reverse transcription and integration; and *env* encodes the envelope glycoproteins. However, HIV-1 is more complex than other retroviruses, particularly those of the nonprimate group, in that it also contains at least six other genes (*tat, rev, nef, vif, vpr, and vpu*), which code for proteins involved in the regulation of gene expression (Chap. 172). Several of these proteins are felt to play a role in the pathogenesis of HIV disease; their various functions are listed in Fig. 173-5. Flanking these genes are the long terminal repeats (LTRs), which contain regulatory elements involved in gene expression (Fig. 173-5). The major difference between the genomes of HIV-1 and HIV-2 is the fact that HIV-2 lacks the *vpr* gene and has a *vpx* gene not contained in HIV-1.

**MOLECULAR HETEROGENEITY OF HIV-1**  Molecular analyses of various HIV isolates reveal sequence variations over many parts of the viral genome. For example, in different isolates, the degree of difference in the coding sequences of the viral envelope protein ranges from a few percent (very close) to 50%. These changes tend to cluster in hypervariable regions. HIV can evolve by several means, including simple base substitution, insertions and deletions, recombination, and gain and loss of glycosylation sites. The balance of immune pressure and functional constraints on proteins influences the regional level of variation within proteins. For example, Envelope, which is exposed on the surface of the virion and is under immune selective pressure from both antibodies and cytolytic T lymphocytes, is extremely variable, with clusters of mutations in hypervariable domains. In contrast, Reverse Transcriptase, with important enzymatic functions, is relatively conserved, particularly around the active site. The extraordinary variability of HIV-1 is in marked contrast to the relative stability of HTLV-I and -II.

There are three groups of HIV-1: group M (major), which is responsible for most of the infections in the world; group O (outlier), a relatively rare viral form found originally in Cameroon, Gabon, and France; and group N first identified in a Cameroonian woman with AIDS; only a few cases of the latter have been identified. Among primate lentiviruses, HIV-1 is most closely related to viruses isolated from chimpanzees. The M group comprises nine subtypes, or _clades_, designated A, B, C, D, F, G, H, J, and K, as well as a growing number of major circulating recombinant forms (CRFs). These CRFs range from highly prevalent forms such as the AE virus, CRF 01, which is predominant in southeast Asia and often referred to simply as E, despite the fact that the parental E virus has never been found, and AG from west and central Africa, to a large number of CRFs that are more or less rare. The subtypes and CRFs create the major lineages of the M group of HIV-1. The picture has been complicated somewhat when it was found that some subtypes are not equidistant from one another, while others contained sequences so diverse that they could not properly be considered to be the same subtype. Thus, the sub-subtype was introduced, and subtypes A and F are now subdivided into A1 and A2, F1 and F2. It has also been argued that subtypes B and D are really too close to be separate subtypes and should be considered sub-subtypes; it was decided, however, not to increase the confusion by renaming the clades (Fig. 173-6).

The global patterns of HIV-1 variation likely result from accidents of viral trafficking. Subtype B viruses, which now differ by up to 17% in their *env* coding sequences, are the overwhelmingly predominant viruses seen in the United States, Canada, certain countries in South America, western Europe, and Australia. Other subtypes are also present in these countries to varying degrees. It is thought that, purely by chance, subtype B was seeded into the United States in the late 1970s, thereby establishing an overwhelming founder effect. Subtype C viruses (of the M group) are the most common form worldwide; many countries have cocirculating viral subtypes that are giving rise
to CRFs. Figure 173-7 schematically diagrams the worldwide distribution of HIV-1 subtypes by region. The predominant subtype in Europe and the Americas is subtype B. In Africa, >75% of strains recovered to date have been of subtypes A, C, and D, with C being the most common. In Asia, HIV-1 isolates of the CRF01 (AE) lineage and subtypes C and B predominate. CRF01 (AE) accounts for most infections in southeast Asia, while subtype C is prevalent in India (see “HIV Infection and AIDS Worldwide,” below). Sequence analyses of HIV-1 isolates from infected individuals indicate that recombination among viruses of different clades likely occurs as a result of infection of an individual with viruses of more than one subtype, particularly in geographic areas where subtypes overlap.

**TRANSMISSION**

HIV is transmitted by both homosexual and heterosexual contact; by blood and blood products; and by infected mothers to infants either intrapartum, perinatally, or via breast milk. After 20 years of scrutiny, there is no evidence that HIV is transmitted by casual contact or by the virus can be spread by insects, such as by a mosquito bite. 

**SEXUAL TRANSMISSION**

HIV infection is predominantly a sexually transmitted disease (STD) worldwide. Although in the United States ~42% of new HIV infections are among men who have sex with men and ~33% of new HIV infections are by heterosexual transmission, the most common mode of infection worldwide, particularly in developing countries, is clearly heterosexual transmission. Furthermore, the yearly incidence of new cases of AIDS attributed to heterosexual transmission of HIV is steadily increasing in the United States, mainly among minorities, particularly women in minority groups (Fig. 173-8).

HIV has been demonstrated in seminal fluid both within infected mononuclear cells and in the cell-free state. The virus appears to concentrate in the seminal fluid, particularly in situations where there are increased numbers of lymphocytes and monocytes in the fluid, as in genital inflammatory states such as urethritis and epididymitis, conditions closely associated with other STDs (see below). The virus has also been demonstrated in cervical smear and vaginal fluid. There is a strong association of transmission of HIV with receptive anal intercourse, probably because only a thin, fragile rectal mucosal membrane separates the deposited semen from potentially susceptible cells in and beneath the mucosa and trauma may be associated with anal intercourse. Anal douching and sexual practices that traumatize the rectal mucosa also increase the likelihood of infection. It is likely that anal intercourse provides at least two modalities of infection: (1) direct inoculation into blood in cases of traumatic tears in the mucosa; and (2) infection of susceptible target cells, such as Langerhans cells, in the mucosal layer in the absence of trauma (see below). Although the vaginal mucosa is several layers thicker than the rectal mucosa and less likely to be traumatized during intercourse, it is clear that the virus can be transmitted to either partner through vaginal intercourse. In a 10-year prospective study in the United States of heterosexual transmission of HIV, male-to-female transmission was approximately eight times more efficient than female-to-male transmission. This difference may be due in part to the prolonged exposure to infected seminal fluid of the vaginal and cervical mucosa, as well as the endometrium (when

The scale bar at the bottom indicates the genetic distances between the sequences. A1 and A2, F1 and F2 are subtypes; CRF01AE is unique in the envelope gene, but similar to subtype A in the rest of the genome. (Courtesy of Bette Korber, PhD, and Carla Kuiken, PhD, HIV Database, Los Alamos National Laboratory.)
Infections with microorganisms such as Trichomonas vaginalis, Chlamydia trachomatis, Neisseria gonorrhoeae, and herpes simplex virus (HSV; Chap. 163) are important causes of genital ulcerations linked to transmission of HIV. In addition, pathogens responsible for nonulcerative inflammatory STDs such as those caused by Chlamydia trachomatis (Chap. 160), Neisseria gonorrhoeae (Chap. 128), and Trichomonas vaginalis (Chap. 199) are also associated with an increased risk of transmission of HIV infection. Bacterial vaginosis, an infection related to sexual behavior, but not strictly an STD, may also be linked to an increased risk of transmission of HIV infection. Several studies suggest that treating other STDs and genital tract syndromes may help prevent transmission of HIV. This effect is most prominent in populations in which the prevalence of HIV infection is relatively low. In studies conducted in Uganda, the chief predictor of heterosexual transmission of HIV was the level of plasma viremia. In a cohort of couples in which one partner was HIV-infected and one was initially uninfected, the mean serum HIV RNA level was significantly higher among HIV-infected subjects whose partners seroconverted than among those whose partners did not seroconvert. In fact transmission was rare when the infected partner had a plasma level of <1500 copies of HIV RNA per milliliter. Of note, in that study, there were no seroconversions among 50 circumcised male partners. Furthermore, in a number of other studies, lack of circumcision has been strongly associated with a higher risk of HIV infection. This difference may be due to increased susceptibility of uncircumcised men to ulcerative STDs, as well as other factors such as microtrauma. In addition, the highly vascularized inner foreskin tissue contains a high density of Langerhans cells as well as increased numbers of CD4+ T cells, macrophages, and other cellular targets for HIV. Finally, the moist environment under the foreskin may promote the presence or persistence of microbial flora which, via inflammatory changes, may lead to even higher concentrations of target cells for HIV in the foreskin. In some studies the use of oral contraceptives was associated with an increase in incidence of HIV infection over and above that which might be expected by not using a condom for birth control.

Oral sex is a much less efficient mode of transmission of HIV than is receptive anal intercourse. A number of studies have reported that the incidence of transmission of infection by oral sex among couples discordant for HIV was extremely low; indeed, one study reported no cases among 239 men whose only risk was receptive oral intercourse where 28% knew that their partner was HIV-infected. However, there have been several reports of documented HIV transmission resulting solely from receptive fellatio and insertive cunnilingus. There are probably many more cases that go unreported because of the frequent practice of both oral sex and receptive anal intercourse by the same person. Therefore, the assumption that receptive oral sex is com-

TRANSMISSION BY BLOOD AND BLOOD PRODUCTS

HIV can be transmitted to individuals who receive HIV-tainted blood transfusions, blood products, or transplanted tissue as well as to IDUs who are exposed to HIV while sharing injection paraphernalia such as needles, syringes, the water in which drugs are mixed, or the cotton through which drugs are filtered. Parenteral transmission of HIV during injection drug use does not require intravenous puncture; subcutaneous (“skin popping”) or intramuscular (“muscling”) injections can transmit HIV as well, even though these behaviors are sometimes erroneously perceived as low-risk. Among IDUs, the risk of HIV infection increases with the duration of injection drug use; the frequency of needle sharing; the number of partners with whom paraphernalia are shared, particularly in the setting of “shooting galleries” where drugs are sold and large numbers of IDUs may share a limited number of “works”; comorbid psychiatric conditions such as antisocial personality disorder; the use of cocaine in injectable form or smoked as “crack”; and the use of injection drugs in a geographic location with a high prevalence of HIV infection, such as certain inner-city areas in the United States.

From the late 1970s until the spring of 1985, when mandatory testing of donated blood for HIV-1 was initiated, it has been estimated that >10,000 individuals in the United States were infected through transfusions of blood or blood products (Chap. 99). Approximately 9300 individuals in the United States who survived the illness for which they received HIV-contaminated blood transfusions, blood components, or transplanted tissue have developed AIDS. It is estimated that 90 to 100% of individuals who were exposed to such HIV-contaminated products became infected. Transfusions of whole blood, packed red blood cells, platelets, leukocytes, and plasma are all capable of transmitting HIV infection. In contrast, hyperimmune γ globulin, hepatitis B immune globulin, plasma-derived hepatitis B vaccine, and Rh immune globulin have not been associated with transmission of HIV infection. The procedures involved in processing these products either inactivate or remove the virus.

In addition to the above, several thousand individuals in the United States with hemophilia or other clotting disorders were infected with HIV by receipt of HIV-contaminated fresh-frozen plasma or concentrates of clotting factors; ~5470 of these individuals have developed AIDS. Currently, in the United States and in most developed countries, the following measures have made the risk of transmission of HIV infection by transfused blood or blood products extremely small: (1) the screening of all blood for HIV nucleic acid, p24 antigen, and/or anti-HIV antibodies; (2) the self-deferral of donors on the basis of risk behavior; (3) the screening out of HIV-negative individuals with positive surrogate laboratory parameters of HIV infection, such as hepatitis B and C; and (4) serologic testing for syphilis. It is currently estimated that the risk of infection with HIV in the United States via transfused screened blood is approximately 1 in 725,000 to 1 in 835,000 donations. Therefore, among the 12 million donations collected in the United States each year, an estimated 16 infectious donations are available for transfusion. Thus, despite the best efforts of science, one cannot completely eliminate the risk of transfusion-related transmission of HIV since current technology cannot detect HIV RNA for the first 1 to 2 weeks following infection due to the low levels of viremia. In this regard, two individuals in Florida recently contracted HIV from a single donor who had recently become infected; the blood collection system in question had used nucleic acid amplification testing to screen the blood. There have been several reports of sporadic breakdowns in routinely available screening procedures in certain countries, where contaminated blood was allowed to be transfused, resulting in clusters of patients becoming infected. In China, a disturbingly large number of people have become infected by selling blood in situations where the collectors reused needles that were contaminated and in some instances mixed blood products from a number of people, separated the plasma, and re-infused red blood cells back into individual donors. It is estimated that >6% of China’s HIV-infected population were infected while selling blood. There have been no reported cases of transmission of HIV-2 in the United States via donated blood, and, currently, donated blood is screened for both HIV-1 and HIV-2 antibodies. The chance of infection of a hemophiliac via clotting factor concentrates has essentially been eliminated because of the added layer of safety resulting from heat treatment of the concentrates.

Prior to the screening of donors, a small number of cases of transmission of HIV via semen used in artificial insemination and tissues used in organ transplantation were well documented. At present, donors of such tissues are prescreened for HIV infection.

OCCUPATIONAL TRANSMISSION OF HIV: HEALTH CARE WORKERS AND LABORATORY WORKERS

There is a small, but definite, occupational risk of HIV transmission to health care workers and laboratory personnel and potentially others who work with HIV-containing materials, particularly when sharp objects are used. An estimated 600,000 to 800,000 health care workers are stuck with needles or other sharp medical instruments in the United States each year. Large, multi-institutional studies have indicated that the risk of HIV transmission following skin puncture from a needle or a sharp object that was contaminated with blood from a person with documented HIV infection is ~0.3% and after a mucous membrane exposure it is 0.09% (see “HIV and the Health Care Worker,” p. 1136). HIV transmission after non-intact skin exposure has been documented, but the average risk for transmission by this route has not been precisely determined; however, it is estimated to be less than the risk for mucous membrane exposure. Transmission of HIV through intact skin has not been documented. An increased risk for HIV infection following percutaneous exposures to HIV-infected blood is associated with exposures involving a relatively large quantity of blood, as in the case of a device visibly contaminated with the patient’s blood, a procedure that involves a needle placed directly in a vein or artery, or a deep injury. Factors that might be associated with mucocutaneous transmission of HIV include exposure to an unusually large volume of blood, prolonged contact, and a potential portal of entry. In addition, the risk increases for exposures to blood from patients with advanced-stage disease, probably owing to the higher titer of HIV in the blood as well as to other factors, such as the presence of more virulent strains of virus. The use of antiretroviral drugs as postexposure prophylaxis decreases the risk of infection compared to historic controls in occupationally exposed health care workers (see “HIV and the Health Care Worker”). The risk of hepatitis B virus (HBV) infection following a similar type of exposure is 6 to 30% in nonimmune individuals; if a susceptible worker is exposed to HBV, postexposure prophylaxis with hepatitis B immune globulin and initiation of HBV vaccine is >90% effective in preventing HBV infection. The risk of hepatitis C virus (HCV) infection following percutaneous injury is ~1.8% (Chap. 285).

Since the beginning of the HIV epidemic, there have been at least three reported instances in which transmission of infection from a health care worker to patients seemed highly probable. The first involved a dentist in Florida who apparently infected six of his patients, most likely through contaminated instruments. Another case involved an orthopedic surgeon in France who apparently infected a patient during placement of a total hip prosthesis. A third case involved the apparent transmission of HIV from a nurse to a surgical patient in France. An additional situation involved the apparent infection of four patients by an HIV-negative general surgeon in Australia during routine outpatient surgery. The cause of the transmission was felt to be a failure on the part of the surgeon to sterilize instruments properly between procedures on an infected patient. Despite these few cases, the risk of transmission from an infected health care worker to patients is extremely low; in fact, too low to be mea-
MATERNAL-FETAL/INFANT TRANSMISSION

HIV infection can be transmitted from an infected mother to her fetus during pregnancy, during delivery, or by breast-feeding. This is an extremely important form of transmission of HIV infection in developing countries, where the proportion of infected women to infected men is ~1:1. Virologic analysis of aborted fetuses indicates that HIV can be transmitted to the fetus as early as the first and second trimester of pregnancy. However, maternal transmission to the fetus occurs most commonly in the perinatal period. This conclusion is based on a number of considerations, including the time frame of identification of infection by the sequential appearance of classes of antibodies to HIV (i.e., the appearance of HIV-specific IgA antibody within 3 to 6 months after birth); a positive viral culture; the appearance of p24 antigenemia weeks to months after delivery, but not at the time of delivery; a polymerase chain reaction (PCR) assay of infant blood following delivery that is negative at birth and positive several months later; the demonstration that the firstborn twin of an infected mother is more commonly infected than is the second twin; and the evidence that cesarean section results in decreased transmission to the infant. Two studies performed in Rwanda and the former Zaire indicated that the relative proportions of mother-to-child transmissions were 23% to 30% before birth, 50 to 65% during birth, and 12 to 20% via breast-feeding.

In the absence of prophylactic antiretroviral therapy to the mother during pregnancy, labor, and delivery, and to the fetus following birth (see below), the probability of transmission of HIV from mother to infant/fetus ranges from 15% to 25% in industrialized countries and from 25 to 35% in developing countries. These differences may relate to the adequacy of prenatal care as well as to the stage of HIV disease and the general health of the mother during pregnancy. Higher rates of transmission have been reported to be associated with many factors; some of these are well proven by a number of studies, while others appear to be associated with the maternal plasma HIV RNA level. In one of 552 singleton pregnancies in the United States, the rate of mother-to-baby transmission was 0% among women with <1000 copies of HIV RNA per milliliter of blood, 16.0% among women with 1000 to 10,000/mL, 21.3% among women with 10,001 to 50,000/mL, 30.9% among women with 50,001 to 100,000/mL, and 40.6% among women with >100,000/mL. However, there may be no lower “threshold” below which transmission never occurs, since other studies have reported transmission by women with viral RNA levels <50 copies per milliliter. Finally, it has been speculated that if the mother experiences acute primary infection during pregnancy, there is a higher rate of transmission to the fetus, owing to the high levels of viremia that occur during primary infection. However, a study from Thailand reported no increased risk of transmission of HIV from mother-to-child in women who seroconverted during pregnancy. In that study, maternal viral loads at delivery were no different among women who seroconverted during pregnancy and those who were seropositive when first tested. In a study conducted in the United States, zidovudine treatment of HIV-infected pregnant women from the beginning of the second trimester through delivery decreased transmission of the infant for the infant born to mothers who experienced acute primary infection during pregnancy. Among women who experienced acute primary infection during pregnancy, the rate of maternal-to-child transmission is approaching 1% or less in pregnant women who are receiving combination antiretroviral therapy for their HIV infection. Such treatment, combined with cesarean section delivery, has rendered mother-to-child transmission of HIV an unusual event in the United States and other developed nations. In developed countries, current recommendations to reduce perinatal transmission of HIV include universal voluntary HIV testing and counseling of pregnant women, antiretroviral prophylaxis with one or more drugs in cases in which the mother does not require therapy for her HIV infection, combination therapy for women who do require therapy, obstetric management that attempts to minimize exposure of the infant to maternal blood and genital secretions, and avoidance of breast-feeding. It is recommended that the choice of antiretroviral therapy for pregnant women should be based on the same considerations used for women who are not pregnant, with the exception of the recognized and unknown risks and benefits of such therapy during pregnancy. The cost and logistics of the above protocol are not currently feasible for developing countries, particularly those in sub-Saharan Africa where the per capita health care delivery allocation is often only a few dollars per year. Studies have demonstrated that truncated regimens of zidovudine alone or in combination with lamivudine given to the mother during the last few weeks of pregnancy or even only during labor and delivery, and to the infant for a week or less, reduced transmission to the infant by 50% compared to placebo. One important study in Uganda demonstrated that a single dose of nevirapine given to the mother at the onset of labor followed by a single dose to the newborn within 72 h of birth decreased transmission by 50% compared with a regimen of zidovudine to the mother that began at the onset of labor and continued throughout labor and to the infant for 1 week following birth. The cost of the nevirapine for the mother and infant was $4.00, thus making this regimen more affordable. Indeed, short-course nevirapine regimens increasingly are being utilized in developing nations for the prevention of mother-to-child transmission. It is estimated that the successful implementation of such regimens could potentially save 1000 babies per day from becoming infected with HIV, the vast majority of whom are in sub-Saharan Africa.

Breast-feeding is an important modality of transmission of HIV infection in developing countries, particularly where mothers continue to breast feed for prolonged periods. The risk factors for mother-to-child transmission of HIV via breast-feeding are not fully understood; factors that increase the likelihood of transmission include detectable levels of HIV in breast milk, the presence of mastitis, low maternal CD4+ T cell counts, and maternal vitamin A deficiency. The risk of HIV infection through breast-feeding is highest in the early months of breast-feeding. In addition, exclusive breast-feeding has been reported to lower the risk of HIV transmission than mixed feeding. Certainly, in developed countries breast-feeding by an infected mother should be avoided. However, there is disagreement regarding recommendations for breast-feeding in certain developing countries, where breast milk is the only source of adequate nutrition as well as immunity against potentially serious infections for the infant. Studies are being conducted to determine whether intermittent administration of nevi-
TRANSMISSION BY OTHER BODY FLUIDS  Although HIV can be isolated typically in low titers from saliva of a small proportion of infected individuals, there is no convincing evidence that saliva can transmit HIV infection, either through kissing or through other exposures, such as occupationally to health care workers. Saliva contains endogenous antiviral factors; among these factors, HIV-specific immunoglobulins of IgA, IgG, and IgM isotypes are detected readily in salivary secretions of infected individuals. It has been suggested that large glycoproteins such as mucins and thrombospondin-1 sequester HIV into aggregates for clearance by the host. In addition, a number of soluble salivary factors inhibit HIV to various degrees in vitro, probably by targeting host cell receptors rather than the virus itself. Perhaps the best-studied of these, secretory leukocyte protease inhibitor (SLPI), blocks HIV infection in several cell culture systems, and it is found in saliva at levels that approximate those required for inhibition of HIV in vitro. In this regard, higher salivary levels of SLPI in breast-fed infants were associated with a decreased risk of HIV transmission through breast milk. It has also been suggested that submandibular saliva reduces HIV infectivity by stripping gp120 from the surface of virions, and that saliva-mediated disruption and lysis of HIV-infected cells occurs because of the hypotonicity of oral secretions. There have been outlier cases of suspected transmission by saliva, but these have probably been blood-to-blood transmissions. Transmission of HIV by a human bite can occur but is a rare event; at least four cases of such transmission have been reported. In addition, a most unusual form of HIV transmission from infected children to mothers in the former Soviet Union has been identified. In those cases, the children (infected through transfusion) were said to have bleeding sores in the mouth, and the mothers were said to have lacerations and abrasions on and around the nipples of the breast resulting from trauma from the children’s teeth. Breast-feeding had been continued until the children were older than is usual in other developed countries.

Although virus can be identified, if not isolated, from virtually any body fluid, there is no evidence that HIV transmission can occur as a result of exposure to tears, sweat, and urine. However, there have been isolated cases of transmission of HIV infection by body fluids that may or may not have been contaminated with blood. Most of these situations occurred in the setting of a close relative providing intensive nursing care for an HIV-infected person without observing universal precautions. These cases underscore the importance of observing universal precautions in the handling of body fluids and wastes from HIV-infected individuals (see below).

EPIDEMIOLOGY

HIV INFECTION AND AIDS WORLDWIDE  HIV infection/AIDS is a global pandemic, with cases reported from virtually every country. The current estimate of the number of cases of HIV infection among adults worldwide is ~37 million, two-thirds of whom are in sub-Saharan Africa; 50% of cases are women. In addition, an estimated 2.5 million children younger than age 15 are living with HIV/AIDS. The global distribution of these cases is illustrated in Fig. 173-9. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), in 2003 alone there were an estimated 5 million new cases of infection worldwide (>14,000 new infections each day) and 3 million deaths from AIDS, making it the fourth leading cause of mortality worldwide. The cumulative number of AIDS-related deaths worldwide through the year 2003 exceeds 20 million. The HIV epidemic has occurred in "waves" in different regions of the world, each wave having somewhat different characteristics depending on the demographics of the country and region in question and the timing of the introduction of HIV into the population.

As noted above, different subtypes, or clades, of HIV-1 are prevalent in different regions of the world (see above and Fig. 173-7), increasing the difficulty in the development of vaccines and perhaps accounting for different degrees of virulence. It is unlikely that a single vaccine will be applicable to all regions of the world. In this regard, in addition to HIV-1 subtype B, the predominant subtype in the United States, HIV-1 subtypes A, AE, AG, C, D, and O have been detected in individuals in the United States, as might be expected given the degree of international travel that occurs.

Table 173-3 provides the statistics and demographic features of HIV/AIDS in different regions of the world. Although the epidemic was first recognized in the United States and shortly thereafter in western Europe, it very likely began in sub-Saharan Africa (see above), which has been particularly devastated by the epidemic, with the prevalence of infection in many cities in the double digits. In certain sub-Saharan African countries, such as Zimbabwe and Botswana, available seroprevalence data indicate >30% of the adult population aged 15 to 49 is HIV-infected. In addition, among high-risk individuals (e.g., commercial sex workers, patients attending STD clinics) who live in urban areas of sub-Saharan Africa, seroprevalence is now >50% in many countries. According to projections of the United Nations Pop-
ululation Division, by the year 2015 life expectancy at birth in the seven countries in Africa with adult HIV prevalence rates >20% will be 32 years lower on average than the projected life expectancy in the absence of AIDS (Table 173-4). The epidemic in Asian countries, particularly India and China, has lagged temporally behind that in Africa; however, the number of new cases in this region is accelerating rapidly, and the magnitude of the epidemic is projected to exceed that of sub-Saharan Africa in the early part of the twenty-first century. The epidemic is also expanding rapidly in the Baltic States, the Russian Federation, and several Central Asian Republics. The major mode of transmission of HIV worldwide is unquestionably heterosexual sex; this is particularly true and has been so since the beginning of the epidemic in developing countries, where the numbers of infected men and women are approximately equal. The epidemic in most developed countries was first introduced among homosexual men and, to a greater or lesser degree (depending on the individual country), among IDUs. In this regard, the total numbers of AIDS cases in those countries still reflect a high proportion of cases among these high-risk groups. However, in most developed countries, including the United States (see below), there has been a gradual shift such that among new cases of AIDS, there is a greater total prevalence among heterosexuals and IDUs than among homosexual men.

AIDS in the United States AIDS has had and will continue to have an extraordinary public health impact in the United States. As of January 1, 2003, an estimated 886,575 cumulative cases of AIDS had been diagnosed in adults and adolescents in the United States (Table 173-5) and ~502,000 AIDS-related deaths had occurred. In 2002, AIDS was the sixth leading cause of death among Americans aged 25 to 44, having dropped from first within the past few years. The annual number of AIDS-related deaths in the United States fell ~70% from 1995 to 2002 (Fig. 173-10). This trend is due to several factors including the improved prophylaxis and treatment of opportunistic infections, the growing experience among the health professions in caring for HIV-infected individuals, improved access to health care, and a decrease in new infections due to salutational effects and prevention efforts. However, the most influential factor clearly has been the increased use of potent antiretroviral drugs, generally administered in a combination of three or four agents (see below). When one looks at the totality of data collected from the beginning of the epidemic, ~47% of all cases are among men who have had sex with men. However, since the mid-1980s the proportion of newly reported cases of AIDS in this population has declined from 65% of cases diagnosed in 1985 to 40% of cases diagnosed in 2002. Meanwhile, the proportion of new AIDS cases attributed to heterosexual contact has increased dramatically, from 3% in 1985 to 29% in 2002 (Fig. 173-8). Women are increasingly affected; the proportion of AIDS cases in the United States reported among adult and adolescent females has increased from <5% to 26% from 1985 to 2002 (Fig. 173-8). Most cases of transmission by injection drug use and heterosexual contact are reported from the northeast and southeast regions of the country, particularly among minorities. HIV infection and AIDS have disproportionately affected minority populations in the United States. The estimated rates of AIDS diagnoses per 100,000 population among adults and adolescents in 2002 were 76.4 for African Americans, 26.0 for Hispanics, 7.0 for whites, 11.2 for American Indians/Alaska Natives, and 4.9 for Asian/Pacific Islanders (Fig. 173-11).

As of January 1, 2003, an estimated 9,300 cases of AIDS in children ≤13 years old had been diagnosed, and ~55% of these children have died. Approximately 90% of these children were born to mothers who were HIV-infected or who were at risk for HIV infection and, in ~60% of those cases, the mother was either an IDU or the heterosexual partner of an IDU. The estimated number of AIDS cases diagnosed among children perinatally exposed to HIV peaked in 1992 and has decreased in recent years (Fig. 173-12). The decline of these cases is likely associated with the implementation of guidelines for the universal counseling and voluntary HIV testing of pregnant women and the use of antiretroviral therapy for pregnant women and newborn infants in order to prevent infection. Another contributing factor is the effective treatment of HIV infection in children who have become infected.

About 43% of women with AIDS have become infected through injection drug use, compared to 24% of men with AIDS; 53% of women have become infected by heterosexual contact, compared to 7% of men with AIDS. Only 1% of AIDS cases are among hemophiliacs, and 1% are among recipients of blood transfusions, blood products, or transplanted tissue. The relative contribution of the latter groups will gradually decrease, even though individuals infected pre-

HIV disease: AIDS, related disorders

The course of HIV infection (see below). Also, the demography of newly infected individuals has changed considerably since the mid-1980s (see below).

**HIV Prevalence and Incidence in the United States**

It is estimated that between 850,000 and 950,000 adults and adolescents in the United States are living with HIV infection, one-quarter of whom are unaware of their infection. This estimate results in an overall nationwide prevalence of HIV infection of ~0.3%. Prevalence is highest among young adults in their late twenties and thirties and among minorities. An estimated 3% of black men and 1% of black women in their thirties are living with HIV infection. The number of new infections per year is estimated to be ~40,000, and this number has remained stable for more than a decade. The estimated proportion of HIV infections has declined among white males, especially those >30, while the proportion of new HIV infections appears to have increased among young homosexual men and heterosexual women, especially in minority groups. Among newly infected persons in the United States, ~70% are men and ~30% are women (Fig. 173-13). Of these newly infected individuals, half are <25 years. Of new infections among men, the CDC estimates that ~60% were infected through homosexual sex, 25% through injection drug use, and 15% through heterosexual sex. Of new infections among women, ~75% were infected through heterosexual sex and 25% through injection drug use.

HIV infection and AIDS are widespread in the United States; although the epidemic on the whole is plateauing, it is spreading rapidly among certain populations, stabilizing in others, and decreasing in others. Similar to other STDs, HIV infection will not spread homogeneously throughout the population of the United States. However, it is clear that anyone who practices high-risk behavior is at risk for HIV infection. In addition, the increase in infections and AIDS cases among young homosexual men, heterosexuals (particularly sexual partners of IDUs, women, and adolescents) as well as the spread in

Previously through this mode of transmission will continue to develop AIDS. The risk of additional infections via this mode of transmission in the United States is extremely small (see above). In recent years, the incidence of AIDS has decreased considerably, with ~42,000 new cases in 2002 compared to ~60,000 in 1996 (Fig. 173-10). This trend likely reflects both reduced infection rates since the mid-1980s; more widespread use of prophylactic therapies, which delay the onset of AIDS; and the use of highly effective antiretroviral therapy early in the course of HIV infection (see below).
pockets of poverty in both urban and rural regions (particularly among underserved minority populations with inadequate access to health care) testifies to the fact that the epidemic of HIV infection in the United States is a public health problem of major proportions.

PATHOPHYSIOLOGY AND PATHOGENESIS

The hallmark of HIV disease is a profound immunodeficiency resulting primarily from a progressive quantitative and qualitative deficiency of the subset of T lymphocytes referred to as helper T cells, or inducer T cells. This subset of T cells is defined phenotypically by the presence on its surface of the CD4 molecule (Chap. 295), which serves as the primary cellular receptor for HIV. A co-receptor must also be present together with CD4 for efficient fusion and entry of HIV-1 into its target cells (Figs. 173-3 and 173-4). HIV uses two major co-receptors for fusion and entry; these co-receptors are also the primary receptors for certain chemoattractive cytokines termed chemokines and belong to the seven-transmembrane-domain G protein–coupled family of receptors. CCR5 and CXCR4 are the major co-receptors used by HIV (see above and below). Although a number of mechanisms responsible for cytopathicity and immune dysfunction of CD4+ T cells have been demonstrated in vitro, particularly direct infection and destruction of these cells by HIV and activation-induced cell death (see below), it remains unclear which mechanisms or combination of mechanisms are primarily responsible for their progressive depletion and functional impairment in vivo. When the number of CD4+ T cells declines below a certain level (see below), the patient is at high risk of developing a variety of opportunistic diseases, particularly the infections and neoplasms that are AIDS-defining illnesses. Some features of AIDS, such as KS and neurologic abnormalities (see below), cannot be explained completely by the immunosuppressive effects of HIV, since these complications may occur prior to the development of severe immunologic impairment.

The combination of viral pathogenic and immunopathogenic events that occurs during the course of HIV disease from the moment of initial (primary) infection through the development of advanced-stage disease is complex and varied. It is important to appreciate that the pathogenic mechanisms of HIV disease are multifactorial and multiphasic and are different at different stages of the disease. Therefore, it is essential to consider the typical clinical course of an untreated HIV-infected individual in order to more fully appreciate these pathogenic events (Fig. 173-14).

PRIMARY HIV INFECTION, INITIAL VIREMIA, AND DISSEMINATION OF VIRUS

The events associated with primary HIV infection are likely critical determinants of the subsequent course of HIV disease. In particular, the dissemination of virus to lymphoid organs is a major factor in the establishment of a chronic and persistent infection (see below). The initial infection of susceptible cells may vary somewhat with the route of infection. Virus that enters directly into the bloodstream via infected blood or blood products (i.e., transfusions, use of contaminated needles for injecting drugs, sharp-object injuries, maternal-to-fetal transmission either intrapartum or perinatally, or sexual intercourse where there is enough trauma to cause bleeding) is likely cleared from the circulation to the spleen and other lymphoid organs, where it replicates to a critical level and then leads to a burst of viremia that disseminates virus throughout the body. Dendritic cells play an important role in the initiation of HIV infection. These cells express a diversity of C-type lectin receptors on their surface, one of which is called DC-SIGN (see above), DC-SIGN binds with high affinity to the HIV envelope gp120 and can retain infectious particles for days in vitro. Certain studies have demonstrated that following binding to DC-SIGN, HIV is internalized into a low pH nonlysosomal compartment that allows for the retention of infectivity. Upon encountering a susceptible CD4+ T cell target, the dendritic cell markedly enhances the infectivity of the virus for the target cell. This mechanism likely operates in humans when HIV enters “locally” (as opposed to directly into the blood) and encounters mucosal dendritic cells via the vagina, rectum, or urethra during intercourse or via the upper gastrointestinal tract from swallowed infected semen, vaginal fluid, or breast milk. In primary HIV infection, virus replication in CD4+ T cells intensifies prior to the initiation of an HIV-specific immune response (see below), leading to a burst of viremia (Fig. 173-14) and then to a rapid dissemination of virus to other lymphoid organs, the brain, and other tissues. Individuals who experience the “acute HIV syndrome,” which occurs to varying degrees in ~50% of individuals with primary infection, have high levels of viremia measured in millions of copies of HIV RNA per milliliter that last for several weeks (see below). The acute mononucleosis-like symptoms are well correlated with the presence of viremia. Virtually all patients appear to develop some degree of viremia during primary infection, which contributes to virus dissemination throughout the lymphoid tissue, even though they may remain asymptomatic or not recall experiencing symptoms. A more detailed description of the role of lymphoid tissue in the immunopathogenesis of HIV disease is given below. It appears that the initial level of plasma viremia in primary HIV infection does not necessarily determine the rate of disease progression; however, the set point of the level of steady-state plasma viremia after ~1 year does seem to correlate with the rapidity of disease progression (see below).

Evasion of Immune System Control  Inherent to the establishment of chronicity of HIV infection is the ability of the virus to evade elimination and control by the immune system. There are a number of mechanisms whereby the virus accomplishes this evasion. Paramount among these is the ability of the virus to mutate, which becomes particularly relevant after the establishment of chronic infection and which contributes to the maintenance of chronicity. The evolution of mutants that escape control by CD8+ cytolytic T lymphocytes (CTLs) is critical to the propagation and progression of HIV infection. The high rate of virus replication and the continual mutation of virus also contribute to the inability of neutralizing antibody to contain the virus quasispecies present in an individual at any given time. Molecular analysis of clonotypes has demonstrated that clones of CD8+ CTLs that expand greatly during primary HIV infection, and likely represent the high-affinity clones that would be expected to be most efficient in eliminating virus-infected cells, are no longer detectable after their initial burst of expansion. It is thought that the initially expanded clones may have been deleted owing to the overwhelming exposure to viral antigens during the initial burst of viremia, similar to the exhaustion of CD8+ CTLs that has been reported in the murine model of lymphocytic choriomeningitis virus (LCMV) infection. To complicate this phenomenon, virus replication and thus saturation of antigen-presenting cells with viral antigen take place in the lymphoid tissue (see below), which is also the site of generation of HIV-specific CTLs. Another mechanism of evasion by HIV of immune system control is the downregulation of HLA class I molecules on the surface of HIV-infected cells by the Nef protein of HIV, resulting in the lack of ability of the CD8+ CTL to recognize and kill the infected target cell. Although this downregulation of HLA class I molecules would favor elimination of HIV-infected cells by natural killer (NK) cells, this latter mechanism does not seem to effectively remove HIV-infected cells (see below). An important mechanism of evasion of the humoral immune response is the avoidance by the virus of antibody-mediated neutralization through its conformational masking of receptor-binding sites.

CD4+ T cell help is critical for the integrity of antigen-specific immune responses, both humoral and cell-mediated. HIV preferentially infects HIV-specific CD4+ T cells, and so this loss of viral-specific helper T cell responses has potentially profound negative consequences for the immunologic control of HIV replication. Other means of escape of HIV-infected cells from elimination by CD8+ CTLs include the sequestration of infected cells in immunologically privileged sites such as the central nervous system (CNS) as well as the segregation of HIV-specific CTLs and CTL precursors in the peripheral blood where relatively little active virus replication takes place, rather than in the lymphoid tissue, which is the major site of virus replication and spread.

Finally, the escape of HIV from elimination during primary infection allows the formation of a large pool of latently infected cells that cannot be eliminated by virus-specific CTLs (see below). Thus, despite a potent immune response and the marked downregulation of virus replication following primary HIV infection, HIV succeeds in establishing a state of chronic infection with a variable degree of persistent virus replication. In most cases, during this period the patient makes the clinical transition from acute primary infection to a relatively prolonged state of clinical latency (see below).

Latent Reservoir of HIV-Infected Cells: Obstacle to the Eradication of Virus

There exists in virtually all HIV-infected individuals a pool of latently infected, resting CD4+ T cells that serves as at least one component of the persistent reservoir of virus. Such cells manifest postintegration latency in that the HIV provirus integrates into the genome of the cell and can remain in this state until an activation signal drives the expression of HIV transcripts and ultimately replication-competent virus. This form of latency is to be distinguished from preintegration latency, in which HIV enters a resting CD4+ T cell and, in the absence of an activation signal, only a limited degree of reverse transcription of the HIV genome occurs. This period of preintegration latency may last hours to days, and if no activation signal is delivered to the cell, the proviral DNA loses its capacity to initiate a productive infection. If these cells do become activated, reverse transcription proceeds to completion and the virus continues along its replication cycle (see above and Fig. 173-15). The pool of cells that are in the postintegration state of latency is established early during the course of primary HIV infection. Despite the suppression of plasma viremia to <50 copies of
HIV RNA per milliliter by potent combinations of several antiretroviral drugs for as long as 5 years, this pool of latently infected cells persists and can give rise to replication-competent virus. Modeling studies built on projections of decay curves (see below) have estimated that in a setting of prolonged suppression of plasma viremia to <50 copies of HIV RNA per milliliter by antiretroviral therapy (a goal that is difficult to maintain consistently over years), it would require from 7 to 70 years for the pool of latently infected cells to be completely eliminated. Furthermore, the reservoir of latently infected cells is replenished during minor rebounds of virus replication that may occur intermittently, even in patients who for the most part are treated successfully, and certainly during major rebounds of viremia in patients whose therapy is interrupted for a period of weeks or longer. Thus, this persistent pool of latently infected cells is a major obstacle to any goal of eradication of virus from infected individuals, despite the favorable clinical outcomes that have resulted from antiretroviral therapy (see below).

**Viral Dynamics** The dynamics of viral production and turnover have been quantified using mathematical modeling in the setting of the administration of reverse transcriptase and protease inhibitors to HIV-infected individuals in clinical studies. Treatment with these drugs resulted in a precipitous decline in the level of plasma viremia, which typically fell by well over 90% within 2 weeks. The number of CD4+ T cells in the blood increased concurrently, which suggested that the killing of CD4+ T cells was linked directly to the levels of replicating virus. However, it is generally agreed that a significant component of the early rise in CD4+ T cell numbers following the initiation of therapy is due to the redistribution of cells into the peripheral blood from other body compartments as a consequence of alterations in immune system activation. It was determined on the basis of modeling the kinetics of viral decline and the emergence of resistant mutants during therapy that 93 to 99% of the circulating virus originated from recently infected, rapidly turning over CD4+ T cells and that ~1 to 7% of circulating virus originated from longer-lived cells, likely monocyte/macrophages. A negligible amount of circulating virus originated from the pool of latently infected cells (see above) (Fig. 173-16). It was also determined that the half-life of a circulating virion was approximately 30 to 60 min and that of productively infected cells was 1 day. Given the relatively steady level of plasma viremia and of infected cells, it appears that extremely large amounts of virus (~10^6 to 10^7 virions) are produced and cleared from the circulation each day. In addition, data suggest that the minimum duration of the HIV-1 replication cycle in vivo is ~2 days. Other studies have demonstrated that the decrease in plasma viremia that results from antiretroviral therapy correlates closely with a decrease in virus replication in lymph nodes, further confirming that lymphoid tissue is the main site of HIV replication and the main source of plasma viremia.

The level of steady-state viremia, called the viral set point, at ~1 year has important prognostic implications for the progression of HIV disease. It has been demonstrated that HIV-infected individuals who have a low set point at 6 months to 1 year progress to AIDS much more slowly than individuals whose set point is very high at that time (Fig. 173-17). Levels of viremia generally increase as disease progresses. Measurement of the level of viremia is critical in guiding therapeutic decisions in HIV-infected individuals (see below).

**Clinical Latency versus Microbiologic Latency** With the exception of long-term nonprogressors (see below), the level of CD4+ T cells in the blood decreases progressively in HIV-infected individuals. The slope of this decline is usually a good predictor of the pattern of the clinical course and the development of advanced disease. The decline in CD4+ T cells may be gradual or abrupt, the latter usually reflecting a significant spike in the level of plasma viremia. Most patients are entirely asymptomatic while this progressive decline is taking place (see below) and are often described as being in a state of clinical latency. However, this term is misleading; it does not mean disease latency, since progression is generally relentless during this period. Furthermore, clinical latency should not be confused with microbiologic latency, since virus replication manifested by low-level viremia is present in the vast majority of patients during the period of clinical latency. Even in those rare patients who have <50 copies of HIV RNA per milliliter in the absence of therapy, there is virtually always some degree of ongoing virus replication, as determined by sensitive molecular methods such as PCR techniques that detect cell-associated viral RNA or that concentrate virus from large volumes of blood.

**ADVANCED HIV DISEASE** In untreated patients or in patients in whom therapy has not adequately controlled virus replication (see below), after a variable period, usually measured in years, the CD4+ T cell count falls below a critical level (~200/μL) and the patient becomes highly susceptible to opportunistic disease (Fig. 173-14). For this reason, the CDC case definition of AIDS includes all HIV-infected individuals with CD4+ T cell counts below this level (Table 173-1).

Patients may experience constitutional signs and symptoms or may develop an opportunistic disease abruptly without any prior symptoms, although the latter scenario is unusual. The depletion of CD4+ T cells continues to be progressive and unrelenting in this phase. It is not uncommon for CD4+ T cell counts to drop as low as 10/μL or even to zero, yet such patients may survive for months or even years. This situation has become increasingly common as patients are treated more aggressively and are given prophylaxis against the common life-threatening opportunistic infections (see below). In this regard, control of plasma viremia by antiretroviral therapy, even in individuals with extremely low CD4+ T cell counts, has increased survival in these patients despite the fact that their CD4+ T cell counts may not significantly increase as a result of therapy. Ultimately, patients who

![FIGURE 173-16](https://example.com/figure173-16.png)\[caption\] Dynamics of HIV infection in vivo. See text for detailed description. (From AS Perelson et al: Science 271:1580, 1996.)

![FIGURE 173-17](https://example.com/figure173-17.png)\[caption\] Relationship between levels of virus and rates of disease progression. Kaplan–Meier curves for AIDS-free survival stratified by baseline HIV-1 RNA categories (copies per milliliter). (From Mellors et al.)
progress to this severest form of immunodeficiency usually succumb to opportunistic infections or neoplasms (see below).

LONG-TERM SURVIVORS AND LONG-TERM NONPROGRESSORS The prognosis for HIV-infected individuals who have access to health care and antiretroviral therapy has improved greatly since the beginning of the epidemic. The median time from primary HIV infection to the development of AIDS in untreated individuals in the developed world is ~10 years. This period has been markedly extended by the wide availability of combinations of antiretroviral drugs in the developed world; the full extent of this benefit has yet to be realized. It is important to distinguish between the terms long-term survivor and long-term nonprogressor. Long-term nonprogressors are by definition long-term survivors; however, the reverse is not always true. The definitions of these categories are empirical and continue to change as more data are collected from prospective cohort studies. Predictions from one study that annotated the availability of effective antiretroviral therapy estimated that ~13% of homosexual/bisexual men who were infected at an early age may remain free of clinical AIDS for >20 years. Originally, individuals were considered to be long-term survivors if they remained alive for 10 to 15 years after initial infection. Currently, individuals are considered to be long-term survivors if they remain alive for ≥20 years after initial infection. In most such individuals the disease has progressed, in that they have significant immunodeficiency, and many have experienced opportunistic diseases. Some of these individuals the disease has progressed, in that they have significant immunodeficiency, and many have experienced opportunistic diseases. The mechanisms of this stabilization are not entirely clear but may relate to the beneficial effects of antiretroviral therapy and prophylaxis against opportunistic infections. In addition, a number of viral and/or host determinants likely contribute to the long-term survival of these individuals. Quantitative and qualitative aspects of the HIV-specific immune response, as well as recognized and unrecognized genetic factors (see below), may also contribute to the long-term survival of these individuals.

Definitions of long-term nonprogressors have varied considerably over the years, and so such individuals constitute a heterogeneous group. Originally, individuals considered to be long-term nonprogressors were those who had been infected with HIV for a long period (>10 years), whose CD4+ T cell counts were in the normal range and remained stable over years, and who had not received antiretroviral therapy. Such patients had low, but usually detectable, levels of plasma viremia, generally normal immune function according to commonly measured parameters (skin tests, in vitro lymphocyte responses to various mitogens and antigens), and normal-appearing lymphoid tissue architecture as determined on lymph node biopsy. The definition rested more on the status of the immune system than on the absolute control of plasma viremia. In general, long-term nonprogressors manifested robust HIV-specific immune responses, both humoral (neutralizing antibodies) and cell-mediated (HIV-specific CTLs). However, this may also be true of some individuals early in the course of disease who ultimately progress to advanced disease. No qualitative abnormalities in the virus were detected in most of these patients. However, a small subset of patients did have defective virus; in particular, in one cohort of five long-term nonprogressors, the virus had a defect in the nef gene. In another report, a blood donor in Australia who was HIV-infected and a group of seven individuals who were infected by blood or blood products from that donor remained free of HIV-related disease and maintained normal and stable CD4+ T cell counts for several years after infection. Sequence analysis of viruses isolated from the donor and recipients revealed similar deletions in the nef gene and the region of overlap of nef and the U3 region of the HIV LTR (Fig. 173-5). The vast majority of these originally reported long-term nonprogressors have now gone on to progressive disease. More recently, cohorts of rare long-term nonprogressors have been described who have been infected for >20 years with normal CD4+ T cell counts and have maintained normal functional parameters. Some patients experience progressive generalized lymphadenopathy (see below) early in the course of infection; others experience varying degrees of transient lymphadenopathy. Lymphadenopathy reflects the cellular activation and immune response to the virus in the lymphoid tissue, which is generally characterized by follicular or germinal center hyperplasia. Lymphoid tissue involvement is a common denominator of virtually all patients with HIV infection, even those with minimal plasma viremia as measured by sensitive assays such as PCR.

Simultaneous examinations of lymph tissue and peripheral blood in patients and monkeys during various stages of HIV and SIV infec-
tion, respectively, have led to substantial insight into the pathogenesis of HIV disease. Using a combination of PCR techniques for HIV DNA and HIV RNA in tissue and HIV RNA in plasma, in situ hybridization for HIV RNA, and light and electron microscopy, the following picture has emerged. During acute HIV infection, a high level of viral replication in individual cells is demonstrated in lymphoid tissue and is associated with a burst of plasma viremia. A profound degree of cellular activation occurs (see below) and is reflected in follicular or germinal center hyperplasia. At this time copious amounts of extracellular virions are trapped on the processes of the follicular dendritic cells (FDCs) in the germinal centers of the lymph nodes (Fig. 173-18A). Virions that have bound complement components on their surfaces attach to the surface of FDCs via interactions with complement receptors and likely via Fc receptors that bind to antibodies that are attached to the virions. In situ hybridization reveals expression of virus in individual cells of the paracortical area and, to a lesser extent, the germinal center (Fig. 173-18B). The persistence of trapped virus after the transition from acute to chronic infection likely reflects a steady state whereby trapped virus turns over and is replaced by fresh virions, which are continually produced to a greater or lesser degree in individual patients.

During early-stage HIV disease, the architecture of the germinal centers is generally preserved and may even be hyperplastic owing to in situ proliferation of cells (mostly B lymphocytes) and recruitment to the lymph nodes of a number of cell types (B cells, CD4+ and CD8+ T cells). Electron microscopy demonstrates a fine network of FDCs with many long, finger-like processes that envelop virtually every lymphocyte in the germinal center (Fig. 173-18C). Extracellular virions can be seen attached to the processes, yet the FDCs appear to be relatively healthy. The trapping of antigen is a physiologically normal function for the FDCs, which present antigen to B cells and contribute to the generation of B cell memory. However, in the case of HIV, the trapped virions serve as a persistent source of cellular activation, resulting in the secretion of proinflammatory cytokines such as interleukin (IL) 1β, tumor necrosis factor (TNF) α, and IL-6, which can upregulate virus replication in infected cells (see below). Furthermore, although trapped virus is coated by neutralizing antibodies, it has been demonstrated that these virions remain infectious for CD4+ T cells while attached to the processes of the FDCs. CD4+ T cells that migrate into the germinal center to provide help to B cells in the generation of an HIV-specific immune response are susceptible to infection by these trapped virions. Thus, in HIV infection, a normal physiologic function of the immune system, which contributes to the clearance of virus as well as to the generation of a specific immune response, can also have deleterious consequences. It is difficult to demonstrate infection of the FDCs at this point, or even in advanced disease; however, rare examples of virus budding off FDCs have been reported.

As the disease progresses, the architecture of the germinal centers begins to show disruption, and the trapping efficiency of the lymph node diminishes. Electron microscopy reveals swollen organelles, and the FDCs begin to undergo cell death. The mechanisms of FDC death remain unclear; there is no indication by electron microscopy of copious virus replication or budding of virions off the cell in great quantities. As the disease progresses to an advanced stage, there is complete disruption of the architecture of the germinal centers, accompanied by...
in HIV-infected individuals with active TB, compared to pre-TB levels has also been shown that levels of plasma viremia are greatly elevated in addition to the fact that HIV-infected individuals are more likely to recognize infection in HIV-infected individuals (see below and Chap. 150). Plasma viremia is a common opportunistic infection in HIV-infected individuals, and levels of viremia after successful treatment of the active TB. In vitro studies demonstrated that virus replication was markedly enhanced in lymphocytes of HIV-infected individuals who were skin test–positive for purified protein derivative (PPD) when PPD antigen was added to culture, resulting in cellular activation. Confirmatory evidence that antigen-induced activation was a major contributor to the accelerated viremia in HIV-infected individuals with active TB was provided by studies in which HIV-infected individuals were immunized with common recall antigens such as tetanus toxoid, influenza, or pneumococcal polysaccharide. Under these circumstances, a transient elevation of plasma viremia accompanied the cellular activation induced by the immunization. A greater degree of induction of virus was seen in those individuals with early-stage as opposed to advanced stage HIV disease, and the degree of virus induction correlated with the level of immune system activation.

Persistent immune activation may have several deleterious consequences. From a virologic standpoint, although quiescent CD4+ T cells can be infected with HIV, reverse transcription, integration, and virus spread are much more efficient in activated cells. Furthermore, cellular activation induces expression of virus in cells latently infected with HIV (see above). From an immunologic standpoint, chronic exposure of the immune system to a particular antigen over an extended period may ultimately lead to an inability to sustain an adequate immune response to the antigen in question. Furthermore, the ability of the immune system to respond to a broad spectrum of antigens may be compromised if immunocompetent cells are maintained in a state of chronic activation. In addition, activation of the immune system may favor the elimination of cells via programmed cell death (apoptosis) (see below) as well as the secretion of certain cytokines that can induce HIV expression (see below).

**Apoptosis** Apoptosis is a form of programmed cell death that is a normal mechanism for the elimination of effete cells in organogenesis as well as in the cellular proliferation that occurs during a normal immune response (Chap. 295). Apoptosis is strictly dependent on cellular activation, and the aberrant cellular activation associated with HIV disease (see above) is correlated with a heightened state of apoptosis. It has been hypothesized that, in HIV infection, sequential activation signals delivered to CD4+ T cells induce apoptosis. Cross-linking of the CD4 molecule by gp120 or gp120/anti-gp120 complexes delivers the first of two signals required for apoptosis. The second signal supposedly leading to cell death is delivered via the T cell receptor by antigen. According to this hypothesis, direct infection of CD4+ T cells is not required for apoptosis to occur, although it has been demonstrated that alterations in tyrosine kinase activity of HIV-infected cells may be sufficient to induce apoptosis. HIV can trigger both Fas-dependent and Fas-independent pathways of apoptosis. Mechanisms involved in this process include upregulation of Fas and Fas ligand, inactivation of the immune system to respond to a broad spectrum of antigens may be compromised if immunocompetent cells are maintained in a state of chronic activation. In addition, activation of the immune system may favor the elimination of cells via programmed cell death (apoptosis) (see below) as well as the secretion of certain cytokines that can induce HIV expression (see below).

**Apoptosis** Apoptosis is a form of programmed cell death that is a normal mechanism for the elimination of effete cells in organogenesis as well as in the cellular proliferation that occurs during a normal immune response (Chap. 295). Apoptosis is strictly dependent on cellular activation, and the aberrant cellular activation associated with HIV disease (see above) is correlated with a heightened state of apoptosis. It has been hypothesized that, in HIV infection, sequential activation signals delivered to CD4+ T cells induce apoptosis. Cross-linking of the CD4 molecule by gp120 or gp120/anti-gp120 complexes delivers the first of two signals required for apoptosis. The second signal supposedly leading to cell death is delivered via the T cell receptor by antigen. According to this hypothesis, direct infection of CD4+ T cells is not required for apoptosis to occur, although it has been demonstrated that alterations in tyrosine kinase activity of HIV-infected cells may be sufficient to induce apoptosis. HIV can trigger both Fas-dependent and Fas-independent pathways of apoptosis. Mechanisms involved in this process include upregulation of Fas and Fas ligand,
upregulation of caspase-1 and caspase-6, downregulation of the anti-apoptotic Bcl-2 protein, and activation of cyclin-dependent kinases. Certain viral gene products have been associated with enhanced susceptibility to apoptosis including Envelope, Tat, and Vpr. In contrast, Nef has been shown to possess antiapoptotic properties. A number of studies, including those examining lymphoid tissue, have demonstrated that the rate of apoptosis is elevated in HIV infection and that apoptosis is seen in “bystander” cells such as CD8+ T cells and B cells as well as in CD4+ T cells. The intensity of apoptosis correlates with the general state of activation of the immune system and not with the stage of disease or with viral burden. The potential role of apoptosis in the pathogenesis of HIV disease is underscored by results from animal studies that show an increased frequency of apoptosis in CD4+ T cells in primates infected with pathogenic strains of SIV but not in primates infected with nonpathogenic strains of SIV. It is likely that apoptosis of immunocompetent cells contributes to the immune abnormalities in HIV disease; however, this is probably a nonspecific mechanism that merely reflects the aberrant state of immune activation.

Autoimmune Phenomena The autoimmune phenomena that are common in HIV-infected individuals reflect, at least in part, chronic immune system activation as well as molecular mimicry by viral components. Although these phenomena usually occur in the absence of autoimmune disease, a wide spectrum of clinical manifestations that may be associated with the immune system have been described (see below). Autoimmune phenomena include antibodies to lymphocytes and, less commonly, to platelets and neutrophils. Antiplatelet antibodies have some clinical relevance, in that they may contribute to the thrombocytopenia of HIV disease (see below). Antibodies to nuclear and cytoplasmic components of cells have been reported, as have antibodies to cardiolipin; CD4 molecules; CD43 molecules, C1q-A; variable chains; Fas; denatured collagen; and IL-2. In addition, autoantibodies to a range of serum proteins, including albumin, immunoglobulin, and thyroglobulin, have been reported. There is antigenic cross-reactivity between HIV viral proteins (gp120 and gp41) and MHC class II determinants, and anti-MHC class II antibodies have been reported in HIV infection. These antibodies could potentially lead to the elimination of MHC class II-bearing cells via antibody-dependent cellular cytotoxicity (ADCC) (Chap. 295). In addition, regions of homology exist between HIV envelope glycoproteins and IL-2 as well as MHC class I molecules.

The Cytokine Network in HIV Pathogenesis The immune system is homeostatically regulated by a complex network of immunoregulatory cytokines, which are pleiotropic and redundant and operate in an autocrine and paracrine manner. They are expressed continuously, even during periods of apparent quiescence of the immune system. On perturbation of the immune system by antigenic challenge, the expression of cytokines increases to varying degrees (Chap. 295). Cytokines that are important components of this immunoregulatory network have been demonstrated to play a major role in the regulation of HIV expression in vitro. Potent modulation of HIV expression has been demonstrated either by manipulating endogenous cytokines or by adding exogenous cytokines to culture. Cytokines that induce HIV expression in one or more of these systems include IL-1, IL-2, IL-3, IL-6, IL-12, TNF-α, TNF-β, macrophage colony-stimulating factor (M-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Among these cytokines, the most consistent and potent inducers of HIV expression are the proinflammatory cytokines TNF-α, IL-1β, and IL-6. Interferon (IFN)-α and -β suppress HIV replication, whereas transforming growth factor (TGF) β, IL-4, IL-10, and IFN-γ can either induce or suppress HIV expression, depending on the system involved. The CC-chemokines RANTES, macrophage inflammatory protein (MIP) 1α, and MIP-1β (Chap. 295) inhibit infection by and spread of R5 (macrophage-tropic) HIV-1 strains, while stromal cell–derived factor (SDF) 1 inhibits infection by and spread of X4 (T cell–tropic) strains (see below). The alpha defensin family of cytokines has been shown to inhibit both R5 and X4 viruses, and other soluble factors that have not yet been fully characterized have also been shown to suppress HIV replication. Blocking of endogenous HIV-inducing cytokines or addition of inhibitors of HIV suppressor cytokines in cultures of peripheral blood and lymph node mononuclear cells from HIV-infected individuals has demonstrated that HIV replication is controlled tightly by endogenous cytokines that act synergistically and in an autocrine and paracrine manner, similar to their physiologic function in the regulation of the immune system. Indeed, the net level of virus replication in an HIV-infected individual reflects at least in part a balance between inductive and suppressive host factors, mediated mainly by cytokines.

The molecular mechanisms of HIV regulation are best understood for NF-kB, which activates NF-kB proteins that function as transcriptional activators of HIV expression. The HIV-inducing effect of IL-1β is thought to occur at the level of viral transcription in an NF-kB-independent manner. IL-6, GM-CSF, and IFN-γ regulate HIV expression mainly by posttranscriptional mechanisms. Elevated levels of TNF-α and IL-6 have been demonstrated in plasma and cerebrospinal fluid (CSF), and increased expression of TNF-α, IL-1β, IFN-γ, and IL-6 has been demonstrated in the lymph nodes of HIV-infected individuals. The mechanisms whereby the CC-chemokines RANTES, MIP-1α, and MIP-1β inhibit infection of R5 strains of HIV involve blocking of the binding of the virus to its co-receptor, the CC-chemokine receptor CCR5 (see above and below). Of note is the fact that CC-chemokines that inhibit infection by R5 strains of virus actually enhance infection by X4 strains of virus by inducing intracellular signal transduction through the CCR5 and CD4 molecules. The mechanisms whereby other less well characterized factors (see above) inhibit HIV replication are not completely understood.

Lymphocyte Turnover in HIV Infection The immune systems of patients with HIV infection are characterized by a profound increase in lymphocyte turnover that is immediately reduced with effective antiretroviral therapy. Studies utilizing in vivo or in vitro labelling of lymphocytes in the S-phase of the cell cycle have demonstrated a tight correlation between the degree of lymphocyte turnover and plasma levels of HIV RNA. This increase in turnover is seen in CD4+ and CD8+ T lymphocytes as well as B lymphocytes and can be observed in peripheral blood and lymphoid tissue. Mathematical models derived from these data suggest that one can view the lymphoid pool as consisting of dynamically distinct subpopulations of cells that are differentially affected by HIV infection. A major consequence of HIV infection appears to be a shift in cells from a more quiescent pool to a pool with a higher turnover rate. It is likely that a consequence of a higher rate of turnover is a higher rate of death. The role of the thymus in adult human T cell homeostasis and HIV pathogenesis is an area of controversy. While some data point to an important role for the thymus in maintaining T cell numbers and suggest that impairment of thymic function may be responsible for the declines in CD4+ T cells seen in the setting of HIV infection, other studies have concluded that the thymus plays a minor role in HIV pathogenesis. Among the data supporting an important role for the thymus are those that demonstrate an increase in the levels of T cell receptor excision circles (TRECs) following initiation of antiretroviral therapy. TRECs are byproducts of T cell development and represent episomal fragments of DNA that are excised during T cell receptor gene rearrangement (Chap. 295). Levels of TRECs will be the net result of changes in thymic output and changes in T cell turnover. An increase in thymic output and/or a decrease in T cell turnover will lead to an increase in levels of TRECs. While it is clear that levels of TRECs increase following initiation of antiretroviral therapy, it is not clear whether this is a consequence of increased thymic output or decreased T cell turnover.

Cellular Tropism for HIV: Role of Co-Receptors HIV-1 utilizes two major co-receptors along with CD4 to bind to, fuse with, and enter target cells; these co-receptors are CCR5 and CXCR4, which are receptors for certain endogenous chemokines and belong to the seven-transmembrane-domain G protein–coupled family of receptors (see
X4 viruses, TES, MIP-1 α readily block entry of HIV. For example, the CC-chemokines RANTES, MIP-1α, and MIP-1β, which are the natural ligands for CCR5, block entry of R5 viruses, whereas SDF-1, the natural ligand for CXCRR4, blocks entry of X4 viruses. The mechanism of inhibition of viral entry is a steric inhibition of binding that is not dependent on signal transduction (Fig. 173-20).

The transmitting virus is almost invariably an R5 virus that predominates during the early stages of HIV disease. In ~40% of HIV-infected individuals, there is a transition to a predominantly X4 virus that is associated with a relatively rapid progression of disease. However, at least 60% of infected individuals progress in their disease while maintaining predominance of an R5 virus. Other chemokine receptor family members may function as co-receptors for HIV and SIV entry, but to a much lesser extent than do CCR5 and CXCR4; these include CCR3, BOB/GPR15, Bonzo/STR133/TYMSTR, CCR2, CCR8, CXCR1(V28), and GPR1.

The basis for the tropism of different envelope glycoproteins for either CCR5 or CXCR4 relates to the ability of the HIV envelope, particularly the third variable region (V3 loop) of gp120, to interact with these co-receptors. In this regard, binding of gp120 to CD4 induces a conformational change in gp120 that increases its affinity for CCR5. It appears that the interaction of gp120 with CXCR4 is less dependent on the conformational change induced in gp120 by CD4. In fact, there are X4 strains of HIV that bind to CXCR4 in the absence of surface-bound or soluble CD4. Finally, R5 viruses are more efficient in infecting monocyte/macrophages and microglial cells of the brain (see “Neuropathogenesis,” below).

**CELLULAR TARGETS OF HIV**

Although the CD4+ T lymphocytes and CD4+ cells of monocyte lineage are the principal targets of HIV, virtually any cell that expresses the CD4 molecule together with coreceptor molecules (see above and below) can potentially be infected with HIV. Circulating dendritic cells have been reported to express low levels of CD4, and depending on their stage of maturation, these cells can be infected with HIV (see below). Epidermal Langerhans cells express CD4 and have been infected by HIV in vivo. In vitro, HIV has been reported also to infect a wide range of cells and cell lines that express low levels of CD4, no detectable CD4, or only CD4 mRNA; among these are FDCs; megakaryocytes; eosinophils; astrocytes; oligodendrocytes; microglial cells; CD8+ T cells; B cells; NK cells; renal epithelial cells; cervical cells; rectal and bowel mucosal cells such as enterochromaffin, goblet, and columnar epithelial cells; trophoblastic cells; and cells from a variety of organs, such as liver, lung, heart, salivary gland, eye, prostate, testis, and adrenal gland. Since the only cells that have been shown unequivocally to be infected with HIV and to support replication of the virus are CD4+ T lymphocytes and cells of monocyte/macrophage lineage, the relevance of the in vitro infection of these other cell types is questionable.

Of potentially important clinical relevance is the demonstration that thymic precursor cells, which were assumed to be negative for CD3, CD4, and CD8 molecules, actually do express low levels of CD4 and can be infected with HIV in vitro. In addition, human thymic epithelial cells transplanted into an immunodeficient mouse can be infected with HIV by direct inoculation of virus into the thymus. Since these cells may play a role in the normal regeneration of CD4+ T cells, it is possible that their infection and depletion contribute, at least in part, to the impaired ability of the CD4+ T cell pool to completely reconstitute itself in certain infected individuals in whom antiretroviral therapy has suppressed viral replication to <50 copies of HIV RNA per milliliter (see below). In addition, CD34+ monocyte precursor cells have been shown to be infected in vivo in patients with advanced HIV disease. It is likely that these cells express low levels of CD4, and therefore it is not essential to invoke CD4-independent mechanisms to explain the infection.

**ABNORMALITIES OF MONONUCLEAR CELLS**

### CD4+ T Cells

The range of T cell abnormalities in advanced HIV infection is broad. The defects are both quantitative and qualitative and affect virtually every limb of the immune system (see below), indicating the critical dependence of the integrity of the immune system on the inducer/helper function of CD4+ T cells. In advanced HIV disease, virtually all of the observed immune defects can ultimately be explained by the quantitative depletion of CD4+ T cells. However, T cell dysfunction (see below) can be demonstrated in patients early in the course of infection, even when the CD4+ T cell count is in the low-normal range. The degree and spectrum of dysfunctions increase as the disease progresses. One of the first abnormalities to be detected is a defect in response to remote recall antigens, such as tetanus toxoid and influenza, at a time when mononuclear cells can still respond normally to mitogenic stimulation. Defects in responses to soluble antigens are followed in time by the loss of T cell proliferative responses to alloantigens, and subsequently to mitogens. Essentially every T cell function has been reported to be abnormal at some stage of HIV infection. These abnormalities include defective T cell cloning and colony-forming efficiencies, impaired expression of IL-2 receptors, defective IL-2 production, and decreased IFN-γ production in response to antigens. The proportion of CD4+ T cells that express CD28, which is a major co-stimulatory molecule necessary for the normal activation of T cells, is reduced during HIV infection. Cells lacking expression of CD28 do not respond normally...
to activation signals and may express markers of terminal activation including HLA-DR, CD38, and CD45RO. CD4+ T cells from HIV-infected individuals express abnormally low levels of CD40 ligand, which may contribute to the dysregulation of B cell function observed in HIV disease.

It is difficult to explain completely the profound immunodeficiency noted in HIV-infected individuals solely on the basis of direct infection and quantitative depletion of CD4+ T cells. This is particularly apparent during the early stages of HIV disease, when CD4+ T cell numbers may be only marginally decreased. In this regard, it is likely that CD4+ T cell dysfunction results from a combination of depletion of cells due to direct infection of the cell and a number of virus-related but indirect effects on the cell (Table 173-6). Indeed, it has been demonstrated that patients with high levels of plasma viremia have a variety of subtle abnormalities of CD4+ T cell function, particularly involving aberrancies in signal transduction pathways. These abnormalities could be due either to aberrant activation induced by the cascade of cytokines that are expressed in viremic patients or by the direct effect of virus on the cell. In this regard, certain of these abnormalities may lead to the generation of autoantibodies to self-MHC determinants. In fact, anti-HLA-DR antibodies have been demonstrated in the sera of HIV-infected individuals (see “Autoimmune Phenomena,” above). These antibodies could contribute to the elimination of HLA-DR+ T cells by ADCC; in addition, it has been suggested that these antibodies may inhibit certain T cell functions that involve HLA-DR molecules.

HIV envelope glycoproteins gp120 and gp160 manifest high-affinity binding to CD4 as well as to various chemokine receptors (see above). Intracellular signals transduced by gp120 have been associated with a number of immunopathogenic processes including anergy, apoptosis, and abnormalities of cell trafficking. The mechanisms responsible for these abnormalities include dysregulation of the T cell receptor–phosphoinositide pathway, p56lck activation, phosphorylation of focal adhesion kinase, activation of the MAP kinase and ras signaling pathways, and downregulation of the co-stimulatory molecules CD40 ligand and CD80.

Finally, the inexorable decline in CD4+ T cell counts that occurs in most HIV-infected individuals may result in part from the inability of the immune system to regenerate the rapidly turning over CD4+ T cell pool efficiently enough to compensate for both HIV-mediated and naturally occurring attrition of cells. At least two major mechanisms may contribute to the failure of the CD4+ T cell pool to reconstitute itself adequately over the course of HIV infection. The first is the destruction of lymphoid precursor cells, including thymic and bone marrow progenitor cells (see above); the other is the gradual disruption of the lymphoid tissue microenvironment, which is essential for efficient regeneration of immunocompetent cells (see above).

**CD8+ T Cells** A relative C8+ T lymphocytosis is generally associated with high levels of HIV plasma viremia and may in part reflect the expansion of clones of HIV-specific CD8+ CTLs. During the late stages of HIV infection, there may be a significant reduction in the numbers of CD8+ T cells despite the presence of high levels of viremia. HIV-specific CD8+ CTLs have been demonstrated in HIV-infected individuals early in the course of disease (see below). The emergence of HIV escape mutants may ultimately evade these HIV-specific CD8+ T cells. However, as the disease progresses, the functional capability of these cells may decrease and may be lost entirely. The cause of this loss of cytolytic activity is unclear. However, it has been demonstrated that, as disease progresses, CD8+ T cells assume an abnormal phenotype characterized by expression of activation markers such as HLA-DR with an absence of expression of the IL-2 receptor (CD25) and a loss of clonogenic potential. In this regard, it has been reported that nonprogressors can be distinguished from progressors by the maintenance in the former of a high proliferative capacity of their HIV-specific CD8+ T cells coupled to increases in perforin expression. It has been reported that the phenotype of CD8+ T cells in HIV-infected individuals may be of prognostic significance. Those individuals whose CD8+ T cells developed a phenotype of HLA-DR+/CD38– following seroconversion had stabilization of their CD4+ T cell counts, whereas those whose CD8+ T cells developed a phenotype of HLA-DR+/CD38+ had a more aggressive course and a poorer prognosis. In addition to the defects in HIV-specific CTLs, functional defects in other MHC-restricted CTLs, such as those directed against influenza and CMV, have been demonstrated. CD8+ T cells secrete a variety of soluble factors that inhibit HIV replication including the CC-chemokines RANTES, MIP-1α, MIP-1β, and the alpha defensins -1, -2, and -3, as well as one or more as yet poorly identified factors (see above). The presence of high levels of HIV viremia in vivo as well as exposure of CD8+ T cells in vitro to HIV envelope has been shown to be associated with a variety of cellular functional abnormalities. Finally, since the integrity of CD8+ T cell function depends in part on adequate induction from CD4+ T cells, the defect in CD8+ CTLs is likely compounded by the quantitative loss and qualitative dysfunction of CD4+ T cells.

B Cells  The predominant defect in B cells from HIV-infected individuals is one of aberrant cellular activation, which is reflected by spontaneous proliferation and immunoglobulin secretion and by increased spontaneous secretion of TNF-α and IL-6. In addition, B cells from HIV viremic patients manifest a decreased capacity to mount a proliferative response to ligation of the B cell antigen receptor (surface IgM) at the same time as they are capable of robust differentiation in response to a variety of stimuli. B cells from HIV-infected individuals manifest enhanced spontaneous in vitro transformation with EBV, a process that is likely due to defective T cell immune surveillance. The in vivo counterpart of this phenomenon is an increase in the incidence of EBV-related B cell lymphomas. Untransformed B cells cannot be infected with HIV. However, HIV or its products can activate B cells directly. Proteins of the HIV gp120 envelope protein have been shown to induce polyclonal B cell activation. In addition, it has been reported that products of the VH genes on the surface of B cells can serve as a receptor for HIV. B cells from patients with high levels of viremia bind virions to their surface via the CD21 complement receptor. It is likely that in vivo activation of B cells by virus products during the viremic state accounts at least in part for the spontaneous activation of these cells noted ex vivo. B cells from HIV-infected individuals express abnormally low levels of HLA-DR and CD21 on their surface. Cognate B cell–CD4+ T cell interactions are abnormal in viremic HIV-infected individuals. B cells respond poorly to CD4+ T cell help; this is due at least in part to an intrinsic defect in responder B cells with regard to their inability to normally upregulate CD25 (IL-2 receptor) and thus to proliferate normally in response to IL-2; in addition, B cells fail to adequately upregulate CD80 and CD86 following stimulation with activated T cells. In vivo, the aberrant activated state of B cells manifests itself by hypergammaglobulinemia and by the presence of circulating immune complexes and autoantibodies (see above). HIV-infected individuals respond poorly to primary and secondary immunizations with protein and polysaccharide antigens. These B cell defects are likely responsible in part for the increase in certain bacterial infections seen in advanced HIV disease in adults, as well as for the important role of bacterial infections in the morbidity and mortality of HIV-infected children, who cannot mount an adequate humoral response to common bacterial pathogens. The absolute number of circulating B cells may be depressed in primary HIV infection; however, this phenomenon is usually transient and likely reflects in part a redistribution of cells out of the circulation and into the lymphoid tissue. In certain patients, the number of circulating B cells decreases in advanced-stage disease.

Monocyte/Macrophages  Circulating monocytes are generally normal in number in HIV-infected individuals. Monocytes express the CD4 molecule and several co-receptors for HIV on their surface, including CCR5, CXCR4, and CCR3, and thus are targets of HIV infection. Of note is the fact that the degree of cytopathicity of HIV for cells of the monocyte lineage is low, and HIV can replicate extensively in cells of the monocyte lineage with little cytopathic effect. Hence, monocyte-lineage cells may play a role in the disseminaton of HIV in the body and can serve as reservoirs of HIV infection, thus representing an obstacle to the eradication of HIV by antiretroviral drugs. In vivo infection of circulating monocytes is difficult to demonstrate; however, infection of tissue macrophages and macrophage-lineage cells in the brain (infiltrating macrophages or resident microglial cells) and lung (pulmonary alveolar macrophages) can be demonstrated easily. Tissue macrophages are an important source of HIV during opportunistic infections. Infection of monocyte precursors in the bone marrow may directly or indirectly be responsible for certain of the hematologic abnormalities in HIV-infected individuals. A number of abnormalities of circulating monocytes have been reported in HIV-infected individuals, including decreased secretion of IL-1 and IL-12; increased secretion of IL-10; defects in antigen presentation and induction of T cell responses; increased expression of Fc receptor–mediated clearance, abnormalities of Fc receptor function, C3 receptor–mediated clearance, oxidative burst responses, and certain cytotoxic functions such as ADCC, possibly related to low levels of expression of Fc and complement receptors. Exposure of monocytes to viral proteins such as gp120 and Tat, as well as to certain cytokines, can cause abnormal activation, and this may play a role in cellular dysfunction (see above).

Dendritic and Langerhans Cells  Dendritic cells play an important role in the initiation of HIV infection by virtue of the ability of HIV to bind to cell surface C-type lectin receptors, particularly DC-SIGN (see above). This allows efficient presentation of virus to CD4+ T cell targets that become infected; complexes of infected CD4+ T cells and dendritic cells provide an optimal microenvironment for virus replication. There has been considerable disagreement regarding the HIV infectibility and hence the depletion as well as the dysfunction of dendritic cells themselves. Depending on their state of maturation, dendritic cells express varying levels of CD4 as well as several chemokine receptors. In this regard, it appears that the ability of a dendritic cell to become infected depends in part on its state of maturation. Mature dendritic cells have been demonstrated to be infectable by both R5 and X4 isolates of HIV-1. Immature tissue dendritic cells have been less well studied in their native state. Even in those dendritic cells in which infection occurs, the efficiency of infection and level of productivity of infection is quite low compared to CD4+ T cells.

Natural Killer Cells  The role of NK cells is to provide immunosurveillance against virus-infected cells, certain tumor cells, and alloimmune cells (Chap. 295). Functional abnormalities in NK cells have been observed throughout the course of HIV disease, and the severity of these abnormalities increases as disease progresses. Most studies report that NK cells are normal in number and phenotype in HIV-infected individuals; however, a numerical decrease in the CD16+/CD56+ subpopulation of NK cells has been reported together with an increase in activation markers. The abnormality in NK cell function is thought to result from a defect in postbinding lysis. However, the lytic machinery does not appear to be impaired, since NK cells from HIV-infected individuals mediate ADCC normally. The addition of either IL-2, IL-12, IL-15, or IFN-α to cultures improves the defective in vitro NK cell function of HIV-infected individuals. HIV-mediated down-regulation of HLA-A and -B, but not HLA-C and -D molecules may inhibit NK-mediated killing of HIV-infected target cells. NK cells serve as important sources of HIV-inhibitory CC-chemokines. NK cells isolated from HIV-infected individuals constitutively produce high levels of MIP-1α, MIP-1β, and RANTES. In addition, high levels of these chemokines are seen when NK cells are stimulated with IL-2 or IL-15 or when CD16 is cross-linked during the process of lytic killing of target cells. HIV-infected patients with high levels of plasma viremia manifest a decreased ability, compared to HIV-infected individuals who are aviremic, of their NK cells to block HIV replication in vitro in assays of both cell contact and supernatant-mediated suppression of virus. In addition, viremic patients have a decrease in expression of activating receptors (responsible for killer activity) and an increase in certain inhibitory receptors (responsible for inhibition of killer activity) on NK cells, suggesting one potential mechanism whereby viremia might inhibit the ability of NK cells to kill HIV-infected target cells.

GENETIC FACTORS IN HIV PATHOGENESIS  Several reports have described MHC alleles and other host factors that may influence the pathogenesis and course of HIV disease. These include associations with certain HIV-related manifestations, such as KS and diffuse lymphadenopathy, or with the type of clinical course, such as long-term survival or rapid progression (Table 173-7). A number of mechanisms have been proposed whereby MHC-encoded molecules might predispose an individual either to rapid progression or to nonprogression to AIDS. These proposed mechanisms include the ability to present certain immunodominant HIV T helper or CTL epitopes, leading to a relatively protective immune response against HIV and hence to slow progression of disease. In contrast, certain MHC class I or class II alleles might predispose an individual to an immunopathogenic response against
viral epitopes in certain tissues, such as the CNS or lungs, or against certain HIV-infected cell types, such as macrophages or dendritic cells/Langerhans cells. In addition, certain rare MHC class I and class II alleles might facilitate rapid recognition of HIV-infected cells from the infecting partner in primary HIV infection and promote rejection of these cells by alloreactive responses. Similarly, common MHC alleles could lead to less effective removal of HIV-infected allogeneic cells. It has been clearly demonstrated that maximal HLA heterozygosity for class I loci (A, B, and C) is associated with a delayed onset of AIDS among HIV-infected individuals, whereas homozygosity for these loci was associated with a more rapid progression to AIDS and death. This observation is likely due to the fact that individuals who are heterozygous at HLA loci are able to present a greater variety of antigenic peptides to cytotoxic T lymphocytes than are homozygotes, resulting in a more effective immune response against a number of pathogens including HIV. Of particular note is the fact that the HLA class I alleles B*35 and Cw*04 were consistently associated with rapid development of AIDS. Other data have indicated that transporter associated with antigen-presenting (TAP) genes play a role in determining the outcome of HIV infection. HLA profiles that reflect certain combinations of MHC-encoded TAP and class I and class II genes are strongly associated with different rates of progression to AIDS. A recent finding of genetic association with HIV disease progression has highlighted the role for NK cells in HIV disease. A single nucleotide

polymorphism (SNP) in the killer immunoglobulin-like receptor (KIR) gene was shown to be strongly associated with rapid progression to AIDS. However, when the KIR3 DS1 SNP was present with HLA-B Bw4-80I, the resultant phenotype was delayed progression to AIDS, even though this HLA-B allele alone has no effect on HIV disease progression. Furthermore, the KIR3 DS1/HLA-B Bw4-80I-carrying individuals had a significantly reduced viral load, beginning early in the course of infection. This points to the potential role of NK cells in the maintenance of the viral set point, strongly suggesting that HLA-B Bw4-80I serves as the ligand activating this KIR receptor, resulting in the death of the target cell.

The most dramatic example of a genetic factor influencing HIV infection and/or pathogenesis relates to the gene that codes for the HIV co-receptor CCR5. Rare individuals have been reported who had had repetitive sexual exposure to HIV in high-risk situations but remained uninfected. The peripheral blood mononuclear cells of two such individuals were found to be highly resistant to infection in vitro with R5 strains of HIV-1, but they were readily infected with X4 strains. Genetic analysis revealed that these two individuals inherited a homozygous defect in the gene that codes for CCR5, the cellular co-receptor for R5 strains of HIV-1. The defective CCR5 allele contained a 32-bp deletion corresponding to the second extracellular loop of the receptor. The encoded protein was severely truncated, and the receptor was nonfunctional, explaining the refractoriness to infection with R5 strains of HIV-1. Population studies revealed that ~1% of the Caucasian population of western European ancestry possessed the homozygous defect. Up to 20% of this group had the homozygous defect. Of note, cohort studies of hundreds of DNA samples originating from western and central Africa and Japan did not reveal a single mutant allele, suggesting that the allele is either absent or extremely rare in Africa and Japan. In a cohort of 1400 HIV-1–infected Caucasian individuals, no subject homozygous for the mutation was found, strongly supporting the concept that the homozygous defect confers protection against infection. This finding is particularly compelling in light of the fact that transmitting viruses are strongly biased towards R5 strains of HIV-1 (see above). Furthermore, there was a higher frequency of individuals homozygous for the genetic defect among HIV-infected patients who were long-term nonprogressors compared to HIV-infected individuals who progressed more rapidly (see above). Of note, several individuals have been identified who were homozygous for the CCR5-Δ32 defect who in fact did become infected with HIV. These individuals were found to have an X4 strain of HIV that was associated in some cases with an accelerated course of disease. Slow progression of HIV disease is also seen in individuals who are homozygous for the CCR2-64I mutation or SNP; this is felt to be due to dimerization of CXCR4 with the mutated CCR2-64I resulting in a decreased expression of CXCR4 on the cell surface. Delayed progression of disease is also seen in those individuals who have any of a number of SNPs in the CCR5 promoter. In addition, individuals who carry a certain allele (IL-10-5-592A) of the IL-10 promoter are at increased risk of infection and, once infected, progress more rapidly than homozygotes for the alternative genotype. The mechanism of this effect is felt to be a downregulation of the inhibitory cytokine IL-10 resulting in facilitation of HIV replication. The SNP, IL-4-589T, increases IL-4 production. This allele associates with a slower progression to AIDS, presumably through the downregulation of CCR5 by higher and more sustained levels of IL-4. Separate SNPs have been found in the RANTES gene that correlate with either an increased or decreased expression of this chemokine (Table 173-7). As expected, based upon the effect of RANTES as an inhibitor of R5 HIV, RANTES-28G SNP upregulates RANTES and is associated with delayed progression to AIDS. The opposite effects are seen with SNP RANTES In1.1C. This SNP decreases RANTES expression and correlates strongly with rapid progression to AIDS. Other SNPs that decrease RANTES expression are associated with a higher rate of HIV infection, reinforcing the central role for R5 viruses in the establishment of HIV infection.

Additional genes have been found that are associated with rapid progression to AIDS or susceptibility to significant AIDS complication. Homozygosity for the vitamin D receptor form B correlates with rapid progression to AIDS. The mechanism is thought to relate to the known effects of vitamin D on immune modulation. The TNF-α SNP-238A is associated with a higher frequency of lipodystrophy. The underlying causes of this complication of AIDS remain to be defined, including the role of combination antiretroviral therapy. Finally, SNP IL-6-174G has been shown to lead to higher levels of IL-6. Homozygosity at this locus correlates with an increased risk of development of KS. Not surprisingly, homozygosity for SNP IL-6-174C, which results in lower levels of IL-6, was protective, correlating with significantly lower levels of KS.

NEUROPATHOGENESIS HIV-infected individuals can experience a variety of neurologic abnormalities due either to opportunistic infections and neoplasms (see below) or to direct effects of HIV or its products. With regard to the latter, HIV has been demonstrated in the brain and CSF of infected individuals with and without neuropsychiatric abnormalities. The main cell types that are infected in the brain in vivo are the perivascular macrophages and the microglial cells; monocytes that have already been infected in the blood can migrate into the brain, where they then reside as macrophages, or macrophages can be directly infected within the brain. The precise mechanisms whereby HIV enters the brain are unclear; however, they are felt to relate, at least in part, to the ability of virus-infected and immune-activated macrophages to induce adhesion molecules such as E-selectin and vascular cell adhesion molecule-1 (VCAM-1) on brain endothelium. Other studies have demonstrated that HIV gp120 enhances the expression of intercellular adhesion molecule-1 (ICAM-1) in glial cells; this effect may facilitate entry of HIV-infected cells into the CNS and may promote syncytia formation. Virus isolates from the brain are preferentially R5 strains as opposed to X4 strains (see above); in this regard, HIV-infected individuals who are heterozygous for CCR5-Δ32 appear to be relatively protected against the development of HIV encephalopathy compared to wild-type individuals. Distinct HIV envelope sequences are associated with the clinical expression of the AIDS dementia complex (see below). Although there have been reports of infrequent HIV infection of neuronal cells and astrocytes, there is no convincing evidence that brain cells other than those of monocyte/macrophage lineage can be productively infected in vivo.

HIV-infected individuals may manifest white matter lesions as well as neuronal loss. Given the relative absence of evidence of HIV infection of neurons either in vivo or in vitro, it is unlikely that direct infection of these cells accounts for their loss. Rather, the HIV-mediated effects on neurons and oligodendrocytes are felt to involve indirect pathways whereby viral proteins, particularly gp120 and Tat, trigger the release of endogenous neurotoxins from macrophages and to a lesser extent from astrocytes. In addition, it has been demonstrated that both HIV-1 Nef and Tat can induce chemotaxis of leukocytes, including monocytes, into the CNS. Neurotoxins can be released from monocytes as a consequence of infection and/or immune activation. Monocyte-derived neurotoxic factors have been reported to kill neurons via the N-methyl-D-aspartate (NMDA) receptor. In addition, HIV gp120 shed by virus-infected monocytes could cause neurotoxicity by antagonizing the function of vasoactive intestinal peptide (VIP), by elevating intracellular calcium levels, and by decreasing nerve growth factor levels in the cerebral cortex. A variety of monocyte-derived cytokines can contribute directly or indirectly to the neurotoxic effects in HIV infection; these include TNF-α, IL-1, IL-6, TGF-β, IFN-γ, platelet-activating factor, and endothelin. Furthermore, among the CC-chemokines, elevated levels of monocyte chemotactic protein (MCP)1 in the brain and CSF have been shown to correlate best with the presence and degree of HIV encephalopathy. In addition, infection and/or predetermination of monocytes/macrophages can result in increased production of eicosanoids, nitric oxide, and quinolinic acid, which may contribute to neurotoxicity. Astrocytes may play diverse roles in HIV
neuropathogenesis. Reactive gliosis or astrocytosis has been demonstrated in the brains of HIV-infected individuals, and TNF-α and IL-6 have been shown to induce astrocyte proliferation. In addition, astrocyte-derived IL-6 can induce HIV expression in infected cells in vitro. Furthermore, it has been suggested that astrocytes may down-regulate macrophage-produced neurotoxins. It has been reported that HIV-infected individuals with the E4 allele for apolipoprotein E (apo E) are at increased risk for AIDS encephalopathy and peripheral neuropathy. The likelihood that HIV or its products are involved in neuropathogenesis is supported by the observation that neuropsychiatric abnormalities may undergo remarkable and rapid improvement upon the initiation of antiretroviral therapy; this is true of HIV-infected children as well as adults. In fact, there has been a remarkable decrease in the incidence of HIV encephalopathy in the era of successful combination antiretroviral therapy.

PATHOGENESIS OF KAPOSI’S SARCOMA There are at least four distinct epidemiologic forms of KS: (1) the classic form that occurs in older men of predominantly Mediterranean or eastern European Jewish backgrounds with no recognized contributing factors; (2) the equatorial African form that occurs in all ages, also without any recognized precipitating factors; (3) the form associated with organ transplantation and its attendant iatrogenic immunosuppressed state; and (4) the form associated with HIV-1 infection. In the latter two forms, KS is an opportunistic disease; in HIV-infected individuals, unlike typical opportunistic infections, its occurrence is not strictly related to the level of depression of CD4+ T cell counts (see below). The pathogenesis of KS is complex; fundamentally, it is an angioproliferative disease that is not a true neoplastic sarcoma, at least not in its early stages. It is a manifestation of excessive proliferation of spindle cells that are believed to be of vascular origin and have features in common with endothelial and smooth-muscle cells. In HIV disease the development of KS is dependent on the interplay of a variety of factors including HIV-1 itself, human herpes virus 8 (HHV-8), immune activation, and cytokine secretion. A number of epidemiologic and virologic studies have clearly linked HHV-8, which is also referred to as Kaposi’s sarcoma–associated herpesvirus (KSHV), to KS not only in HIV-infected individuals but also in individuals with the other forms of KS. HHV-8 is a γ-herpesvirus related to EBV and herpesvirus saimiri. It encodes a homologue to human IL-6 and in addition to KS has been implicated in the pathogenesis of body cavity lymphoma, multiple myeloma, and monoclonal gammapathy of undetermined significance. Sequences of HHV-8 are found universally in the lesions of KS, and patients with KS are virtually all seropositive for HHV-8. HHV-8 DNA sequences can be found in the B cells of 30 to 50% of patients with KS and 7% of patients with AIDS without clinically apparent KS.

Between 1 and 2% of eligible blood donors are positive for antibodies to HHV-8, while the prevalence of HHV-8 seropositivity in HIV-infected men is 30 to 35%. The prevalence in HIV-infected women is ~4%. This finding is reflective of the lower incidence of KS in women. It has been debated whether HHV-8 is actually the transforming agent in KS; the bulk of the cells in the tumor lesions of KS are not neoplastic cells. However, it has been demonstrated that endothelial cells can be transformed in vitro by HHV-8. In this regard, HHV-8 possesses a number of genes including homologues of the IL-8 receptor, Bcl-2, and cyclin D, which can potentially transform the host cell. Despite the complexity of the pathogenic events associated with the development of KS in HIV-infected individuals, it is generally agreed that HHV-8 is indeed the etiologic agent of this disease. The initiation and/or propagation of KS requires an activated state and is mediated, at least in part, by cytokines. A number of factors, including TNF-α, IL-1β, IL-6, GM-CSF, basic fibroblast growth factor, and oncostatin M, function in an autocrine and paracrine manner to sustain the growth and survival of the KS spindle cells. In this regard, KSHV-derived IL-6 has been demonstrated to induce proliferation of lymphoma cells and to inhibit the cytostatic effects of INF-α on KSHV-infected lymphoma cells. It has been suggested that the HIV Tat protein plays a major role in the pathogenesis of KS. In this regard, it has been demonstrated that IFN-γ can induce endothelial cells to proliferate and to invade the extracellular matrix in response to HIV Tat. This occurs as a result of the upregulation by IFN-γ of the expression and activity of the receptors for Tat, which are the integrins αvβ3 and αvβ5. In addition, the HIV-1 Tat protein has been shown to act synergistically with basic fibroblast growth factor in the induction of lesions resembling KS lesions in mice by increasing matrix-metalloproteinase-2 secretion and activation in endothelial cells. Glucocorticoids have been shown to have a stimulatory effect, and human chorionic gonadotropin an inhibitory effect, on KS spindle cells, suggesting that modulation of the balance of autocrine factors may have therapeutic potential in KS. It has been demonstrated that HIV protease inhibitors have potent anti-angiogenic properties and, as such, promote regression of KS.

IMMUNE RESPONSE TO HIV As detailed above and below, following the initial burst of viremia during primary infection, HIV-infected individuals mount a robust immune response that usually substantially curtails the levels of plasma viremia and likely contributes to delaying the ultimate development of clinically apparent disease for a median of 10 years. This immune response contains elements of both humoral and cell-mediated immunity (Table 173-8; Fig. 173-21). It is directed against multiple antigenic determinants of the HIV virion as well as against viral proteins expressed on the surface of infected cells. Ironically, those CD4+ T cells with T cell receptors specific for HIV are theoretically those CD4+ T cells most likely to bind to infected cells and themselves be infected and destroyed. Thus, an early consequence of HIV infection may be interference with the generation of an effective immune response through the elimination or compromise of HIV-specific CD4+ T lymphocytes.

Although a great deal of investigation has been directed toward delineating and better understanding the components of this immune response, it remains unclear which of these phenomena are most important in delaying progression of infection and which, if any, play a role in the pathogenesis of HIV disease. This lack of knowledge has also hampered the ability to develop an effective vaccine for HIV disease.

HUMORAL IMMUNE RESPONSE Antibodies to HIV usually appear within 6 weeks and almost invariably within 12 weeks of primary infection (Fig. 173-22); rare exceptions are individuals who have defects in the ability to produce HIV-specific antibodies. Detection of these antibodies forms the basis of most diagnostic screening tests for HIV infection. The appearance of HIV-binding antibodies detected by ELISA and western blot assays occurs prior to the appearance of neutralizing antibodies; the latter generally appear following the initial decreases in plasma viremia, which is more closely related to the appearance of HIV-specific CD8+ T lymphocytes. The first antibodies detected are

FIGURE 173-21 Schematic representation of the different immunologic effector mechanisms felt to be active in the setting of HIV infection. Detailed descriptions are given in the text. TCR, T cell receptor; ADCC, antibody dependent cellular cytotoxicity; MHC, major histocompatibility complex.

Neutralizing antibodies to the envelope proteins (gp160, gp120, p88, and gp41) and antibodies to the gag proteins are followed by the appearance of antibodies associated with a decrease in the serum levels of free p24 antigen. The development of antibodies to p24 may be associated with a decrease in the serum levels of free p24 antigen. Antibodies to the gag proteins are followed by the appearance of antibodies to the envelope proteins (gp160, gp120, p88, and gp41) and to the products of the pol gene (p31, p51, and p66). In addition, one may see antibodies to the low-molecular-weight regulatory proteins encoded by the HIV genes vpr, vpu, vif, rev, tat, and nef.

While antibodies to multiple antigens of HIV are produced, the precise functional significance of these different antibodies is unclear. The best studied have been the antibodies directed toward the envelope proteins of the virus. As noted above, the envelope of HIV consists of an outer envelope glycoprotein with a molecular mass of 120 kDa and a transmembrane glycoprotein with a molecular mass of 41 kDa. These are initially synthesized as a 160-kDa precursor that is cleaved by cellular proteases. Most of the envelope antibodies are directed either toward an epitope in the gp41 region comprising amino acids 579 to 613 or toward a hypervariable region in the gp120 molecule, known as the V3 loop region, comprising amino acids 303 through 338. This V3 region is a major site for the development of mutations that lead to variants of HIV that are not well recognized by the immune system. Antibodies directed toward the envelope proteins of HIV have been characterized both as being protective and as possibly contributing to the pathogenesis of HIV disease. Among the protective antibodies are those that function to neutralize HIV directly and prevent the spread of infection to additional cells, as well as those that participate in ADCC. Neutralizing antibodies may be a component of primary HIV infection, and some long-term nonprogressors have been reported to have increased titers of neutralizing antibodies. Neutralizing antibodies appear to be of two forms, type-specific and group-specific. Type-specific neutralizing antibodies are generally directed to the V3 loop region. These antibodies neutralize only viruses of a given strain and are present in low titer in most infected individuals. Group-specific neutralizing antibodies are capable of neutralizing a wide variety of HIV isolates. At least two forms of group-specific antibodies have been identified: those binding to amino acids 423 to 437 of gp120 and those binding to amino acids 728 to 745 of gp41. The other major class of protective antibodies are those that participate in ADCC, which is actually a form of cell-mediated immunity (Chap. 295) in which NK cells that bear Fc receptors are armed with specific anti-HIV antibodies that bind to the NK cells via their Fc portion. These armed NK cells then bind to and destroy cells expressing HIV antigens. Antibodies to both gp120 and gp41 have been shown to participate in ADCC-mediated killing of HIV-infected cells.

FIGURE 173-22 Relationship between antigenemia and the development of antibodies to HIV. Antibodies to HIV proteins are generally seen 6 to 12 weeks following infection and 3 to 6 weeks after the development of plasma viremia. Late in the course of illness, antibody levels to p24 decline, generally in association with a rising titer of p24 antigen.

In addition to playing a role in host defense, HIV-specific antibodies have also been implicated in disease pathogenesis. Antibodies directed to gp41, when present in low titer, have been shown in vitro to be capable of facilitating infection of cells through an Fc receptor-mediated mechanism known as antibody enhancement. Thus, the same regions of the envelope protein of HIV that give rise to antibodies capable of mediating ADCC also elicit the production of antibodies that can facilitate infection of cells in vitro. In addition, it has been postulated that anti-gp120 antibodies that participate in the ADCC killing of HIV-infected cells might also kill uninfected CD4+ T cells if the uninfected cells had bound free gp120, a phenomenon referred to as bystander killing.

Cellular Immune Response

Given the fact that T cell–mediated immunity is known to play a major role in host defense against most viral infections (Chap. 295), it is generally thought to be an important component of the host immune response to HIV. T cell immunity can be divided into two major categories, mediated respectively by the helper/inducer CD4+ T cells and the cytotoxic/immunoregulatory CD8+ T cells.

HIV-specific CD4+ T cells can be detected in the majority of HIV-infected patients through the use of flow cytometry to measure single-
cell IFN-γ production in response to HIV antigens, binding to MHC class II tetramers, or HIV p24 lymphocyte proliferation assays. Although these cells, with their high affinity for binding to HIV-infected cells, may be among the first to be infected and destroyed during HIV infection, they also are likely to undergo clonal expansions in response to HIV antigens and thus survive as a population of cells. No clear correlations exist between levels of HIV-specific CD4+ T lymphocytes and plasma HIV RNA levels; however, in the setting of high viral loads, CD4+ T cell responses to HIV antigens appear to shift from one of proliferation to one of IFN-γ production. Thus, while a reverse correlation exists between the level of p24-specific proliferation and levels of plasma HIV viremia, the nature of the causal relationship between these parameters is unclear. Through the use of computer modeling, several regions of the HIV-1 envelope molecule have been identified that are structurally analogous to other known T cell epitopes by virtue of having structures known as amphipathic helices. Peptides from these envelope regions have been used to identify the presence of CD4+ T cells specific for these regions in the peripheral blood of HIV-infected individuals. Other studies have demonstrated that peripheral blood T cells of some healthy, HIV-negative individuals also react to the envelope proteins of HIV. It is unclear whether or not this represents the presence of a degree of protective immunity in these individuals.

MHC class I–restricted, HIV-specific CD8+ T cells have been identified in the peripheral blood of patients with HIV-1 infection. These cells include CTLs and T cells that can be induced by HIV antigens to express cytokines such as IFN-γ. CTLs have been identified in the peripheral blood of patients within weeks of HIV infection. These CD8+ T lymphocytes, through their HIV-specific antigen receptors, bind to and cause the lytic destruction of target cells bearing autologous MHC class I molecules associated with HIV antigens. Two types of CTL activity can be demonstrated in the peripheral blood or lymph node mononuclear cells of HIV-infected individuals. The first type directly lysos appropriate target cells in culture without prior in vitro stimulation (spontaneous CTL activity). The other type of CTL activity reflects the precursor frequency of CTLs (CTLp); this type of CTL activity can be demonstrated by stimulation of CD8+ T cells in vitro with a mitogen such as phytohemagglutinin or anti-CD3 antibody. Following primary HIV infection, the qualitative nature of the HIV-specific CTL response is an important predictor of eventual clinical outcome. Patients who mount a broad CD8+ CTL response generally have a more favorable clinical course than do patients who mount a more restricted CTL response. These data are consistent with studies in the SIV model where deletion of CD8+ T cells leads to a more accelerated clinical course.

In addition to CTLs, CD8+ T cells capable of being induced by HIV antigens to express cytokines such as IFN-γ also appear in the setting of HIV-1 infection. It is not clear whether these are the same or different effector pools compared to those cells mediating cytotoxicity; in addition, the relative roles of each in host defense against HIV are not fully understood. It does appear that these CD8+ T cells are driven to in vivo expansion by HIV antigen. There is a direct correlation between levels of CD8+ T cells capable of producing IFN-γ in response to HIV antigens and plasma levels of HIV-1 RNA. Thus, while these cells are clearly induced by HIV-1 infection, their overall ability to control infection remains unclear. Multiple HIV antigens, including Gag, Env, Pol, Tat, Rev, and Nef, can elicit CD8+ T cell responses. Among patients who control viral replication in the absence of antiretroviral drugs are a subset of patients whose peripheral blood contains a population of CD8+ T cells that undergo substantial proliferation and perforin expression in response to HIV antigens. It is possible that these cells play an important role in HIV-specific host defense.

At least three other forms of cell-mediated immunity to HIV have been described: CD8+ T cell–mediated suppression of HIV replication, ADCC, and NK cell activity. CD8+ T cell–mediated suppression of HIV replication refers to the ability of CD8+ T cells from an HIV-infected patient to inhibit the replication of HIV in tissue culture in a noncytolytic manner. There is no requirement for HLA compatibility between the CD8+ T cells and the HIV-infected cells. This effector mechanism is thus nonspecific and appears to be mediated by soluble factor(s) including the CC-chemokines RANTES, MIP-1α, and MIP-1β (see above) and the alpha defensin family of cytokotines. The CC-chemokines are potent suppressors of HIV replication and operate at least in part via blockade of the co-receptor (CCR5) on peripheral blood mononuclear cells for R5 or macrophage-tropic strains of HIV (see above). The alpha defensins appear able to inhibit replication of either R5 or X4 viruses. The mechanism of this inhibition remains unclear. ADCC, as described above in relation to humoral immunity, involves the killing of HIV-expressing cells by NK cells armed with specific antibodies directed against HIV antigens. Finally, NK cells alone have been shown to be capable of killing HIV-infected target cells in tissue culture. This primitive cytotoxic mechanism of host defense is directed toward nonspecific surveillance for neoplastic transformation and viral infection through recognition of altered class I MHC molecules.

**DIAGNOSIS AND LABORATORY MONITORING OF HIV INFECTION**

The establishment of HIV as the causative agent of AIDS and related syndromes early in 1984 was followed by the rapid development of sensitive screening tests for HIV infection. By March, 1985, blood donors in the United States were routinely screened for antibodies to HIV. In June 1996, blood banks in the United States added the p24 antigen capture assay to the screening process to help identify the rare infected individuals who were donating blood in the time (up to 3 months) between infection and the development of antibodies. In 2002 the ability to detect early infection with HIV was further enhanced by the licensure of nucleic acid amplification testing as a routine part of blood donor screening. These refinements decreased the interval between infection and detection (window period) from 22 days for antibody testing to 16 days with p24 antigen testing and subsequently to 12 days with nucleic acid testing. The development of sensitive assays for monitoring levels of plasma viremia ushered in a new era of being able to monitor the progression of HIV disease more closely. Utilization of these tests, coupled with the measurement of levels of CD4+ T lymphocytes in peripheral blood, is essential in the management of patients with HIV infection.

**DIAGNOSIS OF HIV INFECTION**

The diagnosis of HIV infection depends upon the demonstration of antibodies to HIV and/or the direct detection of HIV or one of its components. As noted above, antibodies to HIV generally appear in the circulation 2 to 12 weeks following infection. The standard screening test for HIV infection is the ELISA, also referred to as an enzyme immunoassay (EIA). This solid-phase assay is an extremely good screening test with a sensitivity of >99.5%. Most diagnostic laboratories use a commercial EIA kit that contains antigens from both HIV-1 and HIV-2 and thus are able to detect either. These kits use both natural and recombinant antigens and are continuously updated to increase their sensitivity to newly discovered species, such as group O viruses (Fig. 173-6). EIA tests are generally scored as positive (highly reactive), negative (nonreactive), or indeterminate (partially reactive). While the EIA is an extremely sensitive test, it is not optimal with regard to specificity. This is particularly true in studies of low-risk individuals, such as volunteer blood donors. In this latter population, only 10% of EIA-positive individuals are subsequently confirmed to have HIV infection. Among the factors associated with false-positive EIA tests are antibodies to class II antigens, autoantibodies, hepatic disease, recent influenza vaccination, and acute viral infections. For these reasons, anyone suspected of having HIV infection based upon a positive or inconclusive EIA result must have the result confirmed with a more specific assay. One can estimate whether or not an individual has a recent infection with HIV-1 by comparing the results on a standard assay that will score positive for
all infected individuals to the results on an assay modified to be less sensitive (“detuned assay”) that will only score positive for individuals with established HIV infection.

The most commonly used confirmatory test is the western blot (Fig. 173-23). This assay takes advantage of the fact that multiple HIV antigens of different, well-characterized molecular weights elicit the production of specific antibodies. These antigens can be separated on the basis of molecular weight, and antibodies to each component can be detected as discrete bands on the western blot. A negative western blot is one in which no bands are present at molecular weights corresponding to HIV gene products. In a patient with a positive or indeterminate EIA and a negative western blot, one can conclude with certainty that the EIA reactivity was a false positive. On the other hand, a western blot demonstrating antibodies to products of all three of the major genes of HIV (\textit{gag, pol,} and \textit{env}) is conclusive evidence of infection with HIV. Criteria established by the U.S. Food & Drug Administration (FDA) in 1993 for a positive western blot state that a result is considered positive if antibodies exist to two of the three HIV proteins: p24, gp41, and gp120/160. Using these criteria, \(\sim 10\%\) of all blood donors deemed positive for HIV-1 infection lacked an antibody band to the \textit{pol} gene product p31. Some 50\% of these blood donors were subsequently found to be false positives. Thus, the absence of the p31 band should increase the suspicion that one may be dealing with a false-positive test result. In this setting it is prudent to obtain additional confirmation with an RNA-based test and/or a follow-up western blot. By definition, western blot patterns of reactivity that do not fall into the positive or negative categories are considered “indeterminate.” There are two possible explanations for an indeterminate western blot result. The most likely explanation in a low-risk individual is that the patient being tested has antibodies that cross-react with one of the proteins of HIV. The most common patterns of cross-reactivity are antibodies that react with p24 and/or p55. The least likely explanation in this setting is that the individual is infected with HIV and is in the process of mounting a classic antibody response. In either instance, the western blot should be repeated in 1 month to determine whether or not the indeterminate pattern is a pattern in evolution. In addition, one may attempt to confirm a diagnosis of HIV infection with the p24 antigen capture assay or one of the tests for HIV RNA (discussed below). While the western blot is an excellent confirmatory test for HIV infection in patients with a positive or indeterminate EIA, it is a poor screening test. Among individuals with a negative EIA and PCR for HIV, 20 to 30\% may show one or more bands on western blot. While these bands are usually faint and represent cross-reactivity, their presence creates a situation in which other diagnostic modalities [such as DNA PCR, RNA PCR, the (b)DNA assay, or p24 antigen capture] must be employed to ensure that the bands do not indicate early HIV infection.

A guideline for the use of these serologic tests in attempting to make a diagnosis of HIV infection is depicted in Fig. 173-24. In patients in whom HIV infection is suspected, the appropriate initial test is the EIA. If the result is negative, unless there is strong reason to suspect early HIV infection (as in a patient exposed within the previous 3 months), the diagnosis is ruled out and retesting should be performed only as clinically indicated. If the EIA is indeterminate or positive, the test should be repeated. If the repeat is negative on two occasions, one can assume that the initial positive reading was due to a technical error in the performance of the assay and that the patient is negative. If the repeat is indeterminate or positive, one should proceed to the HIV-1 western blot. If the western blot is positive, the diagnosis is HIV-1 infection. If the western blot is negative, the EIA can be assumed to have been a false positive for HIV-1 and the diagnosis of HIV-1 infection is ruled out. It would be prudent at this point to perform specific serologic testing for HIV-2 following the same type of algorithm. If the western blot for HIV-1 is indeterminate, it should be repeated in 4 to 6 weeks; in addition, one may proceed to a p24 antigen capture assay, HIV-1 RNA assay, or HIV-1 DNA PCR and specific serologic testing for HIV-2. If the p24 and HIV RNA assays are negative and there is no progression in the western blot, a diagnosis of HIV-1 is ruled out. If either the p24 or HIV-1 RNA assay is positive and/or the HIV-1 western blot shows progression, a tentative diagnosis of HIV-1 infection can be made and later confirmed with a follow-up western blot demonstrating a positive pattern.

As mentioned above, a variety of laboratory tests are available for the direct detection of HIV or its components (Table 173-9; Fig. 173-25). These tests may be of considerable help in making a diagnosis of HIV infection when the western blot results are indeterminate. In addition, the tests detecting levels of HIV RNA can be used to determine prognosis and to assess the response to antiretroviral therapies.
simplest of the direct detection tests is the p24 antigen capture assay. This is an EIA-type assay in which the solid phase consists of antibodies to the p24 antigen of HIV. It detects the viral protein p24 in the blood of HIV-infected individuals where it exists either as free antigen or complexed to anti-p24 antibodies. Overall, ~30% of individuals with untreated HIV infection have detectable levels of free p24 antigen. This increases to about 50% when samples are treated with a weak acid to dissociate antigen-antibody complexes. Throughout the course of HIV infection, an equilibrium exists between p24 antigen and anti-p24 antibodies. During the first few weeks of infection, before an immune response develops, there is a brisk rise in p24 antigen levels (Fig. 173-22). After the development of anti-p24 antibodies, these levels decline. Late in the course of infection, when circulating levels of virus are high, p24 antigen levels also increase, particularly when detected by techniques involving dissociation of antigen-antibody complexes. This assay has its greatest use as a screening test for HIV infection in patients suspected of having the acute HIV syndrome, as high levels of p24 antigen are present prior to the development of antibodies. In addition, it is currently used routinely along with the HIV EIA and nucleic acid test to screen blood donors in the United States for evidence of HIV infection. The ability to measure and monitor levels of HIV RNA in the plasma of patients with HIV infection has been of extraordinary value in furthering our understanding of the pathogenesis of HIV infection and in providing a diagnostic tool in settings where measurements of anti-HIV antibodies may be misleading, such as in acute infection and neonatal infection. Three assays are predominantly used for this purpose. They are the reverse transcriptase PCR (RT-PCR; Amplicor); the branched DNA (bDNA; VERSANT); and the nucleic acid sequenced based assay (NASBA; NucliSens). Available RNA detection tests have a sensitivity of 50 to 75 copies of HIV RNA per milliliter of plasma, while the DNA PCR tests can detect proviral DNA at a frequency of one copy per 10,000 to 100,000 cells. Thus, these tests are extremely sensitive. One frequent consequence of a high degree of sensitivity is some loss of specificity, and false-positive results have been reported with each of these techniques. For this reason, a positive EIA with a confirmatory western blot remains the “gold standard” for a diagnosis of HIV infection, and the interpretation of other test results must be done with this in mind.

In the RT-PCR technique, following DNase treatment, a cDNA copy is made of all RNA species present in plasma. Insofar as HIV is an RNA virus, this will result in the production of DNA copies of the HIV genome in amounts proportional to the amount of HIV RNA present in plasma. This cDNA is then amplified and characterized using standard PCR techniques, employing primer pairs that can distinguish genomic DNA from messenger RNA. The bDNA assay involves the use of a solid-phase nucleic acid capture system and signal amplification through successive nucleic acid hybridizations to detect small quantities of HIV RNA. Both tests can achieve a tenfold increase in sensitivity to 40 to 50 copies of HIV RNA per milliliter with a preconcentration step in which plasma undergoes ultracentrifugation to pellet the viral particles. The NASBA technique involves the isothermal amplification of a sequence within the gag region of HIV in the presence of internal standards and employs the production of multiple RNA copies through the action of T7-RNA polymerase. The lower limit of detection for the NASBA is 176 copies/mL.

In addition to being a diagnostic and prognostic tool, RT-PCR is also useful for amplifying defined areas of the HIV genome for sequence analysis and has become an important technique for studies of sequence diversity and microbial resistance to antiretroviral agents. In patients with a positive or indeterminate EIA test and an indeterminate western blot, and in patients in whom serologic testing may be unreliable such as patients with hypogammaglobulinemia or advanced HIV disease, these tests for quantitating HIV RNA in plasma provide valuable tools for making a diagnosis of HIV infection; however, they should be used for diagnosis only when standard serologic testing has failed to provide a definitive result.

### Laboratory Monitoring of Patients with HIV Infection
The epidemic of HIV infection and AIDS has provided the clinician with new challenges for integrating clinical and laboratory data to effect optimal patient management.
The close relationship between clinical manifestations of HIV infection and CD4+ T cell count has made measurement of the latter a routine part of the evaluation of HIV-infected individuals. Determinations of CD4+ T cell counts and measurements of the levels of HIV RNA in serum or plasma provide a powerful set of tools for determining prognosis and monitoring response to therapy. While the CD4+ T cell count provides information on the current immunologic status of the patient, the HIV RNA level predicts what will happen to the CD4+ T cell count in the near future, and hence provides an important piece of prognostic information.

**CD4+ T Cell Counts** The CD4+ T cell count is the laboratory test generally accepted as the best indicator of the immediate state of immunologic competence of the patient with HIV infection. This measurement, which is the product of the percent of CD4+ T cells (determined by flow cytometry) and the total lymphocyte count [determined by the white blood cell count (WBC) and the differential percent] has been shown to correlate very well with the level of immunologic competence. Patients with CD4+ T cell counts <200/μL are at high risk of infection with *P. carinii*, while patients with CD4+ T cell counts <50/μL are at high risk of infection with CMV and mycobacteria of the *M. avium* complex (MAC) (Fig. 173-26). Patients with HIV infection should have CD4+ T cell measurements performed at the time of diagnosis and every 3 to 6 months thereafter. More frequent measurements should be made if a declining trend is noted. According to most guidelines, a CD4+ T cell count <50/μL is an indication for consideration of initiating antiretroviral therapy, and a decline in CD4+ T cell count of >25% is an indication for considering a change in therapy. Once the CD4+ T cell count is <200/μL, patients should be placed on a regimen for *P. carinii* prophylaxis, and once the count is <50/μL, primary prophylaxis for MAC infection is indicated. As with any laboratory measurement, one may wish to obtain two determinations prior to any significant changes in patient management based upon CD4+ T cell count alone.

**HIV RNA Determinations** Facilitated by highly sensitive techniques for the precise quantification of small amounts of nucleic acids, the measurement of serum or plasma levels of HIV RNA has become an essential component in the monitoring of patients with HIV infection. As discussed under diagnosis of HIV infection, the two most commonly used techniques are the RT-PCR assay and the bDNA assay. Both assays generate data in the form of number of copies of HIV RNA per milliliter of serum or plasma and, by employing a 1:10 concentration step with ultracentrifugation, can detect as few as 50 to 75 copies of HIV RNA per milliliter of plasma. Although earlier versions of the bDNA assay generated data that were ~50% of those of the RT-PCR assay, the more recent versions (version 3 or higher) provide numbers essentially identical to those of the RT-PCR test (Fig. 173-25). While it is common practice to describe levels of HIV RNA below these cut-offs as “undetectable,” this is a term that should be avoided as it is imprecise and leaves the false impression that the level of virus is 0. By utilizing more sensitive, nested PCR techniques and by studying tissue levels of virus as well as plasma levels, HIV RNA can be detected in virtually every patient with HIV infection. Measurements of changes in HIV RNA levels over time have been of great value in delineating the relationship between levels of virus and rates of disease progression (Fig. 173-17), the rates of viral turnover, the relationship between immune system activation and viral replication, and the time to development of drug resistance. HIV RNA measurements are greatly influenced by the state of activation of the immune system and may fluctuate greatly in the setting of secondary infections or immunization. For these reasons, decisions based upon HIV RNA levels should never be made on a single determination. Measurements of plasma HIV RNA levels should be made at the time of HIV diagnosis and every 3 to 4 months thereafter in the untreated patient. In general, most guidelines suggest that therapy be considered in patients with >50,000 copies of HIV RNA per milliliter (see below). Following the initiation of therapy or any change in therapy, plasma HIV RNA levels should be monitored approximately every 4 weeks until the effectiveness of the therapeutic regimen is determined by the development of a new steady-state level of HIV RNA. In most instances of effective therapy this will be <50 copies per milliliter. This level of virus is generally achieved within 6 months of the initiation of effective treatment. During therapy, levels of HIV RNA should be monitored every 3 to 4 months to evaluate the continuing effectiveness of therapy.

**HIV Resistance Testing** The availability of multiple antiretroviral drugs as treatment options has generated a great deal of interest in the potential for measuring the sensitivity of an individual’s HIV virus(es) to different antiretroviral agents. HIV resistance testing can be done through either genotypic or phenotypic measurements. In the genotypic assays, sequence analyses of the HIV genomes obtained from patients are compared to sequences of viruses with known antiretroviral resistance profiles. In the phenotypic assays, the in vivo growth of viral isolates obtained from the patient are compared to the growth of reference strains of the virus in the presence or absence of different antiretroviral drugs. A modification of this phenotypic approach utilizes a comparison of the enzymatic activities of the reverse transcriptase or protease genes obtained by molecular cloning of patients’ isolates to the enzymatic activities of genes obtained from reference strains of HIV in the presence or absence of different drugs targeted to these genes. These tests are quite good in identifying those antiretroviral agents that have been utilized in the past in a given patient. In the hands of experts, resistance testing enhances the short-term ability to decrease viral load by ~0.5 log compared to changing drugs merely on the basis of drug history. While some have advocated the use of resistance testing in the selection of an initial treatment regimen, the value of resistance testing in this setting is unknown.

**Other Tests** A variety of other laboratory tests have been studied as potential markers of HIV disease activity. Among these are quantitative culture of replication-competent HIV from plasma, peripheral...
blood mononuclear cells, or resting CD4+ T cells; circulating levels of β2-microglobulin, soluble IL-2 receptor, IgA, acid-labile endogenous interferon, or TNF-α; and the presence or absence of activation markers such as CD38 or HLA-DR on CD8+ T cells. While these measurements have value as markers of disease activity and help to increase our understanding of the pathogenesis of HIV disease, they do not currently play a major role in the monitoring of patients with HIV infection.

CLINICAL MANIFESTATIONS

The clinical consequences of HIV infection encompass a spectrum ranging from an acute syndrome associated with primary infection to a prolonged asymptomatic state to advanced disease. It is best to regard HIV disease as beginning at the time of primary infection and progressing through various stages. As mentioned above, active virus replication and progressive immunologic impairment occur throughout the course of HIV infection in most patients. With the exception of the rare true long-term nonprogressors (see above), HIV disease in untreated patients inexorably progresses even during the clinically latent stage. However, antiretroviral therapy has had a major impact on blocking or slowing the progression of disease over extended periods of time in a substantial proportion of adequately treated patients (see below).

THE ACUTE HIV SYNDROME

It is estimated that 50 to 70% of individuals with HIV infection experience an acute clinical syndrome approximately 3 to 6 weeks after primary infection (Fig. 173-27). Varying degrees of clinical severity have been reported, and although it has been suggested that symptomatic seroconversion leading to the seeking of medical attention indicates an increased risk for an accelerated course of disease, this has not been shown definitively. In fact, there does not appear to be a correlation between the level of the initial burst of viremia in acute HIV infection and the subsequent course of disease. The typical clinical findings in the acute HIV syndrome are listed in Table 173-10; they occur along with a burst of plasma viremia. It has been reported that several symptoms of the acute HIV syndrome (fever, skin rash, pharyngitis, and myalgia) occur less frequently in those infected by injection drug use versus those infected by sexual contact. The syndrome is typical of an acute viral syndrome and has been likened to acute infectious mononucleosis. Symptoms usually persist for 1 to several weeks and gradually subside as an immune response to HIV develops and the levels of plasma viremia decrease. Opportunistic infections have been reported during this stage of infection, reflecting the immunodeficiency that results from reduced numbers of CD4+ T cells and likely also from the dysfunction of CD4+ T cells owing to viral protein and endogenous cytokine-induced perturbations of cells (see “Mechanisms of CD4+ T Lymphocyte Depletion and Dysfunction,” above) associated with the extremely high levels of plasma viremia. A number of immunologic abnormalities accompany the acute HIV syndrome, including multiphasic perturbations of the numbers of circulating lymphocyte subsets. The number of total lymphocytes and T cell subsets (CD4+ and CD8+) are initially reduced. An inversion of the CD4+/CD8+ T cell ratio occurs later because of a rise in the number of CD8+ T cells. In fact, there may be a selective and transient expansion of CD8+ T cell subsets, as determined by T cell receptor analysis (see above). The total circulating CD8+ T cell count may remain elevated or return to normal; however, CD4+ T cell levels usually remain somewhat depressed, although there may be a slight rebound toward normal. Lymphadenopathy occurs in ~70% of individuals with primary HIV infection. Most patients recover spontaneously from this syndrome and many are left with only a mildly depressed CD4+ T cell count that remains stable for a variable period before beginning its progressive decline (see below); in some individuals, the CD4+ T cell count returns to the normal range. Approximately 10% of patients manifest a fulminant course of immunologic and clinical deterioration after primary infection, even after the disappearance of initial symptoms. In most patients, primary infection with or without the acute syndrome is followed by a prolonged period of clinical latency.

THE ASYMPTOMATIC STAGE—CLINICAL LATENCY

Although the length of time from initial infection to the development of clinical disease varies greatly, the median time for untreated patients is ~10 years. As emphasized above, HIV disease with active virus replication is ongoing and progressive during this asymptomatic period. The rate of disease progression is directly correlated with HIV RNA levels. Patients with high levels of HIV RNA in plasma progress to symptomatic disease faster than do patients with low levels of HIV RNA (Fig. 173-17). Some patients referred to as long-term nonprogressors show little if any decline in CD4+ T cell counts over extended periods of time. These patients generally have extremely low levels of HIV RNA. Certain other patients remain entirely asymptomatic despite the fact that their CD4+ T cell counts show a steady progressive decline to extremely low levels. In these patients, the appearance of an opportunistic disease may be the first manifestation of HIV infection. During the asymptomatic period of HIV infection, the average rate of CD4+ T cell decline is ~50/μL per year. When the CD4+ T cell count falls to <200/μL, the resulting state of immunodeficiency is severe enough to place the patient at high risk for opportunistic infection and neoplasms, and hence for clinically apparent disease.

SYMPTOMATIC DISEASE

Symptoms of HIV disease can appear at any time during the course of HIV infection. Generally speaking, the spectrum of illness that one observes changes as the CD4+ T cell count declines. The more severe and life-threatening complications of HIV infection occur in patients with CD4+ T cell counts <200/μL. A diagnosis of AIDS is made in anyone with HIV infection and a CD4+ T cell count <200/μL and in anyone with HIV infection who develops one of the HIV-associated diseases considered to be indicative of a severe defect in cell-mediated immunity (category C, Table 173-2).

While the causative agents of the secondary infections are characterized as opportunistic organisms such as P. carinii, atypical mycobacteria, CMV, and other organisms that do not ordinarily cause disease

**Source:** From B Tindall, DA Cooper: AIDS 5:1, 1991.
in the absence of a compromised immune system, they also include common bacterial and mycobacterial pathogens. Approximately 60% of deaths among AIDS patients are as a direct result of an infection other than HIV, with *P. carinii*, viral hepatitis, and non-AIDS-defining bacterial infections heading the list. Following the widespread use of combination antiretroviral therapy and implementation of guidelines for the prevention of opportunistic infections (Table 173-11), the incidence of secondary infections has decreased dramatically (Fig. 173-28). Overall, the clinical spectrum of HIV disease is constantly changing as patients live longer and new and better approaches to treatment and prophylaxis are developed. In general, it should be stressed that a key element of treatment of symptomatic complications of HIV disease, whether they are primary or secondary, is achieving good control of HIV replication through the use of combination antiretroviral therapy and instituting primary and secondary prophylaxis as indicated.

Disease of the Respiratory System Acute bronchitis and sinusitis are prevalent during all stages of HIV infection. The most severe cases tend to occur in patients with lower CD4+ T cell counts. Sinusitis presents as fever, nasal congestion, and headache. The diagnosis is made by computed tomography (CT) or magnetic resonance imaging (MRI). The maxillary sinuses are most commonly involved; however, disease is also frequently seen in the ethmoid, sphenoid, and frontal sinuses. While some patients may improve without antibiotic therapy, radiographic improvement is quicker and more pronounced in patients who have received antimicrobial therapy. It is postulated that this high incidence of sinusitis results from an increased frequency of infection with encapsulated organisms such as *H. influenzae* and *Streptococcus pneumoniae*. In patients with low CD4+ T cell counts one may see mucormycosis infections of the sinuses. In contrast to the course of this infection in other patient populations, mucormycosis of the sinuses in patients with HIV infection may progress more slowly. In this setting aggressive, frequent local debridement in addition to local and systemic amphotericin B may be needed for effective treatment.

Pulmonary disease is one of the most frequent complications of HIV infection. The most common manifestation of pulmonary disease is pneumonia. The two most common causes of pneumonia are bacterial infections and *P. carinii* infection. Other major causes of pulmonary infiltrates include mycobacterial infections, fungal infections, nonspecific interstitial pneumonitis, KS, and lymphoma.

Pneumonia is seen with an increased frequency in patients with HIV infection; they appear to be particularly prone to infections with encapsulated organisms. *S. pneumoniae* (Chap. 119) and *H. influenzae* (Chap. 130) are responsible for most cases of bacterial pneumonia in patients with AIDS. This may be a consequence of altered B cell function and/or defects in neutrophil function that may be secondary to HIV disease (see above). Pneumococcal infection may be the earliest serious infection to occur in patients with HIV disease. This can present as pneumonia, sinusitis, and/or bacteremia. Patients with HIV infection have a sixfold increase in the incidence of pneumococcal pneumonia and a 100-fold increase in the incidence of pneumococcal bacteremia. Pneumococcal disease may be seen in patients with relatively intact immune systems. In one study, the baseline CD4+ T cell count at the time of a first episode of pneumococcal pneumonia was \( \approx 300/\mu L \). Of interest is the fact that the inflammatory response to pneumococcal infection appears proportional to the CD4+ T cell count. Due to this high risk of pneumococcal disease, immunization with pneumococcal polysaccharide is one of the generally recommended prophylactic measures for patients with HIV infection and CD4+ T cell counts \( > 200/\mu L \). It is less clear if this intervention is of benefit in patients with more advanced disease and high viral loads.

*P. carinii* pneumonia (PCP), once the hallmark of AIDS, has dramatically declined in incidence following the development of effective prophylactic regimens and the widespread use of combination antiretroviral therapy. It is, however, the single most common cause of pneumonia in patients with HIV infection. In the United States and can be identified as a likely etiologic agent in 25% of cases of pneumonia in patients with HIV infection. Approximately 25% of cases of HIV-associated PCP occur in patients who are unaware of their HIV status. The risk of PCP is greatest among those who have experienced a previous bout of PCP and those who have CD4+ T cell counts of \(< 200/\mu L \). Overall, 79% of patients with PCP have CD4+ T cell counts \(< 100/\mu L \) and 95% of patients have CD4+ T cell counts \(< 200/\mu L \). Recurrent fever, night sweats, thrush, and unexplained weight loss are also associated with an increased incidence of PCP. For these reasons, it is strongly recommended that all patients with CD4+ T cell counts \(< 200/\mu L \) (or a CD4 percentage \(< 15 \)) receive some form of PCP prophylaxis. At present the incidence of PCP is approaching zero in patients with known HIV infection receiving appropriate antiretroviral therapy and prophylaxis. In the United States, primary PCP is now occurring at a median CD4+ T cell count of 36/\mu L, while secondary PCP is occurring at a median CD4+ T cell count of 10/\mu L. Patients with PCP generally present with fever and a cough that is usually nonproductive or productive of only scant amounts of white sputum. They may complain of a characteristic retrosternal chest pain that is worse on inspiration and is described as sharp or burning. HIV-associated PCP may have an indolent course characterized by weeks of vague symptoms and should be included in the differential diagnosis of fever, pulmonary complaints, or unexplained weight loss in any patient with HIV infection and \(< 200 \) CD4+ T cells/\mu L. The most common finding on chest x-ray is either a normal film, if the disease is suspected early, or a faint bilateral interstitial infiltrate. The classic finding of a dense perihilar infiltrate is unusual in patients with AIDS. In patients with PCP who have been receiving aerosolized pentamidine for prophylaxis, one may see an x-ray picture of upper lobe cavitary disease, reminiscent of TB. Other less common findings on chest x-ray include lobar infiltrates and pleural effusions. Routine laboratory evaluation is usually of little help in the differential diagnosis of PCP. A mild leukocytosis is common, although this may not be obvious in patients with prior neutropenia. Arterial blood gases may indicate hypoxemia with a decline in PaO\(_2\), and an increase in the arterial-alveolar 2\( \Delta P \) gradient. Arterial blood gas measurements not only aid in making the diagnosis of PCP but also provide important information for staging the severity of the disease and directing treatment (see below). A definitive diagnosis of PCP requires demonstration of the trophozoite or cyst form of the organism in samples obtained from induced sputum, bronchoalveolar lavage, transbronchial biopsy, or open lung biopsy. PCR has been used to detect specific DNA sequences for *P. carinii* in clinical specimens where histologic examinations have failed to make a diagnosis.

In addition to pneumonia, a number of other clinical problems have been reported in HIV-infected patients as a result of infection with *P. carinii*. Otic involvement may be seen as a primary infection, presenting as a polyloid mass involving the external auditory canal. In patients receiving aerosolized pentamidine for prophylaxis against PCP one may see a variety of extrapulmonary manifestations of *P. carinii*. These include ophthalmic lesions of the choroid, a necrotizing vasculitis that resembles Burger’s disease, bone marrow hypoplasia, and intestinal obstruction. Other organs that have been involved include lymph nodes, spleen, liver, kidney, pancreas, pericardium, heart, thyroid, and adrenals. Organ infection may be associated with cystic lesions that may appear calcified on CT or ultrasound.

The standard treatment for PCP or disseminated pneumocystosis is trimethoprim/sulfamethoxazole (TMP/SMX). A high incidence of side effects, particularly skin rash and bone marrow suppression, is seen with TMP/SMX in patients with HIV infection. Alternative treatments for mild to moderate PCP include dapsone/trimethoprim and clindamycin/primaquine. Intravenous pentamidine is the treatment of choice for severe disease in the patient unable to tolerate TMP/SMX. For patients with a PaO\(_2\) \(< 70\) mmHg or with an a \(\rightarrow 2\) gradient \(> 35\) mmHg, adjunct glucocorticoid therapy should be used in addition to specific antimicrobial therapy. In the United States this would be use for 2 days and followed by secondary prophylaxis. Prophylaxis for PCP is indicated for any HIV-infected individual who has experienced a prior bout of

(continued)
PCP, any patient with a CD4+ T cell count of <200/µL or a CD4 percentage <15, any patient with unexplained fever for >2 weeks, and any patient with a history of oropharyngeal candidiasis. The preferred regimen for prophylaxis is TMP/SMX, one double-strength tablet daily. This regimen also provides protection against toxoplasmosis and some bacterial respiratory pathogens. For patients who cannot tolerate TMP/SMX, alternatives include dapsone plus pyrimethamine plus leucovorin, aerosolized pentamidine administered by the Respirgard II nebulizer, and atovaquone. Primary or secondary prophylaxis for PCP can be discontinued in those patients treated with combination antiretroviral therapy who maintain good suppression of HIV (<500 copies per milliliter) and CD4+ T cell counts >200/µL for at least 3 to 6 months.

*M. tuberculosis*, once thought to be on its way to extinction in the United States, experienced a resurgence associated with the HIV epidemic (Chap. 150). Worldwide, approximately one-third of all AIDS-related deaths are associated with TB. In the United States ~5% of AIDS patients have active TB. HIV infection increases the risk of developing active TB by a factor of 100. For the patient with untreated HIV infection and a positive PPD skin test, the rate of reactivation TB is 7 to 10% per year. Untreated TB can accelerate the course of HIV infection. Levels of plasma HIV RNA increase in the setting of active TB and decline in the setting of successful TB treatment. Active TB is most common in patients 25 to 44 years of age, in African Americans and Hispanics, in patients in New York City and Miami, and in patients in developing countries. In these demographic groups, 20 to 70% of the new cases of active TB are in patients with HIV infection. The epidemic of TB embedded in the epidemic of HIV infection probably represents the greatest health risk to the general public and the health care profession associated with the HIV epidemic. In contrast to infection with atypical mycobacteria such as MAC, active TB often develops relatively early in the course of HIV infection and may be an early clinical sign of HIV disease. In one study, the median CD4+ T cell count at presentation of TB was 326/µL. The clinical manifestations of TB in HIV-infected patients are quite varied and generally show different patterns as a function of the CD4+ T cell count. In patients with relatively high CD4+ T cell counts, the typical pattern of pulmonary reactivation occurs in which patients present with fever, cough, dyspnea on exertion, weight loss, night sweats, and a chest x-ray revealing cavitory apical disease of the upper lobes. In patients with lower CD4+ T cell counts, disseminated disease is more common. In these patients the chest x-ray may reveal diffuse or lower lobe bilateral reticulonodular infiltrates consistent with miliary spread, pleural effusions, and hilar and/or mediastinal adenopathy. Infection may be present in bone, brain, meninges, gastrointestinal tract, lymph nodes (particularly cervical lymph nodes), and viscera. Approximately 60 to 80% of patients have pulmonary disease, and 30 to 40% have extrapulmonary disease. Respiratory isolation and a negative-pressure room should be used for patients in whom a diagnosis of pulmonary

![Figure 173-28](image-url)
TB is being considered. This approach is critical to limit nosocomial and community spread of infection. Culture of the organism from an involved site provides a definitive diagnosis. Blood cultures are positive in 15% of patients. In the setting of fulminant disease one cannot rely upon the accuracy of a negative PPD skin test to rule out a diagnosis of TB. TB is one of the conditions associated with HIV infection for which cure is possible. Therapy for TB is generally the same in the HIV-infected patient as in the HIV-negative patient (Chap. 150). Due to pharmacokinetic interactions, rifabutin should be substituted for rifampin in patients receiving the HIV protease inhibitors or nonnucleoside reverse transcriptase inhibitors; both drugs should be avoided in patients receiving ritonavir. Treatment is most effective in programs that involve directly observed therapy. Effective prevention of active TB can be a reality if the health care professional is aggressive in looking for evidence of latent TB by making sure that all patients with HIV infection receive a PPD skin test. Anergy testing is not of value in this setting. HIV-infected individuals with a skin test reaction of >5 mm or those who are close household contacts of persons with active TB should receive treatment with 9 months of isoniazid.

Atypical mycobacterial infections are also seen with an increased frequency in patients with HIV infection. Infections with at least 12 different mycobacteria have been reported, including M. bovis and representatives of all four Runyon groups. The most common atypical mycobacterial infection is with M. avium or M. intracellulare species—MAC. Infections with MAC are seen mainly in patients in the United States and are rare in Africa. It has been suggested that prior infection with M. tuberculosis decreases the risk of MAC infection. MAC infections probably arise from organisms that are ubiquitous in the environment, including both soil and water. The presumed portals of entry are the respiratory and gastrointestinal tract. MAC infection is a late complication of HIV infection, predominantly occurring in patients with CD4+ T cell counts of <500/µL. The average CD4+ T cell count at the time of diagnosis is 10/µL. The most common presentation is disseminated disease with fever, weight loss, and night sweats. At least 85% of patients with MAC infection are mycobacteremic, and large numbers of organisms can often be demonstrated on bone marrow biopsy. The chest x-ray is abnormal in ~25% of patients, with the most common pattern being that of a bilateral, lower lobe infiltrate suggestive of military spread. Alveolar or nodular infiltrates and hilar and/or mediastinal adenopathy can also occur. Other clinical findings include endobronchial lesions, abdominal pain, diarrhea, and lymphadenopathy. The diagnosis is made by the culture of blood or involved tissue. The finding of two consecutive sputum samples positive for MAC is highly suggestive of pulmonary infection. Cultures may take 2 weeks to turn positive. Therapy consists of a macrolide, usually clarithromycin, with ethambutol. Some physicians elect to add a third drug from among rifabutin, ciprofloxacin, or amikacin in patients with extensive disease. Therapy is generally for life; however, with the advent of highly active antiretroviral therapy (HAART), it may be possible to discontinue therapy in patients with sustained suppression of HIV replication and CD4+ T cell counts >100/µL for >6 months. Primary prophylaxis for MAC is indicated in patients with HIV infection and CD4+ T cell counts <500/µL. This may be discontinued in patients in whom HAART induces a sustained suppression of viral replication and increases in CD4+ T cell counts to >100/µL for 3 to 6 months.

*Rhodococcus equi* is a gram-positive pleomorphic acid-fast non-spore-forming bacillus that can cause pulmonary and/or disseminated infection in patients with HIV infection. Fever and cough are the most common presenting signs. Radiographically one may see cavitary lesions and consolidation. Blood cultures are often positive. Treatment is based upon antimicrobial sensitivity testing.

*Fungal infections* of the lung, in addition to PCP, can be seen in patients with AIDS. Patients with pulmonary cryptococcal disease present with fever, cough, dyspnea, and in some cases, hemoptysis. A focal or diffuse interstitial infiltrate is seen on chest x-ray in >90% of patients. In addition, one may see lobar disease, cavitary disease, pleural effusions, and hilar or mediastinal adenopathy. Over half of patients are fungemic, and 90% of patients have concomitant CNS infection. *Coccidioides immitis* is a mold that is endemic in the southwest United States. It can cause a reactivation pulmonary syndrome in patients with HIV infection. Most patients with this condition will have CD4+ T cell counts <250/µL. Patients present with fever, weight loss, cough, and extensive, diffuse reticulonodular infiltrates on chest x-ray. One may also see nodules, cavities, pleural effusions, and hilar adenopathy. While serologic testing is of value in the immunocompetent host, serologies are negative in 25% of HIV-infected patients with coccidioidal infection. Invasive aspergillosis is not an AIDS-defining illness and is generally not seen in patients with AIDS in the absence of neutropenia or neutropenia administration of glucocorticoids. Aspergillosis, however, may have an unusual presentation in the respiratory tract of patients with AIDS where it gives the appearance of a pseudomembranous tracheobronchitis. Primary pulmonary infection of the lung may be seen with histoplasmosis. The most common pulmonary manifestation of histoplasmosis, however, is in the setting of disseminated disease, presumably due to reactivation. In this setting respiratory symptoms are usually minimal, with cough and dyspnea occurring in 10 to 30% of patients. The chest x-ray is abnormal in ~50% of patients, showing either a diffuse interstitial infiltrate or diffuse small nodules.

Two forms of *idiopathic interstitial pneumonia* have been identified in patients with HIV infection: lymphoid interstitial pneumonitis (LIP) and nonspecific interstitial pneumonitis (NIP). LIP, a common finding in children, is seen in about 1% of adult patients with HIV infection. This disorder is characterized by a benign infiltrate of the lung and is felt to be part of the polyclonal activation of lymphocytes seen in the context of HIV and EBV infections. Transbronchial biopsy is diagnostic in 50% of the cases, with an open-lung biopsy required for diagnosis in the remainder of cases. This condition is generally self-limited and no specific treatment is necessary. Severe cases have been managed with brief courses of glucocorticoids. Although rarely a clinical problem since the use of HAART, evidence of NIP may be seen in up to half of all patients with untreated HIV infection. Histologically, interstitial infiltrates of lymphocytes and plasma cells in a perivascular and peribronchial distribution are present. When symptomatic, patients present with fever and nonproductive cough occasionally accompanied by mild chest discomfort. Chest x-ray is usually normal or may reveal a faint interstitial pattern. Similar to LIP, this is a self-limited process for which no therapy is indicated other than appropriate management of the underlying HIV infection.

*Neoplastic diseases* of the lung including KS and lymphoma are discussed below in the section on malignancies.

### Diseases of the Cardiovascular System

Heart disease is a relatively common postmortem finding in HIV-infected patients (25 to 75% in autopsy series). Cardiovascular disease may be seen as a direct consequence of HIV infection or as a consequence of antiretroviral therapy as part of the lipodystrophy syndrome. As a primary consequence of HIV infection, the most common clinically significant finding is a dilated cardiomyopathy associated with congestive heart failure referred to as *HIV-associated cardiomyopathy*. This generally occurs as a late complication of HIV infection and, histologically, displays elements of myocarditis. For this reason some have advocated treatment with intravenous Ig. HIV can be directly demonstrated in cardiac tissue in this setting, and there is debate over whether or not it plays a direct role in this condition. Patients present with typical findings of congestive heart failure, namely edema and shortness of breath. Patients with HIV infection may also develop cardiomyopathy as a side effect of IFN-α nucleoside analogue therapy, which is reversible once therapy is stopped. KS, cryptococcosis, Chagas disease, and toxoplasmosis can involve the myocardium, leading to cardiomyopathy. In one series, most patients with HIV infection and a treatable disease were found to have myocarditis associated with toxoplasmosis. Most of these patients also had evidence of CNS toxoplasmosis. Thus, MRI or double-dose contrast CT scan of the brain...
should be included in the workup of any patient with advanced HIV infection and cardiomyopathy.

A variety of other cardiovascular problems are found in patients with HIV infection. Pericardial effusions may be seen in the setting of advanced HIV infection. Predisposing factors include TB, congestive heart failure, mycobacterial infection, cryptococcal infection, pulmonary infection, lymphoma, and KS. While pericarditis is quite rare, in one series 5% of patients with HIV disease had pericardial effusions that were considered to be moderate or severe. Tamponade and death have occurred in association with pericardial KS, presumably owing to acute hemorrhage. Nonbacterial thrombotic endocarditis has been reported and should be considered in patients with unexplained embolic phenomena. Intravenous pentamidine, when given rapidly, can result in hypotension as a consequence of cardiovascular collapse. A high percentage of patients have hypertriglyceridemia and elevations in serum cholesterol, and coronary artery disease has been a relatively frequent finding at autopsy. This problem appears to becoming even more prevalent as a side effect of HAART. While the clinical significance of these findings has not been precisely defined, recent data suggest a linear relationship between time on HAART and development of ischemic heart disease. In one large series the overall rate of myocardial infarction was 3.5/1000 years; 28% of these events were fatal, and myocardial infarction was responsible for 7% of all deaths in the cohort. The risk of myocardial infarction increased by 26% per year of HAART. This small increase in the risk of death from myocardial infarction in the setting of HAART has to be balanced against the marked increase in overall survival brought about by HAART.

Diseases of the Oropharynx and Gastrointestinal System Oropharyngeal and gastrointestinal diseases are common features of HIV infection. They are most frequently due to secondary infections. In addition, oral and gastrointestinal lesions may occur with KS and lymphoma.

Oral lesions, including thrush, hairy leukoplakia, and aphthous ulcers, are particularly common in patients with untreated HIV infection. Thrush, due to Candida infection, and oral hairy leukoplakia, presumed due to EBV, are usually indicative of fairly advanced immunologic decline; they generally occur in patients with CD4+ T cell counts of <300/μL. In one study, 59% of patients with oral candidiasis went on to develop AIDS in the next year. Thrush appears as a white, cheesy exudate, often on an erythematous mucosa in the posterior oropharynx (see Fig. 187-1). While most commonly seen on the soft palate, early lesions are often found along the gingival border. The diagnosis is made by direct examination of a scraping for pseudohyphal elements. Culturing is of no diagnostic value, as most patients with HIV infection will have a positive throat culture for Candida even in the absence of thrush. Oral hairy leukoplakia presents as white, frondlike lesions, generally along the lateral borders of the tongue and sometimes on the adjacent buccal mucosa (see Fig. 165-1). Despite its name, oral hairy leukoplakia is not considered a premalignant condition. Lesions are associated with florid replication of EBV. While usually more disconcerting as a sign of HIV-associated immunodeficiency than a clinical problem in need of treatment, severe cases have been reported to respond to topical podophyllin or systemic therapy with anti-herpesvirus agents. Aphthous ulcers of the posterior oropharynx are also seen with regularity in patients with HIV infection. These lesions are of unknown etiology and can be quite painful and interfere with swallowing. Topical anesthetics provide immediate symptomatic relief of short duration. The fact that thalidomide is an effective treatment for this condition suggests that the pathogenesis may involve the action of tissue-destructive cytokines. Palatal, glossal, or gingival ulcers may also result from cryptococcal disease or histoplasmosis.

Esophagitis (Fig. 173-29) may present with odynophagia and retrosternal pain. Upper endoscopy is generally required to make an accurate diagnosis. Esophagitis may be due to Candida, CMV, or HSV. While CMV tends to be associated with a single large ulcer, HSV infection is more often associated with multiple small ulcers. The esophagus may also be the site of KS and lymphoma. Like the oral mucosa, the esophageal mucosa may have large, painful ulcers of unclear etiology that may respond to thalidomide. While achlorhydria is a common problem in patients with HIV infection, other gastric problems are generally rare. Among the conditions involving the stomach are KS and lymphoma. Infections of the small and large intestine leading to diarrhea, abdominal pain, and occasionally fever are among the most significant gastrointestinal problems in the HIV-infected patients. They include infections with bacteria, protozoa, and viruses.

Bacteria may be responsible for secondary infections of the gastrointestinal tract. Infections with enteric pathogens such as Salmonella, Shigella, and Campylobacter are more common in homosexual men and are often more severe and more apt to relapse in patients with HIV infection. Patients with untreated HIV have approximately a 20-fold increased risk of infection with S. typhimurium. They may present with a variety of nonspecific symptoms including fever, anorexia, fatigue, and malaise of several weeks duration. Diarrhea is common but may be absent. Diagnosis is made by culture of blood and stool. Long-term therapy with ciprofloxacin is the recommended treatment. HIV-infected patients also have an increased incidence of S. typhi infection in areas of the world where typhoid is a problem. Shigella spp., particularly S. flexneri, can cause severe intestinal disease in HIV-infected individuals. Up to 50% of patients will develop bacteraemia. Campylobacter infections occur with an increased frequency in patients with HIV infection. While C. jejuni is the strain most frequently isolated, infections with many other strains have been reported. Patients usually present with crampy abdominal pain, fever, and bloody diarrhea. Infection may present as proctitis. Stool examination reveals the presence of fecal leukocytes. Systemic infection can occur, with up to 10% of infected patients exhibiting bacteraemia. Most strains are sensitive to erythromycin. Abdominal pain and diarrhea may be seen with MAC infection.

Fungal infections may also be a cause of diarrhea in patients with HIV infection. Histoplasmosis, coccidioidomycosis, and penicilliosis have all been identified as a cause of fever and diarrhea in patients with HIV infection. Peritonitis has been seen with C. immitis. Cryptosporidia, microsporida, and Isospora belli (Chap. 199) are the most common opportunistic protozoa that infect the gastrointestinal tract and cause diarrhea in HIV-infected patients. Cryptosporidial infection may present in a variety of ways, ranging from a self-limited...
or intermittent diarrheal illness in patients in the early stages of HIV infection to a severe, life-threatening diarrhea in severely immunodeficient individuals. In patients with untreated HIV infection and CD4+ T cell counts of <300/μL, the incidence of cryptosporidiosis is ~1% per year. In 75% of cases the diarrhea is accompanied by crampy abdominal pain, and 25% of patients have nausea and/or vomiting. Cryptosporidia may also cause biliary tract disease in the HIV-infected patient, leading to cholecystitis with or without accompanying cholangitis. The diagnosis of cryptosporidial diarrhea is made by stool examination. The diarrhea is noninflammatory, and the characteristic finding is the presence of oocysts that stain with acid-fast dyes. Therapy is predominantly supportive, and marked improvements have been reported in the setting of effective antiretroviral therapy. Treatment with up to 2000 mg/d of nitazoxanide (NTZ) is associated with improvement in symptoms or a decrease in shedding of organisms in about half of patients. Its overall role in the management of this condition remains unclear. Patients can minimize their risk of developing cryptosporidiosis by avoiding contact with human and animal feces and by not drinking untreated water from lakes or rivers.

Microsporidia are small, unicellular, obligate intracellular parasites that reside in the cytoplasm of enteric cells (Chap. 199). The main species causing disease in humans is Enterocytozoon bieneusi. The clinical manifestations are similar to those described for cryptosporidia and include abdominal pain and diarrhea. The small size of the organism may make it difficult to detect; however, with the use of chromotrope-based stains, organisms can be identified in stool samples by light microscopy. Definitive diagnosis generally depends on electron microscopic examination of a stool specimen, intestinal aspirate, or intestinal biopsy specimen. In contrast to cryptosporidia, microsporidia have been noted in a variety of extraintestinal locations, including the eye, muscle, and liver, and have been associated with conjunctivitis and hepatitis. Albendazole, 400 mg bid, has been reported to be of benefit in some patients.

I. belli is a coccidian parasite (Chap. 199) most commonly found as a cause of diarrhea in patients from the Caribbean and Africa. Its cysts appear in the stool as large, acid-fast structures that can be differentiated from those of cryptosporidia on the basis of size, shape, and number of spores. The clinical syndromes of Isospora infection are identical to those caused by cryptosporidia. The important distinction is that infection with Isospora is generally relatively easy to treat with TMP/SMX. While relapses are common, a thrice-weekly regimen, similar to that used to provide prophylaxis against PCP, appears adequate to prevent recurrence.

CMV colitis was once seen in 5 to 10% of patients with AIDS. It is much less common with the advent of HAART. CMV colitis presents as diarrhea, abdominal pain, weight loss, and anorexia. The diarrhea is usually nonbloody, and the diagnosis is achieved through endoscopy and biopsy. Multiple mucosal ulcerations are seen at endoscopy, and biopsies reveal characteristic intranuclear inclusion bodies. Secondary bacteremias may result as a consequence of thinning of the bowel wall. Treatment is with either ganciclovir or foscamet for 3 to 6 weeks. Relapses are common, and maintenance therapy is typically necessary in patients whose HIV infection is poorly controlled. Patients with CMV disease of the gastrointestinal tract should be carefully monitored for evidence of retinitis.

In addition to disease caused by specific secondary infections, patients with HIV infection may also experience a chronic diarrheal syndrome for which no etiologic agent other than HIV can be identified. This entity is referred to as AIDS enteropathy or HIV enteropathy. It is most likely a direct result of HIV infection in the gastrointestinal tract. Histologic examination of the small bowel in these patients reveals low-grade mucosal atrophy with a decrease in mitotic figures, suggesting a hyporegenerative state. Patients often have decreased or absent small-bowel lactase and malabsorption with accompanying weight loss.

The initial evaluation of a patient with HIV infection and diarrhea should include a set of stool examinations, including culture, examination for ova and parasites, and examination for Clostridium difficile toxin. Approximately 50% of the time this workup will demonstrate infection with pathogenic bacteria, mycobacteria, or protozoa. If the initial stool examinations are negative, additional evaluation, including upper and/or lower endoscopy with biopsy, will yield a diagnosis of microsporidial or mycobacterial infection of the small intestine ~30% of the time. In patients for whom this diagnostic evaluation is nonrevealing, a presumptive diagnosis of HIV enteropathy can be made if the diarrhea has persisted for >1 month. An algorithm for the evaluation of diarrhea in patients with HIV infection is given in Fig. 173-30.

Rectal lesions are common in HIV-infected patients, particularly the perirectal ulcers and erosions due to the reactivation of HSV (Fig. 173-31). These may appear quite atypical, as denuded skin without vesicles, and they respond well to treatment with acyclovir, famiclovir, or foscarnet. Other rectal lesions encountered in patients with HIV infection include condylomata acuminata, KS, and intraepithelial neoplasia (see below).
Hepatobiliary Disease  Diseases of the hepatobiliary system are a major problem in patients with HIV infection. It has been estimated that approximately one-third of the deaths of patients with HIV infection are in some way related to liver disease. While this is predominantly a reflection of the problems encountered in the setting of co-infection with hepatitis B or C, it is also a reflection of the hepatic injury, ranging from hepatic steatosis to hypersensitivity reactions to immune reconstitution, that can be seen in the context of antiretroviral therapy.

Approximately 95% of HIV-infected individuals have evidence of infection with HBV; 5 to 40% of patients are co-infected with HCV; and co-infection with hepatitis D, E, and/or G viruses is common. HIV infection has a significant impact on the course of hepatitis virus infection. It is associated with approximately a threefold increase in the development of persistent hepatitis B surface antigenemia. Patients infected with both HBV and HIV have decreased evidence of inflammatory liver disease. The presumption that this is due to the immunosuppressive effects of HIV infection is supported by the observations that this situation can be reversed, and one may see the development of more severe hepatitis following the initiation of effective antiretroviral therapy. In a study of the impact of HIV on hepatitis B infection a tenfold increase in liver-related mortality was noted in patients with HIV and active HBV infection compared to rates in patients with either infection alone. IFN-α is less successful as a treatment of HBV in patients with HIV co-infection, and lamivudine or adefovir/tenofovir is the treatment of choice. It is important to remember that these drugs are also potent antiretroviral agents in the setting of combination antiretroviral therapy. They should not be used as single agents in patients with HIV infection, even if it is only being used to treat HBV, in order to avoid the rapid development of resistant quasispecies of HIV. In contrast to the situation with HBV, HCV infection is more severe in the patient with HIV infection; however, it does not appear to affect overall mortality when other variables such as age, baseline CD4+ T cell count, and use of HAART are taken into account. In the setting of HIV and HCV co-infection, levels of HCV are approximately tenfold higher than in the HIV-negative patient with HCV infection and there is an increased rate of progression to cirrhosis. Treatment for HCV infection consists of pegylated IFN-α and ribavirin. If a 2-log drop in levels of HCV RNA is not seen within 12 weeks, it is unlikely that therapy will be of value. Hepatitis A virus infection is not seen with an increased frequency in patients with HIV infection. It is recommended that all patients with HIV infection who have not experienced natural infection be immunized with hepatitis A and/or hepatitis B vaccines. Infection with hepatitis G virus, also known as GB virus C, is seen in ~50% of patients with HIV infection. For reasons that are currently unclear there are data to suggest that patients with HIV infection co-infected with this virus have a decreased rate of progression to AIDS.

A variety of other infections may also involve the liver. Granulomatous hepatitis may be seen as a consequence of mycobacterial or fungal infections, particularly MAC infection. Hepatic masses may be seen in the context of TB, peliosis hepatis, or fungal infection. Among the fungal opportunistic infections C. immitis and Histoplasma capsulatum are those most likely to involve the liver. Biliary tract disease in the form of papillary stenosis or sclerosing cholangitis has been reported in the context of cryptosporidiosis, CMV infection, and KS.

Many of the drugs used to treat HIV infection are metabolized by the liver and can cause liver injury. Fatal hepatic reactions have been reported with a wide array of antiretrovirals including nucleoside analogues, nonnucleoside analogues, and protease inhibitors. Nucleoside analogues work by inhibiting DNA synthesis. This can result in toxicity to mitochondria, which can lead to disturbances in oxidative metabolism. This may be manifest as hepatic steatosis and, in severe cases, lactic acidosis and fulminant liver failure. It is important to be aware of this condition and to watch for it in patients with HIV infection receiving nucleoside analogues. It is reversible if diagnosed early and the agent(s) discontinued. Tenofovir disoproxil fumarate is associated with at times fatal fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure. Indinavir may cause mild to moderate elevations in serum bilirubin in 10 to 15% of patients in a syndrome similar to Gilbert’s syndrome. A similar pattern of hepatic injury may be seen with atazanavir. In the patient receiving HAART with an unexplained increase in hepatic transaminases, strong consideration should be given to drug toxicity. Pancreatic injury is most commonly a consequence of drug toxicity, notably that secondary to pentamidine or dideoxynucleosides. While up to half of patients in some series have biochemical evidence of pancreatic injury, <5% of patients show any clinical evidence of pancreatitis that is not linked to a drug toxicity.

Diseases of the Kidney and Genitourinary Tract  Diseases of the kidney or genitourinary tract may be a direct consequence of HIV infection, due to an opportunistic infection or neoplasm, or related to drug toxicity. HIV-associated nephropathy was first described in IDUs and was initially thought to be IDU nephropathy in patients with HIV infection; it is now recognized as a true direct complication of HIV infection. HIV-associated nephropathy can be an early manifestation of HIV infection and is also seen in children. Over 90% of reported cases have been in African-American or Hispanic individuals; the disease is not only more prevalent in these populations but also more severe. Proteinuria is the hallmark of this disorder. Overall, microalbuminuria is seen in ~20% of untreated HIV-infected patients; significant proteinuria is seen in closer to 2%. Edema and hypertension are rare. Ultrasound examination reveals enlarged, hyperechogenic kidneys. A definitive diagnosis is obtained through renal biopsy. Histologically, focal segmental glomerulosclerosis is present in 80%, and mesangial proliferation in 10 to 15% of cases. Prior to effective antiretroviral therapy, this disease was characterized by relatively rapid progression to end-stage renal disease. Treatment with prednisone, 60 mg/d, has been reported to be of benefit in some cases. The incidence of this disease in patients receiving adequate antiretroviral therapy has not been well defined; however, the impression is that it has decreased in frequency. It is the leading cause of end-stage renal disease in patients with HIV infection.

Among the drugs commonly associated with renal damage in patients with HIV disease are pentamidine, amphotericin, adefovir, cidofovir, and foscartern. TMP/SMX may compete for tubular secretion with creatinine and cause an increase in the serum creatinine level. Sulfadiazine may crystallize in the kidney and result in an easily reversible form of renal shutdown. One of the most common drug-induced renal complications is indinavir-associated renal calculi. This condition is seen in ~10% of patients receiving this HIV protease inhibitor. It may present with a variety of manifestations, ranging from asymptomatic hematuria to renal colic. Adequate hydration is the mainstay of treatment and prevention for this condition.

Genitourinary tract infections are seen with a high frequency in patients with HIV infection; they present with dysuria, hematuria, and/or pyuria and are managed in the same fashion as in patients without HIV infection. Infections with T. pallidum, the etiologic agent of syphilis, play an important role in the HIV epidemic (Chap. 172). In HIV-negative individuals, genital syphilitic ulcers as well as the ulcers of chancreous infection are major predisposing factors for heterosexual transmission of HIV infection. While most HIV-infected individuals with syphilis have a typical presentation, a variety of formerly rare clinical problems may be encountered in the setting of dual infection. Among them are lues maligna, an ulcerating lesion of the skin due to a necrotizing vasculitis; unexplained fever; nephrotic syndrome; and neurosyphilis. The most common presentation of syphilis in the HIV-infected patient is that of condylomata lata, a form of secondary syphilis. Neurosyphilis may be asymptomatic or may present as acute meningitis, neuroretinitis, deafness, or stroke. The rate of neurosyphilis may be as high as 1% in patients with HIV infection. As a consequence of the immunologic abnormalities seen in the setting of HIV infection, diagnosis and treatment of standard serologic testing may be challenging. On the one hand, a significant number of patients have false-positive Venereal Disease Research Laboratory (VDRL) tests for syphilis; on the other hand, the serologic work-up of these patients can be positive but without clinical manifestations of syphilis.
due to polyclonal B cell activation. On the other hand, the development of a new positive VDRL may be delayed in patients with new infections, and the anti-fluorescent treponema antibody (anti-FTA) test may be negative due to immunodeficiency. Thus, dark-field examination of appropriate specimens should be performed in any patient in whom syphilis is suspected, even if the patient has a negative VDRL. Similarly, any patient with a positive serum VDRL test, neurologic findings, and an abnormal spinal fluid examination should be considered to have neurosyphilis, regardless of the CSF VDRL result. In any setting, patients treated for syphilis need to be carefully monitored to ensure adequate therapy.

Vulvovaginal candidiasis is a common problem in women with HIV infection. Symptoms include pruritus, discomfort, dyspareunia, and dysuria. Vulvar infection may present as a morbilliform rash that may extend to the thighs. Vaginal infection is usually associated with a white discharge, and plaques may be seen along an erythematous vaginal wall. Diagnosis is made by microscopic examination of the discharge for pseudohyphal elements in a 10% potassium hydroxide solution. Mild disease can be treated with topical therapy. More serious disease can be treated with fluconazole. Other causes of vaginitis include Trichomonas and mixed bacteria.

Diseases of the Endocrine System and Metabolic Disorders A variety of endocrine and metabolic disorders are seen in the context of HIV infection. Between 33 and 75% of patients with HIV infection receiving HAART develop a syndrome often referred to as lipodystrophy, consisting of elevations in plasma triglycerides, total cholesterol, and apolipoprotein B, as well as hyperinsulinemia and hyperglycemia. Many of these patients have been noted to have a characteristic set of body habitus changes associated with fat redistribution, consisting of truncal obesity coupled with peripheral wasting (Fig. 173-32). Truncal obesity is apparent as an increase in abdominal girth related to increases in mesenteric fat, a dorsocervical fat pad (“buffalo hump”) reminiscent of patients with Cushing’s syndrome, and enlargement of the breasts. The peripheral wasting or lipodystrophy is particularly noticeable in the face and buttocks and by the prominence of the veins in the legs. These changes may develop at any time ranging from ~6 weeks to several years following the initiation of HAART. The syndrome has been reported in association with regimens containing a variety of different drugs, and while initially reported in the setting of protease inhibitor therapy, it appears similar changes can also be induced by potent protease-sparing regimens. It has been suggested that the lipodystrophy changes are particularly severe in patients receiving thymidine analogues. National Cholesterol Education Program (NCEP) guidelines should be followed in the management of these lipid abnormalities (Chap. 225). Due to concerns regarding drug interactions, the most commonly utilized agents in this setting are gemfibrozil and atorvastatin. In addition to these abnormalities, patients with HIV infection treated with HAART have been found to have an increased incidence of osteonecrosis or avascular necrosis of the hip and shoulders. In a study of asymptomatic patients, 4.4% were found to have evidence of osteonecrosis on MRI. This complication was associated with the use of lipid-lowering agents, systemic glucocorticoids or testosterone; bodybuilding exercise; and the presence of antiretroviral antibodies. Lactic acidosis is also associated with antiretroviral therapy. This is most commonly seen with nucleoside reverse transcriptase inhibitors and can be fatal (see below).

Patients with advanced HIV disease may develop hyponatremia due to the syndrome of inappropriate antidiuretic hormone (vasopressin) secretion (SIADH) as a consequence of increased free water intake and decreased free water excretion. SIADH is usually seen in conjunction with pulmonary or CNS disease. Low serum sodium may also be due to adrenal insufficiency; concomitant high serum potassium should alert one to this possibility. Adrenal gland disease may be due to mycobacterial infections, CMV disease, cryptococcal disease, histoplasmosis, or ketoconazole toxicity.

Thyroid function is generally normal in patients with HIV infection although ~2 to 3% of patients may have elevations in thyroid-stimulating hormone (TSH). In the setting of HAART up to 10% of patients have been noted to have elevated TSH levels, suggesting that this may be a manifestation of immune reconstitution. In advanced HIV disease, infection of the thyroid gland may occur with opportunistic pathogens, including P. carinii, CMV, mycobacteria, Toxoplasma gondii, and Cryptococcus neoformans. These infections are generally associated with a nontender, diffuse enlargement of the thyroid gland. Thyroid function is usually normal. Diagnosis is made by fine-needle aspirate or open biopsy.

Advanced HIV disease is associated with hypogonadism in ~50% of men. While this is generally a complication of underlying illness, testicular dysfunction may also be a side effect of ganciclovir therapy. In some surveys, up to two-thirds of patients report decreased libido and one-third complain of impotence. Androgen replacement therapy should be considered in patients with symptomatic hypogonadism. HIV infection does not seem to have a significant effect on the menstrual cycle outside the setting of advanced disease.

Rheumatologic Diseases Immunologic and rheumatologic disorders are common in patients with HIV infection and range from excessive immediate-type hypersensitivity reactions (Chap. 298) to an increase in the incidence of reactive arthritis (Chap. 305) to conditions character-
ized by a diffuse infiltrative lymphocytosis. The occurrence of these phenomena is an apparent paradox in the setting of the profound immunodeficiency and immunosuppression that characterizes HIV infection. In addition, following the initiation of antiretroviral therapy, one may see a variety of exaggerated immune responses to existing opportunistic infections referred to as immune reactivation syndromes.

Drug allergies are the most significant allergic reactions occurring in HIV-infected patients and appear to become more common as the disease progresses. They occur in 65% of patients who receive therapy with TMP/SMX for PCP. In general, these drug reactions are characterized by erythematous, morbilliform eruptions that are pruritic, tend to coalesce, and are often associated with fever. Nonetheless, 33% of patients can be maintained on the offending therapy, and thus therapeutic alternatives are not an immediate reason to stop the drug. Anaphylaxis is extremely rare in patients with HIV infection, and patients who have a cutaneous reaction during a single course of therapy can still be considered candidates for future treatment or prophylaxis with the same agent. The one exception to this is the nudeoleus analogue abacavir, where fatal hypersensitivity reactions have been reported with rechallenge. A hypersensitivity reaction to abacavir is an absolute contraindication to future therapy. For other agents, including TMP/SMX, desensitization regimens are considerably successful. While the mechanisms underlying these allergic-type reactions remain unknown, patients with HIV infection have been noted to have elevated IgE levels that increase as the CD4+ T cell count declines. The numerous examples of patients with multiple drug reactions suggest that a common pathway is involved.

HIV infection shares many similarities with a variety of autoimmune diseases, including a substantial polyclonal B cell activation that is associated with a high incidence of antiphospholipid antibodies, such as anticardiolipin antibodies, VDRL antibodies, and lupus-like anticoagulants. In addition, HIV-infected individuals have an increased incidence of antinuclear antibodies. Despite these serologic findings, there is no evidence that HIV-infected individuals have an increase in two of the more common autoimmune diseases, i.e., systemic lupus erythematosus and rheumatoid arthritis. In fact, it has been observed that these diseases may be somewhat ameliorated by the concomitant presence of HIV infection, suggesting that an intact CD4+ T cell limb of the immune response plays an integral role in the pathogenesis of these conditions. Similarly, there are anecdotal reports of patients with common variable immunodeficiency (Chap. 297), characterized by hypogammaglobulinemia, who have had a normalization of Ig levels following the development of HIV infection, suggesting a possible role for overactive CD4+ T cell immunity in certain forms of that syndrome. The one autoimmune disease that may occur with an increased frequency in patients with HIV infection is a variant of primary Sjögren’s syndrome (Chap. 304). Patients with HIV infection may develop a syndrome consisting of parotid gland enlargement, dry eyes, and dry mouth that is associated with lymphocytic infiltrates of the salivary gland and lung. In contrast to Sjögren’s syndrome, in which these infiltrates are composed predominantly of CD4+ T cells, in patients with HIV infection the infiltrates are composed predominantly of CD8+ T cells. In addition, while patients with Sjögren’s syndrome are mainly women who have autoantibodies to Ro and La and who frequently have HLA-DR3 or -B8 MHC haplotypes, HIV-infected individuals with this syndrome are usually African-American men who do not have anti-Ro or anti-La and who most often are HLA-DR5. This syndrome appears to be less common with the increased use of effective antiretroviral therapy. The term diffuse infiltrative lymphocytosis syndrome (DILS) has been proposed to describe this entity and to distinguish it from Sjögren’s syndrome.

Approximately one-third of HIV-infected individuals experience arthralgias; furthermore, 5 to 10% are diagnosed as having some form of reactive arthritis, such as Reiter’s syndrome or psoriatic arthritis (Chap. 305). These syndromes occur with increasing frequency as the competency of the immune system declines. This association may be related to an increase in the number of infections with organisms that may trigger a reactive arthritis with progressive immunodeficiency or to a loss of important regulatory T cells. Reactive arthritides in HIV-infected individuals generally respond well to standard treatment; however, therapy with methotrexate has been associated with an increase in the incidence of opportunistic infections and should be used with caution and only in severe cases.

HIV-infected individuals also experience a variety of joint problems without obvious cause that are referred to generically as HIV- or AIDS-associated arthropathy. This syndrome is characterized by subacute oligoarticular arthritis developing over a period of 1 to 6 weeks and lasting 6 weeks to 6 months. It generally involves the large joints, predominately the knees and ankles, and is nonerosive with only a mild inflammatory response. X-rays of the joint are nonrevealing. Nonsteroidal anti-inflammatory drugs are only marginally helpful; however, relief has been noted with the use of intraarticular glucocorticoids. A second form of arthritis also thought to be secondary to HIV infection is called painful articular syndrome. This condition, found in as many as 10% of AIDS patients, presents as an acute, severe, sharp pain in the affected joint. It affects primarily the knees, elbows, and shoulders; lasts 2 to 24 h; and may be severe enough to require narcotic analgesics. The cause of this arthropathy is unclear; however, it is thought to result from a direct effect of HIV on the joint. This condition is reminiscent of the fact that other lentiviruses, in particular the caprine arthritis-encephalitis virus, are capable of directly causing arthritis.

A variety of other immunologic or rheumatologic diseases have been reported in HIV-infected individuals, either de novo or in association with opportunistic infections or drugs. Using the criteria of widespread musculoskeletal pain of at least 3 months’ duration and the presence of at least 11 of 18 possible tender points by digital palpation, 11% of an HIV-infected cohort containing 55% IDUs were diagnosed as having fibrositis (Chap. 315). While the incidence of frank arthropathy was less in this population than in other studied populations that consisted predominantly of homosexual men, these data support the concept that there are musculoskeletal problems that occur as a direct result of HIV infection. In addition there have been reports of leukocytoclastic vasculitides in the setting of zidovudine therapy. CNS angiitis and polymyositis have also been reported in HIV-infected individuals. Septic arthritis is surprisingly rare, especially given the increased incidence of staphylococcal bacteremias seen in this population. When septic arthritis has been reported, it has usually been due to systemic fungal infections with C. neoformans, Sporothrix schenckii, or H. capsulatum, or to systemic mycobacterial infection with M. haemophilium.

Following the initiation of effective antiretroviral therapy, a paradoxical worsening of preexisting, untreated, or partially treated opportunistic infections may be noted. These immune reactivation syndromes are particularly common in patients with underlying untreated mycobacterial infections. They appear to be related to a phenomenon similar to type IV hypersensitivity reactions and reflect the immediate improvements in immune function that occur as levels of HIV RNA drop and the immunosuppressive effects of HIV infection are controlled. In severe cases the use of immunosuppressive drugs such as glucocorticoids may be required to blunt the inflammatory component of these reactions while specific antimicrobial therapy takes effect.

**Diseases of the Hematopoietic System** Disorders of the hematopoietic system including lymphadenopathy, anemia, leukopenia, and/or thrombocytopenia are common throughout the course of HIV infection and may be the direct result of HIV, manifestations of secondary infections and neoplasms, or side effects of therapy (Table 173–12). Direct histologic examination and culture of lymph node or bone marrow tissue are often diagnostic. A significant percentage of bone marrow aspirates from patients with HIV infection have been reported to contain lymphoid aggregates, the precise significance of which is un-
known. Initiation of HAART will lead to reversal of most hematologic complications that are the direct result of HIV infection.

Some patients, otherwise asymptomatic, may develop persistent generalized lymphadenopathy as an early clinical manifestation of HIV infection. This condition is defined as the presence of enlarged lymph nodes (>1 cm) in two or more extr ingual sites for >3 months without an obvious cause. The lymphadenopathy is due to marked follicular hyperplasia in the node in response to HIV infection. The nodes are generally discrete and freely movable. This feature of HIV disease may be seen at any point in the spectrum of immune dysfunction and is not associated with an increased likelihood of developing AIDS. Paradoxically, a loss in lymphadenopathy or a decrease in lymph node size outside the setting of antiretroviral therapy may be a prognostic marker of disease progression. In patients with CD4+ T cell counts ≥200/µL, the differential diagnosis of lymphadenopathy includes KS, TB, and lymphoma. In patients with more advanced disease, lymphadenopathy may also be due to atypical mycobacterial infection, toxoplasmosis, systemic fungal infection, or bacillary angiomatosis. While indicated in patients with CD4+ T cell counts <200/µL, lymph node biopsy is not indicated in patients with early-stage disease unless there are signs and symptoms of systemic illness, such as fever and weight loss, or unless the nodes begin to enlarge, become fixed, or coalesce.

Anemia is the most common hematologic abnormality in HIV-infected patients. While generally mild, anemia can be quite severe and require chronic blood transfusions. Among the specific reversible causes of anemia in the setting of HIV infection are drug toxicity, systemic fungal and mycobacterial infections, nutritional deficiencies, and parvovirus B19 infections. Zidovudine may block erythroid maturation, prior to its effects on other marrow elements. A characteristic feature of zidovudine therapy is an elevated mean corpuscular volume duration, prior to its effects on other marrow elements. A characteristic feature of zidovudine therapy is an elevated mean corpuscular volume (MCV). Another drug used in patients with HIV infection that has a selective effect on the erythroid series is dapsone. This drug can cause a serious hemolytic anemia in patients who are deficient in glucose-6-phosphate dehydrogenase and can create a functional anemia in others through induction of methemoglobinemia. Folate levels are usually normal in HIV-infected individuals; however, vitamin B12 levels may be depressed as a consequence of achlorhydria or malabsorption. True autoimmune hemolytic anemia is rare, although ∼20% of patients with HIV infection may have a positive direct antiglobulin test as a consequence of polyclonal B cell activation. Infection with parvovirus B19 may also cause anemia. It is important to recognize this possibility given the fact that it responds well to treatment with intravenous immunoglobulin. Erythropoietin levels in patients with HIV infection and anemia are generally less than expected given the degree of anemia. Treatment with erythropoietin at doses of 100 µg/kg three times a week may result in an increase in hemoglobin levels. An exception to this is a subset of patients with zidovudine-associated anemia in whom erythropoietin levels may be quite high.

During the course of HIV infection, neutropenia may be seen in approximately half of patients. In most instances it is mild; however, it can be severe and can put patients at risk of spontaneous bacterial infections. This is most frequently seen in patients with severely advanced HIV disease and in patients receiving any of a number of potentially myelosuppressive therapies. In the setting of neutropenia, diseases that are not commonly seen in HIV-infected patients, such as aspergillosis or mucormycosis, may occur. The potential role of colony-stimulating factors in the management of patients with HIV infection has undergone extensive evaluation. Both granulocyte colony-stimulating factor (G-CSF) and GM-CSF increase neutrophil counts in patients with HIV infection regardless of the cause of the neutropenia. Earlier concerns about the potential of these agents to also increase levels of HIV were not confirmed in controlled clinical trials.

Thrombocytopenia may be an early consequence of HIV infection. Approximately 3% of patients with untreated HIV infection and CD4+ T cell counts ≥400/µL have platelet counts <150,000/µL. For untreated patients with CD4+ T cell counts <400/µL, prevalence increases to 10%. Thrombocytopenia is rarely a serious clinical problem in patients with HIV infection and generally responds well to antiretroviral therapy. Clinically, it resembles the thrombocytopenia seen in patients with idiopathic thrombotic thrombocytopenic purpura (Chap. 101). Immune complexes containing anti-gp120 antibodies and anti-anti-gp120 antibodies have been noted in the circulation and on the surface of platelets in patients with HIV infection. Patients with HIV infection have also been noted to have a platelet-specific antibody directed towards a 25-kDa component of the surface of the platelet. Other data suggest that the thrombocytopenia in patients with HIV infection may be due to a direct effect of HIV on megakaryocytes. Whatever the cause, it is very clear that the most effective medical approach to this problem has been the use of HAART. For patients with platelet counts <20,000/µL a more aggressive approach combining intravenous Ig or anti-Rh Ig for an immediate response with antiretroviral therapy for a more lasting response is appropriate. Spleenectomy is a rarely needed option and is reserved for patients refractory to medical management. Because of the risk of serious infection with encapsulated organisms, all patients with HIV infection about to undergo splenectomy should be immunized with pneumococcal polysaccharide. It should be noted that, in addition to causing an increase in the platelet count, removal of the spleen will result in an increase in the peripheral blood lymphocyte count, making CD4+ T cell counts unreliable. In this setting, the clinician should rely on the CD4+ T cell percent for making diagnostic decisions with respect to the likelihood of opportunistic infections. A CD4+ T cell percent of 15 is approximately equivalent to a CD4+ T cell count of 200/µL. In patients with early HIV infection, thrombocytopenia has also been reported as a consequence of classic thrombotic thrombocytopenic purpura (Chap. 101). This clinical syndrome, consisting of fever, thrombocytopenia, hemolytic anemia, and neurologic and renal dysfunction, is a rare complication of early HIV infection. As in other settings, the appropriate management is the use of salicylates and plasma exchange. Other causes of thrombocytopenia include lymphoma, mycobacterial infections, and fungal infections.

**Dermatologic Diseases**

Dermatologic problems occur in >90% of patients with HIV infection. From the macular, roseola-like rash seen with the acute seroconversion syndrome to extensive end-stage KS, cutaneous manifestations of HIV disease can be seen throughout the course of HIV infection. Among the more common nonneoplastic problems are seborrheic dermatitis, eosinophilic pustular folliculitis, and opportunistic infections. Extrapulmonary pneumocytosis may cause a necrotizing vasculitis. Neoplastic conditions are covered below in the section on malignant diseases.

**Seborrhic dermatitis** occurs in 3% of the general population and in up to 50% of patients with HIV infection. Seborrhic dermatitis increases in prevalence and severity as the CD4+ T cell count declines. In HIV-infected patients, seborrhic dermatitis may be aggravated by concomitant infection with *Pityrosporum*, a yeastslike fungus; use of topical antifungal agents has been recommended in cases refractory to treatment.

**Eosinophilic pustular folliculitis** is a rare dermatologic condition that is seen with increased frequency in patients with HIV infection.
It presents as multiple, urticarial perifollicular papules that may coalesce into plaquelike lesions. Skin biopsy reveals an eosinophilic infiltrate of the hair follicle, which in certain cases has been associated with the presence of a mite. Patients typically have an elevated serum IgE level and may respond to treatment with topical anthelminitics. Patients with HIV infection have also been reported to develop a severe form of *Norwegian scabies* with hyperkeratotic psoriasiform lesions.

Both *psoriasis* and *ichthyosis*, although they are not reported to be increased in frequency, may be particularly severe when they occur in patients with HIV infection. Preexisting psoriasis may become guttate in appearance and more refractory to treatment in the setting of HIV infection.

Reactivation herpes zoster (shingles) is seen in 10 to 20% of patients with HIV infection. This reactivation syndrome of varicella-zoster virus indicates a modest decline in immune function and may be the first indication of clinical immunodeficiency. In one series, patients who developed shingles did so an average of 5 years after HIV infection. In a cohort of patients with HIV infection and localized zoster, the subsequent rate of death from AIDS was 1% per month. In that study, AIDS was more likely to develop if the outbreak of zoster was associated with severe pain, extensive skin involvement, or involvement of cranial or cervical dermatomes. The clinical manifestations of reactivation zoster in HIV-infected patients, although indicative of immunologic compromise, are not as severe as those seen in other immunodeficient conditions. Thus, while lesions may extend over several dermatomes (see Fig. 164-3) and frank cutaneous dissemination may be seen, visceral involvement has not been reported. In contrast to patients without a known underlying immunodeficiency state, patients with HIV infection tend to have recurrences of zoster with a relapse rate of ~20%. Acyclovir or famciclovir is the treatment of choice. Foscarnet is of value in patients with acyclovir-resistant infection.

Infection with *herpes simplex virus* in HIV-infected individuals is associated with recurrent orolabial, genital, and perianal lesions as part of recurrent reactivation syndromes (Chap. 163). As HIV disease progresses and the CD4+ T cell count declines, these infections become more frequent and severe. Lesions often appear as beefy red, are exquisitely painful, and have a tendency to occur high in the gluteal cleft (Fig. 173-31). Perirectal HSV may be associated with proctitis and anal fissures. HSV should be high in the differential diagnosis of any HIV-infected patient with a poorly healing, painful perirectal lesion. In addition to recurrent mucous ulcers, recurrent HSV infection in the form of *herpetic whitlow* can be a problem in patients with HIV infection, presenting with painful vesicles or extensive cutaneous erosion. Acyclovir or famciclovir is the treatment of choice in these patients. Foscarnet is of value in patients with acyclovir-resistant virus.

HIV infection and its treatment may be accompanied by cosmetic changes of the skin that are not of great clinical importance but may be troubling to patients. Yellowing of the nails and straightening of the hair, particularly in African-American patients, have been reported as a consequence of HIV infection. Zidovudine therapy has been associated with elongation of the eyelashes and the development of a bluish discoloration to the nails, again more common in African-American patients. Therapy with clofazimine may cause a yellow-orange discoloration of the skin.

**Neurologic Diseases**

Clinical disease of the nervous system accounts for a significant degree of morbidity in a high percentage of patients with HIV infection (Table 173-13). The neurologic problems that occur in HIV-infected individuals may be either primary to the pathogenic processes of HIV infection or secondary to opportunistic infections or neoplasms (see above). Among the more frequent opportunistic diseases that involve the CNS are toxoplasmosis, cryptococcosis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Other less common problems include mycobacterial infections; syphilis; and infection with CMV, HTLV-I, *T. cruzi*, or *Acanthamoeba*. Overall, secondary diseases of the CNS occur in approximately one-third of patients with AIDS. These data anticipate the widespread use of combination antiretroviral therapy, and this frequency is considerably less in patients receiving effective antiretroviral drugs. Primary processes related to HIV infection of the nervous system are reminiscent of those seen with other lentiviruses, such as the Visna-Maedi virus of sheep. Neurologic problems occur throughout the course of disease and may be inflammatory, demyelinating, or degenerative in nature. While only one of these, the *AIDS dementia complex*, or *HIV encephalopathy*, is considered an AIDS-defining illness, most HIV-infected patients have some neurologic problem during the course of their disease. As noted in the section on pathogenesis, damage to the CNS may be a direct result of viral infection of the CNS macrophages or glial cells or may be secondary to the release of neurotoxins and potentially toxic cytokines such as IL-1β, TNF-α, IL-6, and TGF-β. It has been reported that HIV-infected individuals with the E4 allele for apolipoprotein E (apo E) are at increased risk for AIDS encephalopathy and peripheral neuropathy. Virtually all patients with HIV infection have some degree of nervous system involvement with the virus. This is evidenced by the fact that CSF findings are abnormal in ~90% of patients, even during the asymptomatic phase of HIV infection. CSF abnormalities include pleocytosis (50 to 65% of patients), detection of viral RNA (~75%), elevated CSF protein (35%), and evidence of intrathecal synthesis of anti-HIV antibodies (90%). It is important to point out that evidence of infection of the CNS with HIV does not imply impairment of cognitive function. The neurologic function of an HIV-infected individual should be considered normal unless clinical signs and symptoms suggest otherwise.

*Aseptic meningitis* may be seen in any but the very late stages of HIV infection. In the setting of acute primary infection patients may present with headache, fever, and meningeal signs. CSF examination is normal. The diagnosis is made by exclusion after other causes (such as viral, bacterial, or fungal meningitis) have been ruled out.

### Opportunistic Infections

- *Toxoplasmosis*
- *Cryptococcosis*
- *Progressive multifocal leukoencephalopathy* (PML)
- *Cytomegalovirus* (CMV)
- *Syphilis*
- *Mycobacterium tuberculosis* (MtB)
- *HTLV-I infection*
- *Neoplasms*
- *Primary CNS lymphoma* (PCL)
- *Kaposi’s sarcoma* (KS)
- *Result of HIV-1 infection* (HIV)
- *Aseptic meningitis* (AMS)
- *HIV encephalopathy* (AIDS dementia complex)
experience a syndrome of headache, photophobia, and meningismus. Rarely, an acute encephalopathy due to encephalitis may occur. Cranial nerve involvement may be seen, predominantly cranial nerve VII but occasionally V and/or VIII. CSF findings include a lymphocytic pleocytosis, elevated protein level, and normal glucose level. This syndrome, which cannot be clinically differentiated from other viral meningitides (Chap. 361), usually resolves spontaneously within 2 to 4 weeks; however, in some patients, signs and symptoms may become chronic. Aseptic meningitis may occur any time in the course of HIV infection; however, it is rare following the development of AIDS. This fact suggests that clinical aseptic meningitis in the context of HIV infection is an immune-mediated disease.

*Cryptococcal meningitis* is the leading infectious cause of meningitis in patients with AIDS (Chap. 186). It is the initial AIDS-defining illness in ~2% of patients and generally occurs in patients with CD4+ T cell counts <100/µL. Cryptococcal meningitis is particularly common in patients with AIDS in Africa, occurring in ~20% of patients. Most patients present with a picture of subacute meningoencephalitis with fever, nausea, vomiting, altered mental status, headache, and meningeal signs. The incidence of seizures and focal neurologic deficits is low. The CSF profile may be normal or may show only modest elevations in WBC or protein levels. In addition to meningitis, patients may develop cryptococcosis. Approximately one-third of patients also have pulmonary disease. Uncommon manifestations of cryptococcal infection include skin lesions that resemble *molluscum contagiosum*, lymphadenopathy, palatal and glossal ulcers, arthritis, gastroenteritis, myocarditis, and prostatitis. The prostate gland may serve as a reservoir for smoldering cryptococcal infection. The diagnosis of cryptococcal meningitis is made by identification of organisms in spinal fluid with India ink examination or by the detection of cryptococcal antigen. A biopsy may be needed to make a diagnosis of CNS cryptococcosis. Treatment is with intravenous amphotericin B, at a dose of 0.7 mg/kg daily, with flucytosine, 25 mg/kg qid for 2 weeks, followed by fluconazole, 400 mg orally for 10 weeks, and then fluconazole, 200 mg/d until the CD4+ T cell count has increased to >200 cells/µL for 6 months in response to HAART. Symptoms may recur with initiation of HAART as an immune reconstitution syndrome (see above). Other fungi that may cause meningitis in patients with HIV infection are *C. immitis* and *H. capsulatum*. Meningoencephalitis has also been reported due to *Acanthamoeba naegleri*. HIV encephalopathy, also called HIV-associated dementia or AIDS dementia complex, consists of a constellation of signs and symptoms of CNS disease. While this is generally a late complication of HIV infection that progresses slowly over months it can be seen in patients with CD4 counts >350 cells/µL. A major feature of this entity is the development of dementia, defined as a decline in cognitive ability from a previous level. It may present as impaired ability to concentrate, increased forgetfulness, difficulty reading, or increased difficulty performing complex tasks. Initially these symptoms may be indistinguishable from findings of situational depression or fatigue. In contrast to “cortical” dementia (such as Alzheimer’s disease), aphasia, apraxia, and agnosia are uncommon, leading some investigators to classify HIV encephalopathy as a “subcortical dementia” (see below). In addition to dementia, patients with HIV encephalopathy may also have motor and behavioral abnormalities. Among the motor problems are unsteady gait, poor balance, tremor, and difficulty with rapid alternating movements. Increased tone and deep tendon reflexes may be found in patients with spinal cord involvement. Late stages may be complicated by bowel and/or bladder incontinence. Behavioral problems include apathy and lack of initiative, with progression to a vegetative state in some instances. Some patients develop a state of agitation or mild mania. These changes usually occur without significant changes in level of alertness. This is in contrast to the finding of somnolence in patients with a dementia due to toxic/metabolic encephalopathies.

HIV encephalopathy is the initial AIDS-defining illness in ~3% of patients with HIV infection and thus only rarely precedes clinical ev-idence of immunodeficiency. Clinically significant encephalopathy eventually develops in approximately one-fourth of patients with AIDS. As immunologic function declines, the risk and severity of HIV encephalopathy increases. Autopsy series suggest that 80 to 90% of patients with HIV infection have histologic evidence of CNS involvement. Several classification schemes have been developed for grading HIV encephalopathy; a commonly used clinical staging system is outlined in Table 173-14.

The precise cause of HIV encephalopathy remains unclear, although the condition is thought to be a result of direct effects of HIV on the CNS. HIV has been found in the brains of patients with HIV encephalopathy by Southern blot, in situ hybridization, PCR, and electron microscopy. Multinucleated giant cells, macrophages, and microglial cells appear to be the main cell types harboring virus in the CNS. Histologically, the major changes are seen in the subcortical areas of the brain and include pallor and gliosis, multinucleated giant cell encephalitis, and vacuolar myelopathy. Less commonly, diffuse or focal spongiform changes occur in the white matter.

There are no specific criteria for a diagnosis of HIV encephalopathy, and this syndrome must be differentiated from a number of other diseases that affect the CNS of HIV-infected patients (Table 173-13). The diagnosis of dementia depends upon demonstrating a decline in cognitive function. This can be accomplished objectively with the use of a Mini-Mental Status Examination (MMSE) in patients for whom prior scores are available. For this reason, it is advisable for all patients with a diagnosis of HIV infection to have a baseline MMSE. However, changes in MMSE scores may be absent in patients with mild HIV encephalopathy. Imaging studies of the CNS, by either MRI or CT, often demonstrate evidence of cerebral atrophy (Fig. 173-33). MRI may also reveal small areas of increased density on T2-weighted images. Lumbar puncture is an important element of the evaluation of patients with HIV infection and neurologic abnormalities. It is generally most helpful in ruling out or making a diagnosis of opportunistic infections. In HIV encephalopathy, patients may have the nonspecific findings of an increase in CSF cells and protein level. While HIV RNA can often be detected in the spinal fluid and HIV can be cultured from the CSF, this finding is not specific for HIV encephalopathy. There

outbreaks of AES with onset of seizures. Cryptococcal meningitis was the third most common cause, responsible for 13 of the 100 seizures. In 23 cases, no cause could be found, and it is possible that these cases represent a subcategory of HIV encephalopathy. Of these 23 cases, 16 (70%) had two or more seizures, suggesting that anticonvulsant therapy is indicated in all patients with HIV infection and seizures unless a rapidly correctable cause is found. While phenytoin remains the initial treatment of choice, hypersensitivity reactions to this drug have been reported in >10% of patients with AIDS, and therefore the use of phenobarbital or valproic acid must be considered as alternatives.

Patients with HIV infection may present with focal neurologic deficits from a variety of causes. The most common causes are toxoplasmosis, progressive multifocal leukoencephalopathy, and CNS lymphoma. Other causes include cryptococcal infections (discussed above; also Chap. 186), stroke, and reactivation Chagas’ disease.

Toxoplasmosis has been one of the most common causes of secondary CNS infections in patients with AIDS, but its incidence is decreasing in the era of HAART. It is most common in patients from the Caribbean and from France. Toxoplasmosis is generally a late complication of HIV infection and usually occurs in patients with CD4+ T cell counts <200/μL. Cerebral toxoplasmosis is thought to represent a reactivation syndrome. It is 10 times more common in patients with antibodies to the organism than in patients who are seronegative. Patients diagnosed with HIV infection should be screened for IgG antibodies to T. gondii during the time of their initial workup. Those who are seronegative should be counseled about ways to minimize the risk of primary infection including avoiding the consumption of undercooked meat and careful hand washing after contact with soil or changing the cat litter box. The most common clinical presentation of cerebral toxoplasmosis in patients with HIV infection is fever, headache, and focal neurologic deficits. Patients may present with seizure, hemiparesis, or aphasia as a manifestation of these focal deficits or with a picture more influenced by the accompanying cerebral edema and characterized by confusion, dementia, and lethargy, which can progress to coma. The diagnosis is usually suspected on the basis of MRI findings of multiple lesions in multiple locations, although in some cases only a single lesion is seen. Pathologically, these lesions generally exhibit inflammation and central necrosis and, as a result, demonstrate ring enhancement on contrast MRI (Fig. 173-34) or, if MRI is unavailable or contraindicated, on double-dose contrast CT. There is usually evidence of surrounding edema. In addition to toxoplasmosis, the differential diagnosis of single or multiple enhancing mass lesions in the HIV-infected patient includes primary CNS lymphoma (see below) and, less commonly, TB or fungal or bacterial abscesses.

The definitive diagnostic procedure is brain biopsy. However, given the morbidity than can accompany this procedure, it is usually reserved for the patient who has failed 2 to 4 weeks of empirical therapy. If the patient is seronegative for T. gondii, the likelihood that a mass lesion is due to toxoplasmosis is <10%. In that setting, one may choose to be more aggressive and perform a brain biopsy sooner. Standard treatment is sulfadiazine and pyrimethamine with leucovorin as needed for a minimum of 4 to 6 weeks. Alternative therapeutic regimens include clindamycin in combination with pyrimethamine; atovaquone plus pyrimethamine; and azithromycin plus pyrimethamine plus rifabutin. Relapses are common, and it is recommended that patients with a history of prior toxoplasmic encephalitis receive maintenance therapy with sulfadiazine, pyrimethamine, and leucovorin. Patients with CD4+ T cell counts <100/µL and IgG antibody to Toxoplasma should receive primary prophylaxis for toxoplasmosis. Fortunately, the same daily regimen of a single double-strength tablet of TMP/SMX used for P. carinii prophylaxis provides adequate primary protection against toxoplasmosis. Secondary prophylaxis for toxoplasmosis may be discontinued in the setting of effective antiretroviral therapy and increases in CD4+ T cell counts to >200/µL for 6 months.

JC virus, a human polyomavirus that is the etiologic agent of progressive multifocal leukoencephalopathy (PML), is an important opportunistic pathogen in patients with AIDS (Chap. 361). While ~70% of the general adult population have antibodies to JC virus, indicative of prior infection, <10% of healthy adults show any evidence of ongoing viral replication. PML is the only known clinical manifestation of JC virus infection. It is a late manifestation of AIDS and is seen in ~4% of patients with AIDS. The lesions of PML begin as small foci of demyelination in subcortical white matter that eventually coalesce. The cerebral hemispheres, cerebellum, and brainstem may all be involved. Patients typically have a protracted course with multifocal neurologic deficits, with or without changes in mental status. Ataxia, hemiparesis, visual field defects, aphasia, and sensory defects may occur. MRI typically reveals multiple, nonenhancing white matter lesions that may coalesce and have a predilection for the occipital and parietal lobes. The lesions show signal hyperintensity on T2-weighted images and diminished signal on T1-weighted images. Prior to the availability of potent antiretroviral combination therapy, the majority of patients with PML died within 3 to 6 months of the onset of symptomatic PML. Paradoxical worsening of PML has been seen with initiation of HAART as an immune reactivation syndrome. There is no specific treatment for PML; however, regressions of >2.5 years in duration have been reported in patients with PML treated with HAART for their HIV disease. Studies with antiviral agents such as cidofovir have failed to show clear benefit. Factors influencing a favorable prognosis for PML in the setting of HIV infection include a CD4+ T cell count >100/µL at baseline and the ability to maintain an HIV viral load of <500 copies per milliliter. Baseline viral load does not have independent predictive value of survival. PML is one of the few opportunistic infections that continues to occur with some frequency despite the widespread use of HAART.

Reactivation American trypanosomiasis may present as acute meningoencephalitis with focal neurologic signs, fever, headache, vomiting, and seizures. In South America, reactivation of Chagas’ disease is considered to be an AIDS-defining condition and may be the initial AIDS-defining condition. Lesions appear radiographically as single or multiple hypodense areas, typically with ring enhancement and edema. They are found predominantly in the subcortical areas, a feature that differentiates them from the deeper lesions of toxoplasmosis. Trypanosoma cruzi amastigotes, or trypanosomes, can be identified from biopsy specimens or CSF. Other CSF findings include elevated protein and a mild (<100 cells/µL) lymphocytic pleocytosis. Organisms can also be identified by direct examination of the blood. Treatment consists of benznidazole (2.5 mg/kg/day or 5 mg/kg/week) for at least 60 days, followed by maintenance therapy for life with either drug at a dose of 5 mg/kg three times a week. As is the case with cerebral toxoplasmosis, successful therapy with antiretrovirals may allow discontinuation of therapy for Chagas’ disease.

Stroke may occur in patients with HIV infection. In contrast to the other causes of focal neurologic deficits in patients with HIV infection, the symptoms of a stroke are sudden in onset. Among the secondary infectious diseases in patients with HIV infection that may be associated with stroke are vasculitis due to cerebral varicella zoster or neurosyphilis and septic embolism in association with fungal infection. Other elements of the differential diagnosis of stroke in the patient with HIV infection include atherosclerotic cerebral vascular disease, thrombotic thrombocytopenic purpura, and cocaine or amphetamine use.

Primary CNS lymphoma is discussed below in the section on neoplastic diseases.

Spinal cord disease, or myelopathy, is present in ~20% of patients with AIDS, often as part of HIV encephalopathy. In fact, 90% of the patients with HIV-associated myelopathy have some evidence of dementia, suggesting that similar pathologic processes may be responsible for both conditions. Three main types of spinal cord disease are seen in patients with AIDS. The first of these is a vacuolar myelopathy, as discussed above under HIV encephalopathy. This condition is pathologically similar to subacute combined degeneration of the cord such as occurs with pernicious anemia. Although vitamin B12 deficiency can be seen in patients with AIDS, it does not appear to be responsible for the myelopathy seen in the majority of patients. Vacuolar myelopathy is characterized by a subacute onset and often presents with gait disturbances, predominantly ataxia and spasticity; it may progress to include bladder and bowel dysfunction. Physical findings include evidence of increased deep tendon reflexes and extensor plantar responses. The second form of spinal cord disease involves the dorsal columns and presents as a pure sensory ataxia. The third form is also sensory in nature and presents with paresthesias and dysesthesias of the lower extremities. In contrast to the cognitive problems seen in patients with HIV encephalopathy, these spinal cord syndromes do not respond well to antiretroviral drugs, and therapy is mainly supportive.

One important disease of the spinal cord that also involves the peripheral nerves is a myelopathy and polyradiculopathy seen in association with CMV infection. This entity is generally seen late in the course of HIV infection and is fulminating in onset, with lower extremity and sacral paresthesias, difficulty in walking, areflexia, ascending sensory loss, and urinary retention. The clinical course is rapidly progressive over a period of weeks. CSF examination reveals a predominantly neutrophilic pleocytosis, and CMV DNA can be detected by CSF PCR. Therapy with ganciclovir or foscarin can lead to rapid improvement, and prompt initiation of foscarin or ganciclovir therapy is important in minimizing the degree of permanent neurologic damage. Combination therapy with both drugs should be considered in patients who have been previously treated for CMV disease. Other diseases involving the spinal cord in patients with HIV infection include HTLV-I-associated myelopathy (HAM) (Chap. 172), neurosyphilis (Chap. 153), infection with herpes simplex (Chap. 163) or varicella-zoster (Chap. 164), TB (Chap. 150), and lymphoma (Chap. 97).

Peripheral neuropathies are common in patients with HIV infection. They occur at all stages of illness and take a variety of forms. Early in the course of HIV infection, an acute inflammatory demyelinating polyneuropathy resembling Guillain-Barré syndrome may occur (Chap. 366). In other patients, a progressive or relapsing-remitting inflammatory neuropathy resembling chronic inflammatory demyelinating polyneuropathy (CIDP) has been noted. Patients commonly present with progressive weakness, areflexia, and minimal sensory changes. CSF examination often reveals a mononuclear pleocytosis, and peripheral nerve biopsy demonstrates a perivascular infiltrate suggesting an autoimmune etiology. Plasma exchange or intravenous immunoglobulin has been tried with variable success. Because of the immunosuppressive effects of glucocorticoids, they should be reserved for cases that are refractory to other measures. Another autoimmune immune peripheral neuropathy seen in patients with AIDS is mononeuritis multiplex (Chaps. 366 and 306) due to a necrotizing arteritis.
of peripheral nerves. The most common peripheral neuropathy in patients with HIV infection is a **dystal sensory neuropathy** that may be a direct consequence of HIV infection or a side effect of dideoxynucleoside therapy. Two-thirds of patients with AIDS may be shown by electrophysiologic studies to have some evidence of peripheral nerve disease. Presenting symptoms are usually painful burning sensations in the feet and lower extremities. Findings on examination include a stocking-type sensory loss to pinprick, temperature, and touch sensation and a loss of ankle reflexes. Motor changes are mild and are usually limited to weakness of the intrinsic foot muscles. Response of this condition to antiretrovirals has been variable, perhaps because antiretrovirals are responsible for the problem in some instances. When due to dideoxynucleoside therapy, patients with lower extremity peripheral neuropathy may complain of a sensation that they are walking on ice. Other entities in the differential diagnosis of peripheral neuropathy include diabetes mellitus, vitamin B12 deficiency, and side effects from metronidazole or dapsone. For distal symmetric polyneuropathy that fails to resolve following the discontinuation of dideoxynucleosides, therapy is symptomatic; gabapentin, carbamazepine, tricyclics, or analgesics may be effective for dysesthesias. Treatment-naive patients may respond to combination antiretroviral therapy, and preliminary data suggest that nerve growth factor may benefit some cases.

**Myopathy** may complicate the course of HIV infection; causes include HIV infection itself, zidovudine, and the generalized wasting syndrome. HIV-associated myopathy may range in severity from an asymptomatic elevation in creatine kinase levels to a subacute syndrome characterized by proximal muscle weakness and myalgias. Quite pronounced elevations in creatine kinase may occur in asymptomatic patients, particularly after exercise. The clinical significance of this as an isolated laboratory finding is unclear. A variety of both inflammatory and noninflammatory pathologic processes have been noted in patients with more severe myopathy, including myofiber necrosis with inflammatory cells, nemaline rod bodies, cytoplasmic bodies, and mitochondrial abnormalities. Profound muscle wasting, often with muscle pain, may be seen after prolonged zidovudine therapy. This toxic side effect of the drug is dose-dependent and is related to its ability to interfere with the function of mitochondrial polymers. It is reversible following discontinuation of the drug. Red ragged fibers are a histologic hallmark of zidovudine-induced myopathy.

**Ophthalmologic Disease** Ophthalmologic problems occur in approximately half of patients with advanced HIV infection. The most common abnormal findings on funduscopic examination are cotton-wool spots. These are hard white spots that appear on the surface of the retina and often have an irregular edge. They represent areas of retinal ischemia secondary to microvascular disease. At times they are associated with small areas of hemorrhage and thus can be difficult to distinguish from CMV retinitis. In contrast to CMV retinitis, however, these lesions are not associated with visual loss and tend to remain stable or improve over time.

One of the most devastating consequences of HIV infection is CMV retinitis. Patients at high risk of CMV retinitis (CD4 T cell count <100/μL) should undergo an ophthalmologic examination every 3 to 6 months. The majority of cases of CMV retinitis occur in patients with a CD4+ T cell count <50/μL. Prior to the availability of HAART, this CMV reactivation syndrome was seen in 25 to 30% of patients with AIDS. CMV retinitis usually presents as a painless, progressive loss of vision. Patients may also complain of blurred vision, “floaters,” and scintillations. The disease is usually bilateral, affecting one eye more than the other. The diagnosis is made on clinical grounds by an experienced ophthalmologist. The characteristic retinal appearance is that of perivascular hemorrhage and exudate (see Fig. 25-5). In situations where the diagnosis is in doubt due to an atypical presentation or an unexpected lack of response to therapy, vitreous or aqueous humor sampling with molecular diagnostic techniques may be of value. CMV infection of the retina results in a necrotic inflammatory process, and the visual loss that develops is irreversible. CMV retinitis may be complicated by rheumatogenous retinal detachment as a consequence of retinal atrophy in areas of prior inflammation. Therapy for CMV retinitis consists of oral valganciclovir, intravenous ganciclovir, or intravenous foscarnet, with cidofovir as an alternative. Combination therapy with ganciclovir and foscarnet has been shown to be slightly more effective than either ganciclovir or foscarnet alone in the patient with relapsed CMV retinitis. A 3-week induction course is followed by maintenance therapy with oral valganciclovir. If CMV disease is limited to the eye, a ganciclovir-releasing intraocular implant, periodic injections of the antisense nucleic acid preparation for-miviren, or intravitreal injections of ganciclovir or foscarnet may be considered; some choose to combine intraocular implants with oral valganciclovir. Intravitreal injections of cidofovir are generally avoided due to the increased risk of uveitis and hypotony. Maintenance therapy is continued until the CD4+ T cell count remains >100 to 150/μL for >6 months. The majority of patients with HIV infection and CMV disease develop some degree of uveitis with the initiation of antiretroviral therapy. The etiology of this is unknown; however, it has been suggested that this may be due to the generation of an enhanced immune response to CMV as an immune reactivation syndrome. In some instances this has required the use of topical glucocorticoids.

Both HSV and varicella zoster virus can cause a rapidly progressing, bilateral necrotizing retinitis referred to as the **acute retinal necrosis syndrome** or progressive outer retinal necrosis (PORN). This syndrome, in contrast to CMV retinitis, is associated with pain, keratitis, and iritis. It is often associated with oral labial HSV or trigeminal zoster. Ophthalmologic examination reveals widespread pale gray peripheral lesions. This condition is often complicated by retinal detachment. It is important to recognize and treat this condition with intravenous acyclovir as quickly as possible to minimize the loss of vision.

Several other secondary infections may cause ocular problems in HIV-infected patients. *P. carinii* can cause a lesion of the choroid that may be detected as an incidental finding on ophthalmologic examination. These lesions are typically bilateral, are from half to twice the disc diameter in size, and appear as slightly elevated yellow-white plaques. They are usually asymptomatic and may be confused with cotton-wool spots. Chorioretinitis due to toxoplasmosis can be seen alone or, more commonly, in association with CNS toxoplasmosis. Kaposi’s sarcoma may involve the eyelid or conjunctiva while lymphoma may involve the retina.

**Additional Disseminated Infections and Wasting Syndrome** Infections with species of the small, gram-negative rickettsia-like organism *Bartonella* (Chap. 144) are seen with increased frequency in patients with HIV infection. While not considered an AIDS-defining illness by the CDC, many experts view infection with *Bartonella* as indicative of a severe defect in cell-mediated immunity. It is usually seen in patients with CD4+ T cell counts <100/μL. Among the clinical manifestations of *Bartonella* infection are bacillary angiomatosis, cat-scratch disease, and trench fever. Bacillary angiomatosis is usually due to infection with *B. henselae*. It is characterized by a vascular proliferation that leads to a variety of skin lesions that have been confused with the skin lesions of KS. In contrast to the lesions of KS, the lesions of bacillary angiomatosis generally blanch, are painful, and typically occur in the setting of systemic symptoms. Infection can extend to the lymph nodes, liver (peliosis hepatis), spleen, bone, heart, CNS, respiratory tract, and gastrointestinal tract. Cat-scratch disease generally begins with a papule at the site of inoculation. This is followed several weeks later by the development of regional adenopathy and malaise. Infection with *B. quintana* is transmitted by lice and has been associated with case reports of trench fever, endocarditis, adenopathy, and bacillary angiomatosis. The organism is quite difficult to culture, and diagnosis often relies upon identifying the organism in biopsy specimens using the Warthin-Starry or similar stains. Treatment is with either erythromycin or doxycycline for at least 3 months.
**Histoplasmosis** is an opportunistic infection that is seen most frequently in patients in the Mississippi and Ohio River valleys, Puerto Rico, the Dominican Republic, and South America. These are all areas in which infection with *H. capsulatum* is endemic (Chap. 183). Because of this limited geographic distribution, the percentage of AIDS cases in the United States with histoplasmosis is only ~0.5. Histoplasmosis is generally a late manifestation of HIV infection; however, it may be the initial AIDS-defining condition. In one study, the median CD4+ T cell count for patients with histoplasmosis and AIDS was 33/µL. While disease due to *H. capsulatum* may present as a primary infection of the lung, disseminated disease, presumably due to reactivation, is the most common presentation in HIV-infected patients. Patients usually present with a 4- to 8-week history of fever and weight loss. Hepatosplenomegaly and lymphadenopathy are each seen in about 25% of patients. CNS disease, either meningitis or a mass lesion, is seen in 15% of patients. Bone marrow involvement is common, with thrombocytopenia, neutropenia, and anemia occurring in 33% of patients. Approximately 7% of patients may have mucocutaneous lesions consisting of a maculopapular rash and skin or oral ulcers. Respiratory symptoms are usually mild, with chest x-ray showing a diffuse infiltrate or diffuse small nodules in approximately half of cases. Diagnosis is made by culturing the organisms from blood, bone marrow, or tissue. Treatment is typically with amphotericin B, 0.7 to 1.0 mg/kg daily to a total dose of 1 g followed by maintenance therapy with itraconazole. In the setting of mild infection, it may be appropriate to treat with itraconazole alone.

Following the spread of HIV infection to southeast Asia, disseminated infection with the fungus *Penicillium marneffei* was recognized as a complication of HIV infection and is considered an AIDS-defining condition in those parts of the world where it occurs. *P. marneffei* is the third most common AIDS-defining illness in Thailand, following TB and cryptococcosis. It is more frequently diagnosed in the rainy than the dry season. Clinical features include fever, generalized lymphadenopathy, hepatosplenomegaly, anemia, thrombocytopenia, and papular skin lesions with central umbilication. Treatment is with amphotericin B followed by itraconazole.

**Visceral leishmaniasis** (Chap. 196) is recognized with increasing frequency in patients with HIV infection who live in or travel to areas endemic for this protozoal infection transmitted by sandflies. The clinical presentation is one of hepatosplennomegaly, fever, and hematologic abnormalities. Lymphadenopathy and other constitutional symptoms may be present. Organisms can be isolated from cultures of bone marrow aspirates. Histologic stains may be negative, and antibody titers are of little help. Patients with HIV infection usually respond well initially to standard therapy with pentavalent antimony compounds. Eradication of the organism is difficult, however, and relapses are common.

**Generalized wasting** is an AIDS-defining condition; it is defined as involuntary weight loss of >10% associated with intermittent or constant fever and chronic diarrhea or fatigue lasting >30 days in the absence of a defined cause other than HIV infection. It is the initial AIDS-defining condition in ~10% of patients with AIDS in the United States and is an indication for initiation of HAART. A constant feature of this syndrome is severe muscle wasting with scattered myofiber degeneration and occasional evidence of myositis. Glucocorticoids may be of some benefit; however, this approach must be carefully weighed against the risk of compounding the immunodeficiency of HIV infection. Androgenic steroids, growth hormone, and total parenteral nutrition have been used as therapeutic interventions with variable success.

**Neoplastic Diseases** The neoplastic diseases clearly seen with an increased frequency in patients with HIV infection are KS and non-Hodgkin’s lymphoma. In addition, there also appears to be an increased incidence of Hodgkin’s disease; multiple myeloma; leukemia; melanoma; and cervical, brain, testicular, oral, lung, and anal cancers. Recent years have witnessed a marked reduction in the incidence of KS (Fig. 173-28), felt to be primarily due to the use of potent antiretroviral therapy. Rates of non-Hodgkin’s lymphoma have declined as well; however, this decline has not been as dramatic as the decline in rates of KS.

**Kaposi’s sarcoma** is a multicentric neoplasm consisting of multiple vascular nodules appearing in the skin, mucous membranes, and viscera. The course ranges from indolent, with only minor skin or lymph node involvement, to fulminant, with extensive cutaneous and visceral involvement. In the initial period of the AIDS epidemic, KS was a prominent clinical feature of the first cases of AIDS, occurring in 79% of the patients diagnosed in 1981. By 1989 it was seen in only 25% of cases, by 1992 the number had decreased to 9%, and by 1997 the number was <1%. HIV-8 or KSHV has been strongly implicated as a viral cofactor in the pathogenesis of KS (see above).

Clinically, KS has varied presentations and may be seen at any stage of HIV infection, even in the presence of a normal CD4+ T cell count. The initial lesion may be a small, raised reddish-purple nodule on the skin, a discoloration on the oral mucosa, or a swollen lymph node (Fig. 173-35). Lesions often appear in sun-exposed areas, particularly the tip of the nose, and have a propensity to occur in areas of trauma (Koebner phenomenon). Because of the vascular nature of the tumors and the presence of extravasated red blood cells in the lesions, their color ranges from reddish to purple to brown and often take the appearance of a bruise, with yellowish discoloration and tattooing. Lesions range in size from a few millimeters to several centimeters in diameter and may be either discrete or confluent. KS lesions most commonly appear as raised macules; however, they also can be papular, particularly in patients with higher CD4+ T cell counts. Confluent lesions may give rise to surrounding lymphedema and may be disfiguring when they involve the face and disabling when they involve the lower extremities or the surfaces of joints. Apart from skin, lymph nodes, gastrointestinal tract, and lung are the organ systems most commonly affected by KS. Lesions have been reported in virtually every organ, including the heart and the CNS. In contrast to most malignancies, in which lymph node involvement implies metastatic spread and a poor prognosis, lymph node involvement may be seen very early in KS and is of no special clinical significance. In fact, some patients may present with disease limited to the lymph nodes. These are generally patients with relatively intact immune function and thus the patients with the best prognosis. Pulmonary involvement with KS generally presents with shortness of breath. Some 80% of patients with pulmonary KS also have cutaneous lesions. The chest x-ray characteristically shows bilateral lower lobe infiltrates that obscure the margins of the mediastinum and diaphragm (Fig. 173-36). Pleural effusions are seen in 70% of cases of pulmonary KS, a fact that is often helpful in the differential diagnosis. Gastrointestinal involvement is seen in 50% of patients and usually takes one of two forms. The first is mucosal involvement, which may lead to bleeding that can be
severe. These patients sometimes also develop symptoms of gastrointestinal obstruction if lesions become large. The second gastrointestinal manifestation is due to biliary tract involvement. KS lesions may infiltrate the gallbladder and biliary tree, leading to a clinical picture of obstructive jaundice similar to that seen with sclerosing cholangitis. Several staging systems have been proposed for KS. One in common use was developed by the National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group; it distinguishes patients on the basis of tumor extent, immunologic function, and presence or absence of systemic disease (Table 173-16).

A diagnosis of KS is based upon biopsy of a suspicious lesion. Histologically one sees a proliferation of spindle cells and endothelial cells, extravasation of red blood cells, hemosiderin-laden macrophages, and, in early cases, an inflammatory cell infiltrate. Included in the differential diagnosis are lymphoma (particularly for oral lesions), bacillary angiomatosis, and cutaneous mycobacterial infections.

Management of KS (Table 173-17) should be carried out in consultation with an expert since definitive treatment guidelines do not exist. In the majority of cases effective antiretroviral therapy will go a long way in achieving control. Indeed, spontaneous regressions have been reported in the setting of HAART. For patients in whom tumor persists or in whom control of HIV replication is not possible, a variety of options exist. In some cases, lesions remain quite indolent, and many of these patients can be managed with no specific treatment. Fewer than 10% of AIDS patients with KS die as a consequence of their malignancy, and death from secondary infections is considerably more common. Thus, whenever possible one should avoid treatment regimens that may further suppress the immune system and increase susceptibility to opportunistic infections. Treatment is indicated under two main circumstances. The first is when a single lesion or a limited number of lesions are causing significant discomfort or cosmetic problems, such as with prominent facial lesions, lesions overlying a joint, or lesions in the oropharynx that interfere with swallowing or breathing. Under these circumstances, treatment with localized radiation, intraläsional vinblastine, or cryotherapy may be indicated. It should be noted that patients with HIV infection are particularly sensitive to the side effects of radiation therapy. This is especially true with respect to the development of radiation-induced mucositis; doses of radiation directed at mucosal surfaces, particularly in the head and neck region, should be adjusted ac-

cordingly. The use of systemic therapy, either IFN-α or chemotherapy, should be considered in patients with a large number of lesions or in patients with visceral involvement. The single most important determinant of response appears to be the CD4+ T cell count. This relationship between response rate and baseline CD4+ T cell count is particularly true for IFN-α. The response rate for patients with CD4+ T cell counts >600/μL is ~80%, while the response rate for patients with counts <150/μL is <10%. In contrast to the other systemic therapies, IFN-α provides an added advantage of having antiretroviral activity; thus, it may be the appropriate first choice for single-agent systemic therapy for early patients with disseminated disease. A variety of chemotherapeutic agents have also been shown to have activity against KS. Three of them, liposomal daunorubicin, liposomal doxorubicin, and paclitaxel have been approved by the FDA for this indication. Liposomal daunorubicin is approved as first-line therapy for patients with advanced KS. It has fewer side effects than conventional chemotherapy. In contrast, liposomal doxorubicin and paclitaxel are approved only for KS patients who have failed standard chemotherapy. Response rates vary from 23 to 88%, appear to be comparable to what had been achieved earlier with combination chemotherapy regimens, and are greatly influenced by CD4+ T cell count.

Lymphomas occur with an increased frequency in patients with congenital or acquired T cell immunodeficiencies (Chap. 297). AIDS is no exception; at least 6% of all patients with AIDS develop lymphoma at some time during the course of their illness. This is a 120-fold increase in incidence compared to the general population. In contrast to the situation with KS, primary CNS lymphoma, and most opportunistic infections, the incidence of AIDS-associated systemic lymphomas has not experienced as dramatic a decrease as a consequence of the widespread use of effective antiretroviral therapy. Lymphoma occurs in all risk groups, with the highest incidence in patients with hemophilia and the lowest incidence in patients from the Caribbean or Africa with heterosexually acquired infection. Lymphoma is a late manifestation of HIV infection, generally occurring in patients with CD4+ T cell counts <200/μL. As HIV disease progresses, the risk of lymphoma increases. In contrast to KS, which occurs at a relatively constant rate throughout the course of HIV disease, the attack rate for lymphoma increases exponentially with increasing duration of HIV infection and decreasing level of immunologic function. At 3 years following a diagnosis of HIV infection, the risk of lymphoma is 0.8% per year; by 8 years after infection, it is 2.6% per year. As people with HIV infection live longer as a consequence of improved antiretroviral therapy and better treatment and prophylaxis of opportunistic infections, it is anticipated that the incidence of lymphomas may increase.

Three main categories of lymphoma are seen in patients with HIV infection: grade III or IV immunoblastic lymphoma, Burkitt’s lym-

lymphoma, and primary CNS lymphoma. Approximately 90% of these lymphomas are B cell in phenotype, and half contain EBV DNA. These tumors may be either monoclonal or oligoclonal in nature and are probably in some way related to the pronounced polyclonal B cell activation seen in patients with AIDS.

Immunoblastic lymphomas account for ~60% of the cases of lymphoma in patients with AIDS. These are generally high grade and would have been classified as diffuse histiocytic lymphomas in earlier classification schemes. This tumor is more common in older patients, increasing in incidence from 0% in HIV-infected individuals <1 year old to >3% in those >50. One variant of immunoblastic lymphoma is body cavity lymphoma. This malignancy presents with lymphomatous pleural, pericardial, and/or peritoneal effusions in the absence of discrete nodal or extranodal masses. The tumor cells do not express surface markers for B cells or T cells. HHV-8 DNA sequences have been found in the genome of the malignant cells (see above).

Small non-cleaved cell lymphoma (Burkitt’s lymphoma) accounts for ~20% of the cases of lymphoma in patients with AIDS. It is most frequent in patients 10 to 19 years old and usually demonstrates characteristic c-myc translocations from chromosome 8 to chromosomes 14 or 22. Burkitt’s lymphoma is not commonly seen in the setting of immunodeficiency other than HIV-associated immunodeficiency, and the incidence of this particular tumor is over 1000-fold higher in the setting of HIV infection than in the general population. In contrast to African Burkitt’s lymphoma, where 97% of the cases contain EBV genome, only 50% of HIV-associated Burkitt’s lymphomas are EBV-positive.

Primary CNS lymphoma accounts for ~20% of the cases of lymphoma in patients with HIV infection. In contrast to HIV-associated Burkitt’s lymphoma, primary CNS lymphomas are usually positive for EBV. In one study, the incidence of Epstein-Barr positivity was 100%. This malignancy does not have a predilection for any particular age group. The median CD4+ T cell count at the time of diagnosis is ~50/μL. Thus, CNS lymphoma generally presents at a later stage of HIV infection than systemic lymphoma. This fact may at least in part explain the poorer prognosis for this subset of patients.

The clinical presentation of lymphoma in patients with HIV infection is quite varied, ranging from focal seizures to rapidly growing mass lesions in the oral mucosa (Fig. 173-37) to persistent unexplained fever. At least 80% of patients present with extranodal disease, and a similar percentage have B-type symptoms of fever, night sweats, or weight loss. Virtually any site in the body may be involved. The most common extranodal site is the CNS, which is involved in approximately one-third of all patients with lymphoma. Approximately 60% of these cases are primary CNS lymphoma. Primary CNS lymphoma generally presents with focal neurologic deficits, including cranial nerve findings, headaches, and/or seizures. MRI or CT generally reveals a limited number (one to three) of 3- to 5-cm lesions (Fig. 173-38). The lesions often show ring enhancement on contrast administration and may occur in any location. Locations that are most commonly involved with CNS lymphoma are deep in the white matter. Contrast enhancement is usually less pronounced than that seen with toxoplasmosis. The main diseases in the differential diagnosis are cerebral toxoplasmosis and cerebral Chagas’ disease. In addition to the 20% of lymphomas in HIV-infected individuals that are primary CNS lymphomas, CNS disease is also seen in HIV-infected patients with systemic lymphoma. Approximately 20% of patients with systemic lymphoma have CNS disease in the form of leptomeningeal involvement. This fact underscores the importance of lumbar puncture in the staging evaluation of patients with systemic lymphoma.

Systemic lymphoma is seen at earlier stages of HIV infection than primary CNS lymphoma. In one series the mean CD4+ T cell count was 189/μL. In addition to lymph node involvement, systemic lymphoma may commonly involve the gastrointestinal tract, bone marrow, liver, and lung. Gastrointestinal tract involvement is seen in ~25% of patients. Any site in the gastrointestinal tract may be involved, and patients may complain of difficulty swallowing or abdominal pain. The diagnosis is usually suspected on the basis of CT or MRI of the abdomen. Bone marrow involvement is seen in ~20% of patients and may lead to pancytopenia. Liver and lung involvement are each seen in ~10% of patients. Pulmonary disease may present as either a mass lesion, multiple nodules, or an interstitial infiltrate.

Both conventional and unconventional approaches have been employed in an attempt to treat HIV-related lymphomas. Systemic lymphoma is generally treated by the oncologist with combination therapy and may occur in any location. Locations that are most commonly involved with CNS lymphoma are deep in the white matter. Contrast enhancement is usually less pronounced than that seen with toxoplasmosis. The main diseases in the differential diagnosis are cerebral toxoplasmosis and cerebral Chagas’ disease. In addition to the 20% of lymphomas in HIV-infected individuals that are primary CNS lymphomas, CNS disease is also seen in HIV-infected patients with systemic lymphoma. Approximately 20% of patients with systemic lymphoma have CNS disease in the form of leptomeningeal involvement. This fact underscores the importance of lumbar puncture in the staging evaluation of patients with systemic lymphoma.

Systemic lymphoma is seen at earlier stages of HIV infection than primary CNS lymphoma. In one series the mean CD4+ T cell count was 189/μL. In addition to lymph node involvement, systemic lymphoma may commonly involve the gastrointestinal tract, bone marrow, liver, and lung. Gastrointestinal tract involvement is seen in ~25% of patients. Both conventional and unconventional approaches have been employed in an attempt to treat HIV-related lymphomas. Systemic lymphoma is generally treated by the oncologist with combination...
chemotherapy. Earlier disappointing figures are being replaced with more optimistic results for the treatment of systemic lymphoma following the availability of more effective combination antiretroviral therapy. As in most situations in patients with HIV disease, those with the higher CD4+ T cell counts tend to do better. Response rates as high as 72% and disease-free intervals >15 months have been reported. Treatment of primary CNS lymphoma remains a significant challenge. Treatment is complicated by the fact that this illness usually occurs in patients with advanced HIV disease. Palliative measures such as radiation therapy provide some relief. The prognosis remains poor in this group, with median survival <1 year.

Evidence of infection with human papilloma virus (HPV), associated with intraepithelial dysplasia of the cervix or anus, is approximately twice as common in HIV-infected individuals as in the general population and can lead to intraepithelial neoplasia and eventually invasive cancer. In two separate studies, HIV-infected men without anorectal symptoms were studied for evidence of dysplasia, and Papanicolaou (Pap) smears were found to be abnormal in 40%. These changes were persistent at 1 year follow-up, raising the possibility of a subsequent transition to a more malignant condition. While the incidence of an abnormal Pap smear of the cervix is ~5% in otherwise healthy women, the incidence of abnormal cervical smears in women with HIV infection is 60%. Based on this finding, invasive cervical cancer was added to the list of AIDS-defining conditions. Thus far, however, only small increases in the incidence of cervical or anal cancer have been seen as a consequence of HIV infection. However, given this high rate of dysplasia, a comprehensive gynecologic and rectal examination, including Pap smear, is indicated at the initial evaluation and 6 months later for all patients with HIV infection. If these examinations are negative at both time points, the patient should be followed with yearly evaluations. If an initial or repeat Pap smear shows evidence of severe inflammation with reactive squamous changes, the next Pap smear should be performed at 3 months. If, at any time, a Pap smear shows evidence of squamous intraepithelial lesions, colposcopic examination with biopsies as indicated should be performed. HAART has been found to reduce the rate of progression and in some instances to induce regression of HPV-induced dysplasia.

**IDIOPATHIC CD4+ T LYMPHOCYTOPENIA**

A syndrome was recognized in 1992 that was characterized by an absolute CD4+ T cell count of <300/µl or <20% of total T cells on more than one occasion; no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II on testing; and the absence of any defined immunodeficiency or therapy associated with decreased levels of CD4+ T cells. By mid-1993, ~100 patients had been described. After extensive multicenter investigations, a series of reports were published in early 1993, which together allowed a number of conclusions. Idiopathic CD4+ lymphocytopenia (ICL) is a very rare syndrome, as determined by studies of blood donors and cohorts of HIV-seronegative homosexual men. Cases were clearly identified as early as 1983, and cases remarkably similar to ICL had been identified decades ago. The definition of ICL based on CD4+ T cell counts coincided with the ready availability of testing for CD4+ T cells in patients suspected of being immunosuppressed. Although, as a result of immune deficiency, certain patients with ICL develop some of the opportunistic diseases (particularly cryptococcosis) seen in HIV-infected patients, the syndrome is demographically, clinically, and immunologically unlike HIV infection and AIDS. Fewer than half of the reported ICL patients had risk factors for HIV infection, and there were wide geographic and age distributions. The fact that a significant proportion of patients did have risk factors probably reflects a selection bias, in that physicians who take care of HIV-infected patients are more likely to monitor CD4+ T cells. Approximately one-third of the patients are women, compared to 16% of women among HIV-infected individuals in the United States. Many patients with ICL remained clinically stable, and their condition did not deteriorate progressively as is common with seriously immunodeficient HIV-infected patients. Certain patients with ICL even experienced spontaneous reversal of the CD4+ T lymphocytopenia. Immunologic abnormalities in ICL are somewhat different from those of HIV infection. ICL patients often also have decreases in CD8+ T cells and in B cells. Furthermore, immunoglobulin levels were either normal or, more commonly, decreased in patients with ICL, compared to the usual hypergammaglobulinemia of HIV-infected individuals. Finally, virologic studies revealed no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II or of any other mononuclear cell–tropic virus. Furthermore, there was no epidemiologic evidence to suggest that a transmissible microbe was involved. The cases of ICL were widely dispersed, with no clustering. Close contacts and sexual partners who were studied were clinically well and were serologically, immunologically, and HIV-1–visually negative for HIV. ICL is a heterogeneous syndrome, and it is highly likely that there is no common cause; however, there may be common causes among subgroups of patients that are currently unrecognized.

Patients who present with laboratory data consistent with ICL should be worked up for underlying diseases that could be responsible for the immune deficiency. If no underlying cause is detected, no specific therapy should be initiated. However, if opportunistic diseases occur, they should be treated appropriately (see above). Depending on the level of the CD4+ T cell count, patients should receive prophylaxis for the commonly encountered opportunistic infections.

**TREATMENT**

**General Principles of Patient Management**

The treatment of patients with HIV infection requires not only a comprehensive knowledge of the possible disease processes that may occur but also the ability to deal with the problems of a chronic, potentially life-threatening illness. Great advances have been made in the treatment of patients with HIV infection. The appropriate use of potent combination antiretroviral therapy and other treatment and prophylactic interventions is of critical importance in providing each patient with the best opportunity to live a long and healthy life despite the presence of HIV infection. In contrast to the earlier days of this epidemic, a diagnosis of HIV infection need no longer be equated with an inevitably fatal disease. In addition to medical interventions, the health care provider has a responsibility to provide each patient with appropriate counseling and education concerning their disease as part of a comprehensive care plan. Patients must be educated about the potential transmissibility of their infection and about the fact that while health care providers may refer to levels of the virus as "undetectable," this is more a reflection of the sensitivity of the assay being used to measure the virus than a comment on the presence or absence of the virus. It is important for patients to be aware that the virus is still present and capable of being transmitted at all stages of HIV disease. Thus, there need to be frank discussions concerning sexual practices and the sharing of needles. The treating physician must not only be aware of the latest medications available for patients with HIV infection but must also educate patients concerning the natural history of their illness and listen and be sensitive to their fears and concerns. As with other diseases, therapeutic decisions should be made in consultation with the patient, when possible, and with the patient’s proxy if the patient is incapable of making decisions. In this regard, it is recommended that all patients with HIV infection, and in particular those with CD4+ T cell counts <200/µl, designate a trusted individual with durable power of attorney to make medical decisions on their behalf, if necessary.

No matter how well prepared a patient is for adversity, the discovery of a diagnosis of HIV infection is a devastating event. For this reason, it is recommended that anyone about to undergo testing have "pretest counseling" to prepare him or her at least partially should the results demonstrate the presence of HIV infection. Following a diagnosis of HIV infection, the health care provider should be prepared to activate support systems immediately for the newly diagnosed patient. These should include an experienced social worker or nurse who can spend time talking to the person and ensuring that he or she is emo-
tionally stable. Most communities have HIV crisis centers that can be of great help in these difficult situations.

Following a diagnosis of HIV infection, there are several examinations and laboratory studies that should be performed to help determine the extent of disease and provide baseline standards for future reference (Table 173-18). In addition to routine chemistry and hematology screening panels and chest x-ray, one should also obtain a CD4+ T cell count, two separate plasma HIV RNA levels, a VDRL test, and an anti-Toxoplasma antibody titer. A PPD test should be done, and a MMSE performed and recorded. Patients should be immunized with pneumococcal polysaccharide and, if seronegative for these viruses, with hepatitis A and hepatitis B vaccines. The status of hepatitis C infection should be determined. In addition, patients should be counseled with regard to sexual practices and needle sharing, and counseling should be offered to those whom the patient knows or suspects may also be infected. Once these baseline activities are performed, short- and long-term medical management strategies should be developed based upon the most recent information available and modified as new information becomes available. The field of HIV medicine is changing rapidly, and it is difficult to remain fully up to date. Fortunately there are a series of excellent sites on the internet that are frequently updated, and they provide the most recent information on a variety of topics, including consensus panel reports on treatment (Table 173-19).

Antiretroviral Therapy

Combination antiretroviral therapy, or HAART, is the cornerstone of management of patients with HIV infection. Following the initiation of widespread use of HAART in the United States in 1995 to 1996, marked declines have been noted in the incidence of most AIDS-defining conditions (Fig. 173-28). Suppression of HIV replication is an important component in prolonging life as well as improving the quality of life in patients with HIV infection. Unfortunately, many of the most important questions related to the treatment of HIV disease currently lack definitive answers. Among them are the questions of when should therapy be started, what is the best initial regimen, when should a given regimen be changed, and what should it be changed to when a change is made. Notwithstanding these uncertainties, the physician and patient must come to a mutually agreeable plan based upon the best available data. In an effort to facilitate this process, the United States Department of Health and Human Services has published a series of frequently updated guidelines including the “Principles of Therapy of HIV Infection,” “Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents,” and “Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus.” At present, an extensive clinical trials network, involving both clinical investigators and patient advocates, is in place attempting to develop improved approaches to therapy. Consortia comprising representatives of academia, industry, and the federal government are involved in the process of drug development, including a wide-ranging series of clinical trials. As a result, new therapies and new therapeutic strategies are continually emerging. New drugs are often available through expanded access programs prior to official licensure. Given the complexity of this field, decisions regarding antiretroviral therapy are best made in consultation with experts. Currently licensed drugs for the treatment of HIV infection fall into three categories: those that inhibit the viral reverse transcriptase enzyme (Table 173-20, Fig. 173-39), those that inhibit the viral protease enzyme, and those that interfere with viral entry. There are numerous drug-drug interactions that one must take into consideration when using these agents (Table 173-21).

The FDA-approved reverse transcriptase inhibitors include the nucleoside analogues zidovudine, didanosine, zalcitabine, stavudine, lamivudine, abacavir, and emtricitabine; the nucleotide analogue tenofovir; and the nonnucleoside reverse transcriptase inhibitors nevirapine, delavirdine, and efavirenz (Fig. 173-39; Table 173-20). These were the first class of drugs that were licensed for the treatment of HIV infection. They are indicated for this use as part of combination regimens. It should be stressed that none of these drugs should be used as monotherapy for HIV infection. Thus, when lamivudine or tenofovir are used to treat hepatitis B infection in the setting of HIV infection, one should ensure that the patient is also on additional antiretroviral medication. The reverse transcriptase inhibitors block the HIV replication cycle at the point of RNA-dependent DNA synthesis, the reverse transcription step. While the nonnucleoside reverse transcriptase inhibitors are quite selective for the HIV-1 reverse transcriptase, the nucleoside and nucleotide analogues inhibit a variety of DNA polymerization reactions in addition to those of the HIV-1 reverse transcriptase. For this reason, serious side effects are more common with the nucleoside analogues and include mitochondrial damage that can lead to hepatic steatosis and lactic acidosis as well as peripheral neuropathy and pancreatitis. One of the more recently recognized problems that has been encountered with the widespread use of HAART therapy has been a syndrome of hyperlipidemia, glucose intolerance, and fat distribution often referred to as lipodystrophy syndrome (discussed above under metabolic abnormalities).

Zidovudine (AZT; 3’-azido-2’,3’-dideoxythymidine) was the first drug approved for the treatment of HIV infection and is the prototype nucleoside analogue. These compounds, in which the hydroxyl group in the 3’ position of the ribose moiety is substituted with a hydrogen or other chemical group, act as DNA chain terminators owing to their inability to form a 3’-5’ phosphodiester linkage with another nucleoside. They bind much more avidly to the active site of the DNA-dependent DNA polymerase of HIV (reverse transcriptase) than to the active site of mammalian cell DNA polymerases; this explains their selective effect on HIV replication. Zidovudine also has a relatively high avidity for the DNA polymerase-γ of human mitochondria. This may contribute to the development of the fatty liver and the myopathy sometimes observed in patients taking zidovudine. As with all the nucleoside analogues, the active form of zidovudine is the triphosphate, and the rate of phosphorylation, a thymidine kinase–dependent pathway, may be different in different cells. This may explain why zidovudine is more effective at inhibiting HIV replication in some cells than others. The clinical efficacy of zidovudine was clearly established in 1986 in a phase II, randomized, placebo-controlled trial in patients...

**PROTEASE INHIBITORS**

| Saquinavir mesylate (Invirase—hard gel capsule) | Licensed | In combination with other antiretroviral agents when therapy is warranted | Not indicated | 600 mg q8h | Increases in CD4+ T cell counts, reduction in HIV RNA most pronounced in combination therapy with ddC. 50% reduction in first AIDS-defining event or death in combination with ddC compared to either agent alone | Diarrhea, nausea, headaches, hyperglycemia, fat redistribution, lipid abnormalities. |
| (Fortovase—soft gel capsule) | Licensed | For use in combination with other antiretroviral agents when treatment is warranted | Not indicated | 1200 mg tid | Reduction in the mortality rate and AIDS-defining events for patients who received hard-gel formulation in combination with ddC | Diarrhea, nausea, abdominal pain, headaches, hyperglycemia, fat redistribution, lipid abnormalities. |
| Ritonavir (Norvir)      | Licensed   | In combination with other antiretroviral agents for treatment of HIV infection when treatment is warranted | Not indicated | 600 mg bid | Reduction in the cumulative incidence of clinical progression or death from 34 to 17% in patients with CD4+ T cell count <100/μL treated for a median of 6 months | Nausea, abdominal pain, hyperglycemia, fat redistribution, lipid abnormalities, may alter levels of many other drugs, including saquinavir. |

(continued)
with advanced HIV disease. However, while treatment of patients with early stages of HIV infection was associated with increases in CD4+ T cell count, it was not associated with a better overall outcome than waiting until later to treat. Subsequent trials established the ability of this drug to dramatically decrease the incidence of perinatal transmission of HIV from infected mother to infant. Eventually a series of studies demonstrated the superiority of combination antiretroviral regimens over zidovudine alone, and combination therapy (discussed below) remains the standard of treatment today. Among the side effects of zidovudine at the initiation of therapy are fatigue, malaise, nausea, and headache. These side effects often subside over time. Patients on zidovudine may develop a macrocytic anemia, myopathy, cardiomyopathy, and lactic acidosis associated with fatty infiltration of the liver.

As with every antiretroviral drug, HIV has the ability to develop resistance, with its ability to develop resistance to other antiretroviral agents when other antiretroviral agents are added to new optimized backbone regimens. Disease progression and mortality have been shown to be better with new regimens than with previous regimens. Initially, zidovudine was used as a first-line agent in combination with other agents in treatment-experienced patients, superior to placebo when added to new optimized backbone (37% vs 16% with <400 HIV RNA copies/mL at 24 weeks; +71 vs +35 CD4+ T cells at 24 weeks).

Note: ARC, AIDS-related complex; NRTIs, nonnucleoside reverse transcriptase inhibitors.
Nucleoside Analogues

- **Zidovudine** (d4T; 2',3'-dideoxy-3'-thymidine) is the first drug licensed for the treatment of HIV infection. Like zidovudine, stavudine is a thymidine analogue. These two drugs are antagonistic in vitro and in vivo and should not be given together. Peripheral neuropathy and hepatic steatosis are the main toxicities of stavudine. It is commonly used with lamivudine as part of an initial treatment regimen.

- **Didanosine** (ddI; 2',3'-dideoxy-3'-inosine) was the second drug licensed for the treatment of HIV infection, followed shortly thereafter by zalcitabine. Didanosine is metabolized to dideoxyadenosine in vivo. It is best absorbed on an empty stomach at a high pH. For this reason, the formulations of didanosine either contain a buffer, and each dose must be administered in no fewer than two tablets to ensure adequate buffering of stomach acid, or are provided as an extended-release enteric-coated capsule. The toxicity profile of didanosine is quite different from that of zidovudine. The most common toxicity is a painful sensory peripheral neuropathy that occurs in ~30% of patients receiving >400 mg/d. It generally resolves with discontinuation of the drug and may not recur if the drug is resumed at a reduced dose. At higher doses than are currently used one may see pancreatitis in ~10% of patients. Pancreatitis associated with didanosine therapy can be fatal. Didanosine should be discontinued if a patient experiences abdominal pain consistent with pancreatitis or if an elevated serum amylase or lipase level is found in association with an edematous pancreas on ultrasound. Didanosine is contraindicated in patients with a prior history of pancreatitis, regardless of etiology.

- **Zalcitabine** (ddC; 2',3'-dideoxythymidine) is rarely used today in the management of patients with HIV infection. Among the nucleoside analogues licensed for the treatment of HIV infection, it is probably the weakest. The main toxicity of ddC is pancreatitis.

- **Stavudine** (d4T; 2',3'-didehydro-3'-deoxythymidine) was the fourth drug licensed for the treatment of HIV infection. Like zidovudine, stavudine is a thymidine analogue. These two drugs are antagonistic in vitro and in vivo and should not be given together. Peripheral neuropathy and hepatic steatosis are the main toxicities of stavudine. It is commonly used with lamivudine as part of an initial treatment regimen.

Lamivudine (3TC; 2',3'-dideoxycytidine) is the fifth of the nucleoside analogues to be licensed in the United States. It is licensed for use in combination with zidovudine in situations where zidovudine is indicated. In actual practice, lamivudine is a frequent element of many different combination regimens currently in use. It is available either alone or in combination with zidovudine (Combivir). One reason behind the excellent synergy seen between lamivudine and the other nucleoside analogues may be that strains of HIV resistant to lamivudine (M184V substitution) appear to have enhanced sensitivity to other nucleosides, and thus development of dual resistance is quite difficult. In addition, there is a suggestion that 3TC-resistant strains of HIV may be less virulent and are less able to generate new mutants than are strains of HIV that are 3TC-sensitive. Lamivudine is among the best tolerated and least toxic nucleoside analogues.

Emtricitabine (FTC; 5-fluoro-1-(2R,5S)-[2-(hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine) is the negative enantiomer of a thio analogue of cytidine with a fluorine in the 5 position. It is licensed for use in combination with other antiretroviral agents for treatment of HIV-1 infection in adults. Similar in activity to lamivudine, resistance to emtricitabine is associated with the M184V mutation in reverse transcriptase. Viruses showing the K65R mutation in reverse transcriptase may have reduced susceptibility to emtricitabine.

Abacavir [(1S,cis)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclopentene-1-methanol sulfate (salt)(2:1)] is a synthetic carbocyclic analogue of the nucleoside guanosine. It is licensed to be used in combination with other antiretroviral agents for the treatment of HIV-1 infection. Hypersensitivity reactions have been reported in ~4% of patients treated with this drug, and patients developing signs or symptoms of hypersensitivity such as fever, skin rash, fatigue, and gastrointestinal symptoms should discontinue the drug and not restart it. Fatal hyper-
sensitivity reactions have been reported with rechallenge. Abacavir hypersensitivity appears to occur with a higher frequency in patients who are HLA-B57. Abacavir-resistant strains of HIV are typically also resistant to lamivudine, didanosine, and zalcitabine.

Tenofovir disoproxil fumarate (9-[(R)-2-[[bis[(isoproxy carbonyl)]oxy]methoxy]phosphinyl]methoxy]propyl]adenine fumarate (1:1)) is an acyclic nucleoside phosphonate diester analogue of adenosine monophosphate. It undergoes diester hydrolysis to form tenofovir and is the first nucleotide analogue to be licensed for treatment of HIV infection. It is indicated in combination with other antiretroviral agents for the treatment of HIV-1 infection. HIV isolates with increased resistance typically express a K65R mutation in reverse transcriptase and a three- to four-fold reduction in sensitivity to tenofovir. Tenofovir is primarily eliminated by the kidneys, and renal impairment with hypophosphatemia may occur. Tenofovir is contraindicated in patients with renal impairment. Coadministration with didanosine leads to a 60% increase in didanosine levels, and thus doses of didanosine need to be adjusted and patients monitored carefully if these two drugs are used in combination.

Nevirapine, delavirdine, and efavirenz are nonnucleoside inhibitors of the HIV-1 reverse transcriptase. They are licensed for use in combination with nucleoside analogues for the treatment of HIV-infected adults. These agents inhibit reverse transcriptase by binding to regions of the enzyme outside the active site and causing conformational changes in the enzyme that render it inactive. Although these agents are active in the nanomolar range, they are also very selective for the reverse transcriptase of HIV-1, have no activity against HIV-2, and, when used as monotherapy, are associated with the rapid emergence of drug-resistant mutants (Table 173-20; Fig. 173-40). Efavirenz is administered once a day, nevirapine twice a day, and delavirdine three times a day. All three drugs are associated with the development of a maculopapular rash, generally seen within the first few weeks of therapy. While it is possible to treat through this rash, it is important to be sure that one is not dealing with a more severe eruption such as...

(continued)
A summary of known resistance mutations for protease inhibitors can develop rapidly in the setting of monotherapy, and thus in the case of reverse transcriptase inhibitors, resistance to protease inhibitors, these agents have been shown to be capable of suppressing levels of HIV replication to under 50 copies per milliliter in the majority of patients for a minimum of 5 years. HIV protease inhibitors are both commonly used as part of initial treatment regimens in combination with two nucleoside analogues. Another common use of these drugs is as part of salvage regimens in patients whose current regimen is inadequate.

The introduction of the HIV-1 protease inhibitors (saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, lopinavir/ritonavir, and atazanavir) to the therapeutic armamentarium of antiretrovirals has had a profound impact on the efficacy of antiretroviral therapy. When used as part of initial regimens in combination with reverse transcriptase inhibitors, these agents have been shown to be capable of suppressing levels of HIV replication to under 50 copies per milliliter in the majority of patients for a minimum of 5 years. HIV protease inhibitors appear to be good substrates for the drug transporters MDR-1 and MRPs. Whether or not genetic variations in these genes will lead to variability in protease inhibitor activity remains to be determined. As in the case of reverse transcriptase inhibitors, resistance to protease inhibitors can develop rapidly in the setting of monotherapy, and thus these agents should only be used as part of combination therapeutic regimens. A summary of known resistance mutations for protease inhibitors is shown in Fig. 173-40.

**Stevens-Johnson syndrome** by looking carefully for signs of mucosal involvement, significant fever, or painful lesions with desquamation. Severe, life-threatening, and in some cases fatal hepatotoxicity, including fulminant and cholestatic hepatitis, hepatic necrosis and hepatic failure, have been reported in patients treated with nevirapine. Many patients treated with efavirenz note a feeling of light-headedness, dizziness, or out of sorts following the initiation of therapy. Some complain of vivid dreams. These symptoms tend to disappear after several weeks of therapy. Aside from difficulties with dreams, taking efavirenz at bedtime may minimize the side effects. Nevirapine and efavirenz are both commonly used as part of initial treatment regimens in combination with two nucleoside analogues. Another common use of these drugs is as part of salvage regimens in patients whose current regimen is inadequate.

**Index Drug** | **Interacting Drug(s)** | **Mechanism/Effect** | **Recommendation**
--- | --- | --- | ---
Rifampin | Protease inhibitors, delavirdine, nevirapine | Induction of metabolism—decreased drug levels | Avoid concomitant use
Ritonavir | Efavirenz Delavirdine | Induction of metabolism—70% increase in ritonavir levels Inhibition of metabolism | Increase efavirenz to 800 mg qd No data to base recommendations
Saqunavir | Nevirapine Ritonavir | Induction of metabolism—drug levels decreased 27% Inhibition of metabolism—3-fold or higher increase in saquinavir drug levels | Clinical significance unknown—consider dosage increase of saquinavir or add ritonavir Various combinations used to optimize saquinavir therapy including 400 mg saquinavir/400 mg ritonavir
Delavirdine | Nelfinavir Efavirenz | Induction of metabolism—5-fold increase in saquinavir drug levels Inhibition of metabolism—saquinavir AUC decreased 62% | Dose saquinavir at 800 mg tid Dose saquinavir at 800 mg tid or 1200 mg bid Avoid concomitant use unless saquinavir is administered with ritonavir
Sildenafl | Protease inhibitors, delavirdine | Inhibition of metabolism—sildenafil AUC increased 2–11-fold | Use 25-mg sildenafil dose and do not repeat for 48 h
St. John’s Wort Terfenadine, astemizole | Protease inhibitors, azole antifungals, macrolides, delavirdine, efavirenz | Inhibition of metabolism | Cardiotoxic life-threatening effects possible—avoid concomitant use
Efavirenz Tipranavir | Ritonavir | Induction of metabolism—decreased blood levels Inhibition of metabolism—tipranavir AUC increased 7–45-fold | Monitor theophylline levels Combination under investigation to optimize tipranavir levels
TMP/SMZ | Ritonavir | TMP AUC decreased 63%, SMX AUC decreased 23% | Clinical significance unknown
Zalcitabine, stavudine, didanosine | Drugs that cause peripheral neuropathy—INH, d4T, ddI, ddC | Potential for increased risk of peripheral neuropathy | Monitor for signs and symptoms such as numbness and tingling in extremities
Zidovudine | Drugs causing bone marrow suppression (i.e., TMP/SMX, ganciclovir, sulfadiazine) | Increased bone marrow suppression | Monitor for anemia, neutropenia—may require supportive therapy (EPO, G-CSF)

**Note:** AUC, area under the curve; C, concentration; EPO, erythropoietin; G-CSF, granulocyte colony stimulating factor; TMP/SMX, trimethoprim/sulfamethoxazole.

**Saquinavir** was the first of the HIV-1 protease inhibitors to be licensed. Initially provided as a hard gel (Invirase) with poor bioavailability, the soft-gel formulation (Fortavase) provides good plasma levels of drug, particularly when administered in conjunction with ritonavir. Saquinavir is metabolized by the cytochrome P450 system, and ritonavir therapy results in inhibition of cytochrome P450 action. Thus, when both drugs are administered together there is the potential for increases in saquinavir levels. The use of low doses of ritonavir to provide pharmacodynamic boosting of other agents has become a fairly common strategy in HIV therapy. Saquinavir is among the best-tolerated protease inhibitors.

**Ritonavir** was the first protease inhibitor for which clinical efficacy was demonstrated. In a study of 1090 patients with CD4+ T cell counts <100/µL who were randomized to receive either placebo or ritonavir in addition to any other licensed medications, patients receiving ritonavir had a reduction in the cumulative incidence of clinical progression or death from 34% to 17%. Mortality decreased from 10.1% to 5.8%. At full doses, ritonavir is poorly tolerated. Among the main side effects are nausea, diarrhea, abdominal pain, and circumoral paresthesia. Ritonavir has a high affinity for several isofoms of cytochrome P450, and its use can result in large increases in the plasma concentrations of drugs metabolized by this pathway. Among the agents affected in this manner are saquinavir, indinavir, macrolide antibiotics, R-warfarin, ondansetron, rifampin, most calcium channel blockers, glucocorticoids, and some of the chemotherapeutic agents used to treat KS. In addition, ritonavir may increase the activity of glucuronosyltransferases, thus decreasing the levels of drugs metabolized by this pathway. Overall, great care must be taken when prescribing additional drugs to patients taking ritonavir. As mentioned above, the pharmacodynamic boosting property of ritonavir, seen with

FIGURE 173-40  Amino acid substitutions conferring resistance to antiretroviral drugs. For each amino acid residue, the letter above the bar indicates the amino acid associated with wildtype virus and the letter(s) below indicate the substitution(s) that confer viral resistance. The number shows the position of the mutation in the protein. Mutations selected by protease inhibitors in Gag cleavage sites are not listed because their contribution to resistance is not yet fully defined. HR1 indicates first heptad repeat; NAMs indicates nRTI-associated mutations; nRTI indicates nucleoside reverse transcriptase inhibitor; NNRTI indicates nonnucleoside reverse transcriptase inhibitor; PI indicates protease inhibitor. Amino acid abbreviations: A, alanine; C, cysteine; D, aspartate; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine. **FIGURE 173-40** — (Continued)
doses as low as 100 to 200 mg twice a day, is often used in the setting of HIV infection to derive more convenient regimens. For example, when given with low-dose ritonavir, saquinavir and indinavir can both be given on twice-a-day schedules and taken with food.

**Indinavir** is among the best studied of the HIV-1 protease inhibitors. It was the first protease inhibitor used in combination with dual nucleoside therapy. The combination of zidovudine, lamivudine, and indinavir was the first “triple combination” shown to have a profound effect on HIV replication. The main side effects of indinavir are nephrolithiasis (seen in 4% of patients) and asymptomatic indirect hyperbilirubinemia (seen in 10%). Indinavir is predominantly metabolized by the liver. The dose should be lowered in patients with cirrhosis. Indinavir shares metabolic pathways with terfenadine, astemizole, cisapride, terodolol, and midazolam. To avoid the potential for cardiac arrhythmias or prolonged sedation, these drugs should not be administered to patients taking indinavir. Levels of indinavir are decreased during concurrent therapy with rifabutin or nevirapine and increased during concurrent therapy with ketocazole, delavirdine, efavirenz, or ritonavir. Dosages should be modified appropriately in these circumstances (Table 173-21).

**Nelfinavir** was approved in 1997 and **amprenavir** was approved in 1999 for the treatment of adult or pediatric HIV infection when antiretroviral therapy is warranted. As with most of the newer antiretroviral agents, these approvals were based on randomized, controlled trials that demonstrated decreases in plasma HIV RNA levels and increases in CD4+ T cell counts. Both agents have unique resistance profiles. Nelfinavir resistance is associated with a D30N substitution in the protease gene. Viruses harboring this single mutation retain sensitivity to other protease inhibitors, and it has been suggested that for this reason nelfinavir is a good initial protease inhibitor. It is not clear, however, whether this theoretical consideration will be borne out in the results of clinical trials. Protease inhibitor resistance typically involves multiple amino acid substitutions and reduced susceptibility across the class. Amprenavir resistance is associated with a unique substitution at amino acid 50 (I50V), and it has been suggested that amprenavir may be of particular value in salvage regimens. This assumption also awaits verification in controlled clinical trials. Nelfinavir and amprenavir are both associated with gastrointestinal side effects. About 1% of patients receiving amprenavir have experienced severe and life-threatening skin reactions. An additional disadvantage of amprenavir is that the original formulation requires the patient to take 8 large capsules twice a day.

**Fosamprenavir** (Lexiva) is a recently licensed prodrug of amprenavir that is rapidly converted to amprenavir by cellular phosphatases. It is supplied as a 700-mg tablet. The recommended dosage is 1400 mg bid or 700 mg bid with ritonavir 100 mg bid or 1400 mg once a day with ritonavir 200 mg once a day.

**Lopinavir/ritonavir** (Kaletra) is a fixed dose combination of the protease inhibitors lopinavir (133.3 mg) and ritonavir (33.3 mg). It is indicated for treatment of HIV-1 infection in combination with other agents. A main advantage of this pill is that it combines the pharmacologic enhancement of low-dose ritonavir with a second protease inhibitor in a single capsule. In a randomized, controlled trial, this combination capsule was found to be superior to nelfinavir.

**Atazanavir** (Reyzitaz) is an azapeptide inhibitor of the HIV-1 protease. Initial studies suggest that total cholesterol and triglyceride levels may not increase as much with atazanavir as is seen with other protease inhibitors. Atazanavir is associated with increases in serum bilirubin and prolongations of the PR interval. Atazanavir-resistant isolates emerging in previously treatment-naive individuals frequently harbor an I50L substitution. This mutation in some instances is associated with increased sensitivity to other protease inhibitors. Atazanavir is an inhibitor of cytochrome P3A and its use may be associated with increased levels of calcium channel blockers, HMBA-CoA reductase inhibitors, and sildenafil. The second class of antiretroviral compounds are the entry inhibitors. These agents act by interfering with the binding of HIV to its receptor or co-receptor by interfering with the process of fusion (see above). A variety of small molecules that bind to HIV-1 co-receptors are currently in clinical trials. The first drug in this class to be licensed is the fusion inhibitor enfuvirtide (Fuzeon), or T-20.

**Enfuvirtide** is a linear 36-amino acid synthetic peptide with the N-terminus acetylated and the C-terminus a carboxamide. It is composed of naturally occurring L-amino acid residues and interferes with the fusion of the viral and cellular membranes by binding to the HR1 region in the gp41 subunit of the HIV-1 envelope. This binding interferes with the coil-coil interaction required to approximate the two membranes. Resistant isolates of HIV exhibit amino acid changes in positions 36 to 45 of gp41. In two independent studies, patients who had persistent viremia despite prior treatment with agents from all three available classes of drugs were randomized to receive an individualized regimen (based upon prior treatment history and resistance profile) with or without enfuvirtide. The change in plasma HIV-1 RNA from baseline was approximately 1 log greater (−1.53 vs. −0.68) in patients randomized to receive enfuvirtide. Among the drawbacks of this agent are the requirement for twice-a-day injection, the occurrence of injection site reactions in 98% of patients, and an increase in bacterial pneumonia in the enfuvirtide-treated patients compared to the patients in the control arm (4.68 vs. 0.61 events per 100 patient years) in the phase III studies.

The principles of therapy for HIV infection have been articulated by a panel sponsored by the U.S. Department of Health and Human Services and the Henry J. Kaiser Family Foundation. These principles are summarized in Table 173-22. As noted in these guidelines, eradication of HIV infection has not yet been possible. Treatment decisions must take into account the fact that one is dealing with a chronic infection. While early therapy is generally the rule in infectious diseases, immediate treatment of every HIV-infected individual upon diagnosis may not be prudent, and therapeutic decisions must take into account the balance between risks and benefits. At present, a reasonable course of action is to initiate antiretroviral therapy in anyone with the acute HIV syndrome; patients with symptomatic disease; patients with asymptomatic disease with CD4+ T cell counts <250/µL or with >50,000 copies of HIV RNA per milliliter (Table 173-23). In addition, one may wish to administer a 6-week course of therapy to uninfected individuals who are currently in clinical trials. The first drug in this class to be licensed is the fusion inhibitor enfuvirtide (Fuzeon), or T-20.

**TABLE 173-22 Principles of Therapy of HIV Infection**

1. Ongoing HIV replication leads to immune system damage and progression to AIDS.
2. Plasma HIV RNA levels indicate the magnitude of HIV replication and the rate of CD4+ T cell destruction. CD4+ T cell counts indicate the current level of competence of the immune system.
3. Rates of disease progression differ among individuals, and treatment decisions should be individualized based upon plasma HIV RNA levels and CD4+ T cell counts.
4. Maximal suppression of viral replication is a goal of therapy; the greater the suppression the less likely the appearance of drug-resistant quasispecies.
5. The most effective therapeutic strategies involve the simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been previously treated and that are not cross-resistant with antiretroviral agents that the patient has already received.
6. The antiretroviral drugs used in combination regimens should be used according to optimum schedules and dosages.
7. The number of available drugs is limited. Any decisions on antiretroviral therapy have a long-term impact on future options for the patient.
8. Women should receive optimal antiretroviral therapy regardless of pregnancy status.
9. The same principles apply to children and adults. The treatment of HIV-infected children involves unique pharmacologic, virologic, and immunologic considerations.
10. Compliance is an important part of ensuring maximal effect from a given regimen. The simpler the regimen, the easier it is for the patient to be compliant.

TABLE 173-23 Indications for the Initiation of Antiretroviral Therapy in Patients with HIV Infection

I. Acute infection syndrome
II. Chronic infection
   A. Symptomatic disease
   B. Asymptomatic diseases*  
      1. CD4+ T cell count <350/µL or decreasing
      2. HIV RNA >50,000 copies mL or increasing
III. Postexposure prophylaxis

* This is the area of greatest controversy. Some experts would wait until the CD4 cell count declines to 200/µL, whereas others would treat everyone regardless of CD4+ T cell count.

Source: Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents. USPHS.

individuals immediately following a high-risk exposure to HIV (see below).

Once the decision has been made to initiate therapy, the health care provider must decide which drugs to use as the first regimen. The decision regarding choice of drugs not only will affect the immediate response to therapy but also will have implications regarding options for future therapeutic regimens. The initial regimen is usually the most effective as far as the virus has yet to develop significant resistance. The two options for initial therapy most commonly in use today are two different three-drug regimens. The first regimen utilizes two nucleoside analogues (one of which is usually lamivudine) and a non-nucleoside reverse transcriptase inhibitor. The second regimen utilizes two nucleoside analogues and a protease inhibitor. Unfortunately there are no clear data at present on which to base distinctions between these two approaches. Following the initiation of therapy one should expect a 1 log (tenfold) reduction in plasma HIV RNA levels within 1 to 2 months and eventually a decline in plasma HIV RNA levels to <50 copies per milliliter. During this same time there should be a rise in copies per milliliter. During this same time there should be a rise in plasma HIV RNA levels to <50 copies per milliliter. This is particularly brisk during the first month of therapy. Many clinicians feel that failure to achieve this endpoint is an indication for a change in therapy. Other reasons for a change in therapy include a persistently declining CD4+ T cell count, clinical deterioration, or drug toxicity (Table 173-24). As in the case of initiating therapy, changing therapy may have a lasting impact on future therapeutic options. When changing therapy because of treatment failure (clinical progression or worsening laboratory parameters), it is important to attempt to provide a regimen with at least two new drugs. In the patient in whom a change is made for reasons of drug toxicity, a simple replacement of one drug is reasonable.

TABLE 173-24 Indications for Changing Antiretroviral Therapy in Patients with HIV Infection*

| Less than a 1-log drop in plasma HIV RNA by 4 weeks following the initiation of therapy |
| A reproducible significant increase (defined as 3-fold or greater) from the nadir of plasma HIV RNA level not attributable to intercurrent infection, vaccination, or test methodology |
| Persistently declining CD4+ T cell numbers |
| Clinical deterioration |
| Side effects |

* Generally speaking, a change should involve the initiation of at least 2 drugs felt to be effective in the given patient. The exception to this is when change is being made to manage toxicity, in which case a single substitution is reasonable.

Source: Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents. USPHS.

As in the case of initial therapy, the simpler the therapeutic regimen, the easier it is for the patient to be compliant. Plasma HIV RNA levels and CD4+ T lymphocyte counts should be monitored every 3 to 4 months during therapy and more frequently if one is contemplating a change in regimen or immediately following a change in regimen.

In an attempt to determine an optimal therapeutic regimen, one may attempt to measure antiretroviral drug susceptibility through genotyping or phenotyping of HIV quasispecies and determine adequacy of dosing through measurement of drug levels. Genotyping may be done through dideoxynucleotide sequencing, DNA chip hybridization, or line probe assays. Phenotypic assays measure the performance of reverse transcriptase or protease in the presence or absence of different concentrations of different drugs. These assays will generally detect quasispecies present at least 10%. The precise role of resistance testing in the management of patients with HIV infection is not yet clear. While randomized studies have suggested that information regarding HIV resistance profiles may improve virologic outcomes in patients failing their current antiretroviral regimen, the degree of improvement thus far has been small and the duration of the benefit limited. Resistance testing may be of particular value in distinguishing drug-resistant virus from poor patient compliance; it may also be of value to help guide initial therapy in a setting where transmission of a drug-resistant isolate is felt to be likely. Measurement of plasma drug levels can also be used to tailor an individual treatment. The inhibitory quotient, defined as the trough blood level/IC50 of the patient’s virus is used by some to determine the adequacy of dosing of a given treatment regimen.

In addition to the licensed medications discussed above, a large number of experimental agents are being evaluated as possible therapies for HIV infection. Therapeutic strategies are being developed that interfere with virtually every step of the replication cycle of the virus (Fig. 173-3). In addition, as more is discovered about the role of the immune system in controlling viral replication, additional strategies, generally referred to as “immune-based therapies,” are being developed as a complement to antiviral therapy. Among the antiviral agents in early clinical trials are additional nucleoside and nucleotide analogues, additional protease inhibitors including nonpeptidomimetic compounds, additional fusion inhibitors, receptor and co-receptor antagonists, integrase inhibitors, and antisense nucleic acids. Among the immune-based therapies being evaluated are IFN-α, bone marrow transplantation, adoptive transfer of lymphocytes genetically modified to resist infection or enhance HIV-specific immunity, active immunotherapy with inactivated HIV or its components, and IL-2.

HIV AND THE HEALTH CARE WORKER

Health care workers, especially those who deal with large numbers of HIV-infected patients, have a small but definite risk of becoming infected with HIV as a result of professional activities. As of January 1, 2002, 57 health care workers in the United States had been documented as having seroconverted to HIV following occupational exposure; 26 have developed AIDS. The individuals who seroconverted include 19 nurses, 6 physicians, 2 surgical technicians, 1 dialysis technician, 1 respiratory therapist, 1 health aide, 1 embalmer/morgue technician, and 2 housekeeper/maintenance workers. The exposures included 48 percutaneous (puncture/cut injury), 5 mucocutaneous (mucous membrane and/or skin), 2 both percutaneous and mucocutaneous, and 2 unknown route of exposure. Forty-nine exposures were to HIV-infected blood, three to concentrated virus in a laboratory, one to visibly bloody fluid, and four to an unspecified fluid. As of January 1, 2002, there had been 138 other cases of HIV infection or AIDS among health care workers who have not reported other risk factors for HIV infection and who report a history of exposure to blood, body fluids, or HIV-infected laboratory material, but for whom seroconversion after exposure was not documented. The number of these workers who actually acquired HIV infection through occupational exposures is not known. Taken together, the data from several large studies suggest that the risk of HIV infection following a percutaneous exposure to HIV-contami-
nated blood is −0.3%, and after a mucous membrane exposure, approximately 0.09%. Although episodes of HIV transmission after non-intact skin exposure have been documented, the average risk for transmission by this route has not been precisely quantified but is estimated to be less than the risk for mucous membrane exposures. The risk for transmission after exposure to fluids or tissues other than HIV-infected blood also has not been quantified but is probably considerably lower than for blood exposures. A seroprevalence survey of 3420 orthopedic surgeons, 75% of whom practiced in an area with a relatively high prevalence of HIV infection and 39% of whom reported percutaneous exposure to patient blood, usually through an accident involving a suture needle, failed to reveal any cases of possible occupational infection, suggesting that the risk of infection with a suture needle may be considerably less than that with a blood-drawing needle.

Most cases of health care worker seroconversion occur as a result of needle-stick injuries. When one considers the circumstances that result in needle-stick injuries, it is immediately obvious that adhering to the standard guidelines for dealing with sharp objects would result in a significant decrease in this type of accident. In one study, 27% of needle-stick injuries resulted from improper disposal of the needle (over half of these were due to recapping the needle), 23% occurred during attempts to start an intravenous line, 22% occurred during blood drawing, 16% were associated with an intramuscular or subcutaneous injection, and 12% were associated with giving an intravenous infusion.

Recommendations regarding postexposure prophylaxis must take into account that several circumstances determine the risk of transmission of HIV following occupational exposure. In this regard, several factors have been associated with an increased risk for occupational transmission of HIV infection including: deep injury, the presence of visible blood on the instrument causing the exposure, injury with a device that had been placed in the vein or artery of the source patient, terminal illness in the source patient, and lack of post-exposure antiretroviral therapy in the exposed health care worker. Other important considerations include pregnancy in the health care worker and the possibility of exposure to drug-resistant virus. Regardless of the decision to use postexposure prophylaxis, the wound should be cleaned immediately and antiseptic applied. If a decision is made to offer postexposure prophylaxis, U.S. Public Health Service guidelines recommend (1) a combination of two nucleoside analogue reverse transcriptase inhibitors given for 4 weeks for routine exposures, or (2) a combination of two nucleoside analogue reverse transcriptase inhibitors plus a third drug given for 4 weeks for high-risk or otherwise complicated exposures, although most clinicians administer the latter regimen in all cases in which a decision is made to treat. Further details are available from the Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HIV, HCV and HBV and Recommendations for Postexposure Prophylaxis (CDC, 2001).

Health care workers can minimize their risk of occupational HIV infection by following the CDC guidelines of July 1991, which include adherence to universal precautions, refraining from direct patient care if one has exudative lesions or weeping dermatitis, and disinfecting and sterilizing reusable devices employed in invasive procedures. The premise of universal precautions is that every specimen should be handled as if it came from someone infected with a bloodborne pathogen. All samples should be double-bagged, gloves should be worn when drawing blood, and spills should be immediately disinfected with bleach.

In attempting to put this small but definite risk to the health care worker in perspective, it is important to point out that ~200 health care workers die each year as a result of occupationally acquired hepatitis B infection. The tragedy in this instance is that these infections and deaths due to HBV could be greatly decreased by more extended use of the HBV vaccine. The risk of HIV infection following a needle-stick injury from a hepatitis antigen—positive patient is much higher than the risk of HIV infection (see “Transmission,” above). There are multiple examples of needle-stick injuries where the patient was positive for both HBV and HIV and the health care worker became infected only with HBV. For these reasons, it is advisable, given the high prevalence of HBV infection in HIV-infected individuals, that all health care workers dealing with HIV-infected patients be immunized with the HBV vaccine.

TB is another infection common to HIV-infected patients that can be transmitted to the health care worker. For this reason, all health care workers should know their PPD status, have it checked yearly, and receive 1 year of isoniazid treatment if their skin test converts to positive. In addition, all patients in whom a diagnosis of TB is being entertained should be placed immediately in respiratory isolation, pending results of the diagnostic evaluation. The emergence of drug-resistant organisms has made TB an increasing problem for health care workers. This is particularly true for the health care worker with pre-existing HIV infection.

One of the most charged issues ever to come between health care workers and patients is that of transmission of infection from HIV-infected health care workers to their patients. This is discussed under “Occupational Transmission of HIV: Health Care Workers and Laboratory Workers.” Theoretically, the same universal precautions that are used to protect the health care worker from the HIV-infected patient will also protect the patient from the HIV-infected health care worker.

**VACCINES**

Historically, vaccines have provided a safe, cost-effective, and efficient means of preventing illness, disability, and death from infectious diseases. Given the fact that human behavior, especially human sexual behavior, is extremely difficult to change, the best hope for preventing the spread of HIV infection rests with the development of a safe and effective vaccine. This task is problematic for a number of reasons, including the high mutability of the virus, the fact that the infection can be transmitted by cell-free or cell-associated virus, the likely need for the development of effective mucosal immunity, and the fact that it has been difficult to establish the precise correlates of protective immunity to HIV infection. Some HIV-infected individuals are long-term nonprogressors (see above), and a number of individuals have been exposed to HIV multiple times but remain uninfected; these facts suggest that there are protective elements of an HIV-specific immune response. In addition, studies using animal models, specifically SIV in the monkey and HIV-1 in the chimpanzee, have been encouraging and suggest that an HIV vaccine is possible. It should be pointed out that while the ideal goal of an HIV vaccine is to prevent infection, a vaccine given to an uninfected individual that significantly alters the course of disease or the infectivity of the individual, should that person become infected, could have an impact not only on the individual in question but also on the spread of infection in the community.

A number of clinical trials ranging from several small phase I studies to determine safety to fewer intermediate-sized phase II trials to determine safety and immunogenicity have taken place and are under way. The single completed phase III trial of a recombinant gp120 protein failed to show protection despite evidence of HIV-specific antibodies and CD4+T cells in phase II. These results suggest the potential importance of CD8+ T cell immunity in host defense against HIV-1. The furthest advanced among the current phase II trials involves a combination approach using a live canarypox vector expressing one or multiple HIV epitopes given together with gp120 or using the gp120 as a boost. This approach has resulted in neutralizing antibodies in virtually all recipients and HIV-specific cytolytic T cells in ~30% of individuals at any given time during the course of the trial. Other work is exploring the effects of recombinant adenovirus or naked DNA in combination with protein immunization.

Other approaches currently being tested in phase I and/or phase II trials in humans include vaccines employing vectors such as modified vaccinia Ankara (MVA), salmonella, and Venezuela equine enceph-
safe sex, and although the incidence of transmission via fellatio is
considerably less than that of rectal or vaginal intercourse, there has been doc-
umentation of transmission of HIV where receptive fellatio was the only
sexual act performed (see “Transmission,” above). Topical microbicides for
vaginal and anal use are being pursued actively as a means by which individu-
als could avoid infection when the in-
sertive partner cannot be relied on to use
a condom. Kissing is considered safe,
although there is a theoretical possibility of transmission via virus in saliva. The
low concentration of virus in saliva of
infected individuals, as well as the pres-
ence in saliva of HIV-inhibitory proteins
(see above), lessens any risk of trans-
mission by kissing.

The most effective way to prevent
transmission of HIV infection among
IDUs is to stop the use of injectable
drugs. Unfortunately, that is extremely
difficult to accomplish unless the indi-
vidual enters a treatment program. For
those who will not or cannot participate
in a drug treatment program and who
will continue to inject drugs, the avoid-
ance of sharing of needles and other paraphernalia (“works”) is the
next best way to avoid transmission of infection. The cultural and
social factors that contribute to the sharing of paraphernalia are com-
plex and difficult to overcome. In addition, needles and syringes may
be in short supply. Under these circumstances, paraphernalia should
be cleaned after each usage with a virucidal solution, such as undiluted
sodium hypochlorite (household bleach). Data from a number of stud-
ies have indicated that programs that provide sterile needles to addicts
in exchange for used needles have resulted in a decrease in HIV trans-
mission without increasing the use of injection drugs. It is important
for IDUs to be tested for HIV infection and counseled, to avoid trans-
mision to their sexual partners. Secondary and tertiary spread of HIV
infection by the heterosexual route within settings of a high level of
injection drug use has increased greatly in the United States (see
above).

Transmission of HIV via transfused blood or blood products has
been decreased dramatically by a combination of screening of all blood
donors for HIV infection by assays for both HIV antibody and p24
antigen and self-deferral of individuals at risk for HIV infection. In
addition, clotting factor concentrates are heat-treated, essentially elim-
inating the risk to hemophiliacs who require these products. Autolo-
gous transfusions are preferable to transfusions from another
individual. However, logistic constraints as well as the unpredictability
of the need for most transfusions limit the feasibility of this approach.
At present the risk of becoming HIV-infected from a contaminated
blood transfusion is approximately 1 in 725,000 to 1 in 835,000 do-
nations.

Treatment of an HIV-infected mother with antiretroviral therapy
during pregnancy and the infant during the first weeks following birth
has proven very effective in dramatically decreasing mother to child
transmission of HIV. In situations such as that seen in certain devel-
oping countries where pregnant women frequently present to a health
care system during labor, administration of a short course (as little as
a single dose of one drug) of antiretroviral therapy to the mother during
labor and to the infant within 48 h of birth has also been successful in
decreasing the incidence of mother to child transmission of HIV.

HIV can be transmitted via breast milk and colostrum. The avoid-
ance of breast-feeding may not be practical in developing countries,
where nutritional concerns override the risk of HIV transmission.
However, it is becoming appreciated that 5 to 15% of infants who
were born of HIV-infected mothers and who were fortunate enough

![Candidate HIV vaccines. See text for detailed discussion. (Adapted from D Baltimore, C Heilman: ScAm
279:98, 1998. Copyright Slim Films.)](image)
not to have been infected intrapartum or peripartum become infected via breast-feeding. Therefore, in developing countries, breast-feeding from an infected mother should be avoided if at all possible. Unfortunately, this is rarely the case, and given the disadvantages of withholding breast-feeding in developing countries (see above), health authorities in most developing countries continue to recommend breast-feeding despite the potential for HIV transmission. Treatment of the infected mother with antiretroviral therapy, in addition to decreasing perinatal mother-to-child transmission can also decrease transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, breast-feeding is absolutely contraindicated when a mother is HIV positive.

Acute infectious gastroenteritis is a common illness that affects persons of all ages worldwide. It is a leading cause of mortality among children in developing countries, accounting for an estimated 2.4 to 2.9 million deaths each year, and is responsible for up to 10 to 12% of all hospitalizations among children in industrialized countries, such as the United States. Elderly persons, especially those with debilitating health conditions, are also at risk of severe complications and death from acute gastroenteritis. Acute gastroenteritis rarely causes mortality among healthy young adults, but it incurs substantial medical and social costs, including those of time lost from work.

Several enteric viruses have been recognized as important etiologic agents of acute infectious gastroenteritis (Table 174-1). Illness caused by these viruses is characterized by the acute onset of vomiting and/or diarrhea, which may be accompanied by fever, nausea, abdominal cramps, anorexia, and malaise. As shown in Table 174-2, several features can help distinguish gastroenteritis caused by viruses from that caused by bacterial agents. However, the distinction based on clinical and epidemiologic parameters alone is often difficult, and laboratory tests may be required to confirm the diagnosis.

The Norwalk and related human caliciviruses affect both adults and children and are a leading cause of epidemics of gastroenteritis. Rotaviruses are the leading cause of severe childhood gastroenteritis worldwide. Enteric adenoviruses and astroviruses are recognized as less common causes of gastroenteritis, and the role of some viruses, such as toroviruses and picobirnaviruses, remains to be elucidated. A brief discussion of these agents of acute infectious gastroenteritis among humans follows.

**Pathogenesis** The exact sites and cellular receptors for attachment of viral particles have not been determined. Data suggest that carbohydrates that are similar to human histo-blood group antigens and are present on the gastrointestinal epithelium of individuals with the secretor phenotype may serve as ligands for the attachment of Norwalk virus. Additional studies must more fully elucidate norovirus-carbohydrate interactions, including potential strain-specific variations. After the infection of volunteers, reversible lesions are noted in the upper jejunum, with broadening and blunting of the villi, shortening of the microvilli, vacuolation of the lining epithelium, crypt hyperplasia, and infiltration of the lamina propria by polymorphonuclear cells and lymphocytes. The lesions persist for at least 4 days after the resolution of symptoms and are associated with malabsorption of carbohydrates and fats and a decreased level of brush-border enzymes. Adenylate cyclase activity is not altered. No histopathologic changes are seen in the stom-
Epidemic prevention relies on situation-specific measures, indicated. No specific antiviral therapy is available. If severe dehydration develops, oral or intravenous fluid therapy is generally not required because the disease is self-limited.

Gastroenteritis caused by Norwalk virus is primarily in research laboratories, although it is increasingly being used in clinical practice. Cloning and sequencing of the genome of Norwalk and several other human caliciviruses have allowed development of assays based on polymerase chain reaction (PCR) for detection of virus in stool and vomitus. Virus-like particles produced by expression of capsid proteins in a recombinant baculovirus vector have been used to develop enzyme immunoassays (EIAs) for detection of virus in stool or a serologic response to a specific viral antigen. These newer diagnostic techniques are considerably more sensitive than previous detection methods such as electron microscopy, immune electron microscopy, and EIAs based on reagents derived from humans. However, no currently available single assay can detect all human caliciviruses because of their great genetic and antigenic diversity. In addition, the assays are still cumbersome and are available primarily in research laboratories, although they are increasingly being adopted by public health laboratories for routine screening of fecal specimens from patients affected by outbreaks of gastroenteritis.

**TREATMENT**

Treatment generally is not required because the disease is self-limited. If severe dehydration develops, oral or intravenous fluid therapy is indicated. No specific antiviral therapy is available.

**Prevention**

Epidemic prevention relies on situation-specific measures, such as control of contamination of food and water, exclusion of ill food handlers, and reduction of person-to-person spread through good personal hygiene and disinfection of contaminated fomites. The role of immunophylaxis is not clear, given the lack of long-term immunity from natural disease and the paradoxical inverse association between the level of immune response and protection from disease.

**ROTAVIRUS**

Etiologic Agent

Rotaviruses are members of the family Reoviridae. The viral genome consists of 11 segments of double-strand RNA that are enclosed in a triple-layered, nonenveloped, icosahedral capsid 75 nm in diameter. Viral protein 6 (VP6), the major structural protein, is the target of commercial immunoassays and determines the group specificity of rotaviruses. There are seven major groups of rotavirus (A through G); human illness is caused primarily by group A and, to a much lesser extent, by groups B and C. Two outer-capsid proteins, VP7 (G-protein) and VP4 (P-protein), determine serotype specificity, induce neutralizing antibodies, and form the basis of the binary classification of rotaviruses (G and P types). The segmented genome of rotavirus allows genetic reassortment (i.e., exchange of genome segments between viruses) during co-infection—a property that may play a role in viral evolution and has been utilized in the development of reassortant animal-human rotavirus–based vaccines.

**Epidemiology**

Nearly all children are infected with rotavirus by 3 to 5 years of age. Neonatal infections are common but are often asymptomatic or mild, presumably because of protection from maternal antibody or breast-feeding. Nevertheless, rotavirus is known to cause disease in neonates, particularly in those admitted to intensive care units, and some data suggest that the clinical manifestations in full-
Term infants may differ from those in preterm infants. First infections after 3 months of age are likely to be asymptomatic, and the incidence of disease peaks among children 4 to 23 months of age. Reinfections are common, but the severity of disease decreases with each repeat infection. Therefore, severe rotavirus infections are relatively uncommon in older children and adults. However, rotavirus can cause illness in parents and caretakers of children with rotavirus diarrhea, immunocompromised persons, travelers, and elderly individuals and should be considered in the differential diagnosis of gastroenteritis among adults.

In temperate climates, rotavirus disease occurs predominantly during the cooler fall and winter months. In the United States, the annual rotavirus epidemic begins in the Southwest in autumn (October through December) and migrates across the continent, peaking in the Northeast during spring (March through May). In tropical settings, rotavirus disease occurs year-round, with less pronounced seasonal peaks.

Rotavirus gastroenteritis is more frequently associated with dehydration than is gastroenteritis caused by other pathogens. Therefore, the proportion of gastroenteritis cases that are attributable to rotavirus increases with increasing severity of illness, ranging from a median of 8% of cases in the community to 18% of cases in outpatients and 30% of cases in hospitalized patients. Each year, rotavirus is estimated to cause ~500,000 childhood deaths worldwide.

During episodes of rotavirus-associated diarrhea, virus is shed in large quantities (10^7 to 10^12/g) in stool. Viral shedding detectable by EIA usually subsides within a week but may persist for >30 days in immunocompromised individuals. Viral shedding may be detected for longer periods by sensitive molecular assays, such as PCR. The virus is transmitted predominantly through the fecal-oral route. Spread through respiratory secretions, person-to-person contact, or contaminated environmental surfaces has also been postulated to explain the rapid acquisition of antibody in the first 3 years of life, regardless of sanitary conditions.

At least 10 different G serotypes of group A rotavirus have been identified in humans, but only 5 types (G1 through G4 and G9) are common. While human rotavirus strains that possess a high degree of genetic homology with animal strains have been identified, animal-to-human transmission appears to be uncommon. Group B rotaviruses have been associated with several large epidemics of severe gastroenteritis among adults in China since 1982 and have recently been identified in India but not in other parts of the world. Group C rotaviruses have been associated with a small proportion of pediatric gastroenteritis cases in several countries worldwide.

**Pathogenesis** Rotaviruses infect and ultimately destroy the mature enterocytes in the villous epithelium of the proximal small intestine. The loss of absorptive villous epithelium coupled with the proliferation of secretory crypt cells results in secretory diarrhea. Brush-border enzymes characteristic of differentiated cells are reduced, and this change leads to the accumulation of unmetabolized disaccharides and consequent osmotic diarrhea. Studies in mice indicate that a nonstructural rotavirus protein, NSP4, functions as an enterotoxin and contributes to secretory diarrhea by altering epithelial cell function and permeability. In addition, rotavirus may evoke fluid secretion through activation of the enteric nervous system in the intestinal wall. Recent data indicate that rotavirus antigen and RNA are present in serum of children with acute rotavirus infection; further investigations are needed to establish the significance of these findings in the pathogenesis of rotavirus disease.

**Clinical Manifestations** The clinical spectrum of rotavirus infection ranges from subclinical illness to severe gastroenteritis leading to the development of life-threatening dehydration. After an incubation period of 1 to 3 days, the illness has an abrupt onset, with vomiting frequently preceding the onset of diarrhea. Up to one-third of patients may have a temperature of >39°C. The stools are characteristically loose and watery and only infrequently contain red or white cells. The gastrointestinal symptoms generally resolve in 3 to 7 days.

Respiratory and neurologic features in children with rotavirus infection have been reported, but causal associations have not been proven. Rotavirus infection has been associated with a variety of other clinical syndromes (e.g., sudden infant death syndrome, necrotizing enterocolitis, intussusception, and diabetes mellitus type 1), but no causal relationship has been confirmed with any of these syndromes.

Rotavirus does not appear to be a major opportunistic pathogen in children with HIV infection. In severely immunodeficient children, rotavirus can cause protracted diarrhea with prolonged viral excretion and, in rare instances, can disseminate systemically. Persons who are immunosuppressed for bone marrow transplantation are also at risk for severe, or even fatal, rotavirus disease.

**Immunity** Protection against rotavirus disease is correlated with the presence of virus-specific secretory IgA antibodies in the intestine and, to some extent, the serum. Because virus-specific IgA production at the intestinal surface is short-lived, complete protection against disease is only temporary. However, each infection and subsequent reinfection confers progressively greater immunity, so severe disease is most common among young children with first or second infections. Immunologic memory is believed to be important in the attenuation of the severity of disease upon reinfection.

**Diagnosis** Illness caused by rotavirus is difficult to distinguish clinically from that caused by other enteric viruses. Because large quantities of virus are shed in feces, the diagnosis can usually be confirmed by a wide variety of commercially available EIAs or by techniques for detecting viral RNA, such as gel electrophoresis, probe hybridization, or PCR.

### TREATMENT

**Rotavirus gastroenteritis can lead to severe dehydration. Thus appropriate treatment should be instituted early. Standard oral rehydration therapy is successful in most children who can take oral fluids, but intravenous fluid replacement may be required for patients who are severely dehydrated or are unable to tolerate oral therapy because of frequent vomiting. The therapeutic role of probiotics, bismuth subcitrate, and enkephalinase inhibitors has been evaluated in clinical studies but is not clearly defined. Antibiotics and antimotility agents should be avoided. In immunocompromised children with chronic symptomatic rotavirus disease, orally administered immunoglobulins or colostrom may resolve symptoms, but the choice of agents and their doses have not been well studied and are often empirical.**

**Prevention** Efforts to develop rotavirus vaccines were pursued because it was apparent—given the similar rates in less developed and industrialized nations—that improvements in hygiene and sanitation were unlikely to reduce disease incidence. In 1998, a rotavirus vaccine was licensed in the United States and was recommended for routine immunization of infants. However, this vaccine was withdrawn in 1999 because it was causally linked with intussusception, with an estimated 1 case per 11,000 vaccinated infants. Other rotavirus vaccines are being developed, including two leading multinational candidate vaccines whose safety and efficacy are currently being studied in large-scale clinical trials.

**OTHER VIRAL AGENTS OF GASTROENTERITIS** Enteric adenoviruses of serotypes 40 and 41 belonging to subgroup F are 70- to 80-nm viruses with double-strand DNA that cause ~2 to 12% of all diarrhea episodes in young children. Unlike adenoviruses that cause respiratory illness, enteric adenoviruses are difficult to cultivate in cell lines, but they can be detected with commercially available EIAs.

Astroviruses, 28- to 30-nm viruses with a characteristic icosahedral structure, contain a positive-sense, single-strand RNA. At least seven serotypes have been identified, of which serotype 1 is most common. Astroviruses are primarily pediatric pathogens, causing ~2 to 10% of cases of mild to moderate gastroenteritis in children. The availability...
of simple immunoassays to detect virus in fecal specimens and of molecular methods to confirm and characterize strains will permit more comprehensive assessment of the etiologic role of these agents.

Enteroviruses are 100- to 140-nm, enveloped, positive-strand RNA viruses that are recognized as causes of gastroenteritis in horses (Berne virus) and cattle (Breda virus). Their role as a cause of diarrhea in humans is still unclear, but a study from Canada demonstrated an association between torovirus excretion and nosocomial gastroenteritis in pediatric patients. In this study, more than half of the patients with torovirus in stool also had a demonstrable immune response. Patients with torovirus infection were older and experienced less vomiting and more bloody diarrhea than did those with rotavirus or astrovirus infection. Further studies are required to confirm these findings.

Picobirnaviruses are small, bi-segmented, double-strand RNA viruses that cause gastroenteritis in a variety of animals. Their role as primary causes of gastroenteritis in humans remains unclear, but several studies have found an association between picobirnaviruses and gastroenteritis in HIV-infected adults.

The recently recognized severe acute respiratory syndrome-associated coronavirus (SARS-CoV) has been associated with gastroenteritis in 20 to 66% of affected patients. In one study of 138 SARS patients in Hong Kong, 20.3% presented with watery diarrhea, and up to 38.4% had diarrhea during their illness. Diarrhea was most common during the first week of illness, lasted for an average of 3.7 days, and was self-limiting in most instances. Studies of intestinal biopsy specimens showed minimal architectural disruption but also revealed active viral replication within both the small and the large intestine. SARS-CoV RNA could be detected in the stool of patients for >10 weeks after the onset of symptoms.

Several other viruses (e.g., enteroviruses, reoviruses, pestiviruses, and paroviruses B) have been identified in the feces of patients with diarrhea, but their etiologic role in gastroenteritis has not been proved.

*Source: Centers for Disease Control and Prevention, 2002.*
Humoral and secretory immunity in the gastrointestinal tract is important for the control of enterovirus infections. Enteroviruses induce specific IgM, which usually persists for <6 months, and specific IgG, which persists for life. Capsid protein VP1 is the predominant target of neutralizing antibody, which generally confers lifelong protection against subsequent disease caused by the same serotype but does not prevent infection or virus shedding. Enteroviruses also induce cellular immunity, but the significance of this mechanism in limiting infection is uncertain. Patients with impaired cellular immunity are not known to develop unusually severe disease when infected with enteroviruses. In contrast, the severe infections in patients with agammaglobulinemia emphasize the importance of humoral immunity in controlling enterovirus infections. IgA antibodies are instrumental in reducing poliovirus replication in and shedding from the gastrointestinal tract. Breast milk contains IgA specific for enteroviruses and can protect humans from infection.

**Epidemiology** Enteroviruses have a worldwide distribution. More than 50% of nonpoliovirus enterovirus infections and more than 90% of poliovirus infections are subclinical. When symptoms do develop, they are usually nonspecific and occur in conjunction with fever; only about 1% of enterovirus infections are associated with specific clinical syndromes. The incubation period for most enterovirus infections ranges from 2 to 14 days but usually is <1 week.

Enterovirus infection is more common in socioeconomically disadvantaged areas, especially in those where conditions are crowded and in tropical areas where hygiene is poor. Infection is most common among infants and young children; serious illness develops most often during the first few days of life and in older children and adults. In developing countries, where children are infected at an early age, poliovirus infection has less often been associated with paralysis; in countries with better hygiene, older children and adults are more likely to be seronegative, become infected, and develop paralysis. Passively acquired maternal antibody reduces the risk of symptomatic infection in neonates. Young children are the most frequent shedders of enteroviruses and are usually the index cases in family outbreaks. In temperate climates, enterovirus infections occur most often in the summer and fall; no seasonal pattern is apparent in the tropics.

Most enteroviruses are transmitted primarily by the fecal-oral route from fecally contaminated fingers or inanimate objects. Patients are most infectious shortly before and after the onset of symptomatic disease, when virus is present in the stool and throat. The ingestion of virus-contaminated food or water can also cause disease. Certain enteroviruses (such as enterovirus 70, which causes acute hemorrhagic conjunctivitis) can be transmitted by direct inoculation from the fingers to the eye. Airborne transmission is important for some viruses that cause respiratory tract disease, such as coxsackievirus A21. Enteroviruses can be transmitted across the placenta from mother to fetus, causing severe disease in the newborn. The transmission of enteroviruses through blood transfusions or insect bites has not been documented. Nosocomial spread of coxsackievirus and echovirus has taken place in hospital nurseries.

**Clinical Features of Infection with Poliovirus** Most infections with poliovirus are asymptomatic. After an incubation period of 3 to 6 days, ~5% of patients present with a minor illness (abortive poliomyelitis) manifested by fever, malaise, sore throat, anorexia, myalgias, and headache. This condition usually resolves in 3 days. About 1% of patients present with aseptic meningitis (nonparalytic poliomyelitis). Examination of cerebrospinal fluid (CSF) reveals lymphocytic pleocytosis, a normal glucose level, and a normal or slightly elevated protein level; CSF polymorphonuclear leukocytes may be present early. In some patients, especially children, malaise and fever precede the onset of aseptic meningitis.

The least common presentation is that of paralytic disease. After one or several days, signs of aseptic meningitis are followed by severe back, neck, and muscle pain and by the rapid or gradual development of motor weakness. In some cases the disease appears to be biphase, with aseptic meningitis followed by apparent recovery but then (1 or 2 days later) by the return of fever and the development of paralytic disease; this form is more common among children than among adults. Weakness is generally asymmetric, is proximal more than distal, and may involve the legs (most commonly); the arms; or the abdominal, thoracic, or bulbar muscles. Paralysis develops during the febrile phase of the illness and usually does not progress after defervescence. Urinary retention may also occur. Examination reveals weakness, fasciculations, decreased muscle tone, and reduced or absent reflexes in affected areas. Transient hyperreflexia sometimes precedes the loss of reflexes. Patients frequently report sensory symptoms, but objective sensory testing usually yields normal results. Bulbar paralysis may lead to dysphagia, difficulty in handling secretions, or dysphonia. Respiratory insufficiency due to aspiration, involvement of the respiratory center in the medulla, or paralysis of the phrenic or intercostal nerves may develop, and severe medullary involvement may lead to circulatory collapse. Most patients with paralysis recover some function weeks to months after infection. About two-thirds of patients have residual neurologic sequelae.

Paralytic disease is more common among older individuals, pregnant women, and persons exercising strenuously or undergoing trauma at the time of CNS symptoms. Tonsillectomy predisposes to bulbar poliomyelitis, and intramuscular injections increase the risk of paralysis in the involved limb(s).

Until recently, poliomyelitis due to live poliovirus vaccine occurred in the United States. The risk of developing poliomylitis after oral vaccination is estimated at 1 case per 2.5 million doses. The risk is ~2000 times higher among immunodeficient persons, especially in persons with hypogammaglobulinemia. Before 1997, an average of eight cases of vaccine-associated poliomyelitis occurred—in both vaccinees and their contacts—in the United States each year. With the change in recommendations first to a sequential regimen of inactivated poliovirus vaccine (IPV) and oral poliovirus vaccine (OPV) in 1997 and then to an all-IPV regimen in 2000, the number of cases of vaccine-associated poliovirus declined. From 1997 to 1999, six such cases were reported in the United States; no cases have been reported since 1999.

The postpolio syndrome presents as a new onset of weakness, fatigue, fasciculations, and pain with additional atrophy of the muscle group involved during the initial paralytic disease 20 to 40 years earlier. The syndrome is more common among women and with increasing time after acute disease. The onset is usually insidious, and weakness occasionally extends to muscles that were not involved during the initial illness. The prognosis is generally good; progression to further weakness is usually slow, with plateau periods that range from 1 to 10 years. The postpolio syndrome is thought to be due to progressive dysfunction and loss of motor neurons that compensated for the neurons lost during the original infection and not to persistent or reactivated poliovirus infection.

**Clinical Features of Infection with Coxsackievirus, Echovirus, and Other Enteroviruses** An estimated 5 to 10 million cases of symptomatic disease due to enterovirus other than poliovirus occur in the United States each year. Enteroviruses are the most common cause of aseptic meningitis and nonspecific febrile illnesses of neonates. Certain clinical syndromes are more likely to be caused by certain serotypes (Table 175-2), but there is much overlap. In 2000–2001, 85% of enterovirus infections were caused by only 10 of the 64 human serotypes. Echoviruses 13 and 18 accounted for 43% of recognized enterovirus infections (Table 175-1).

**Nonspecific Febrile Illness (Summer Gripe)** The most common clinical manifestation of enterovirus infection is a nonspecific febrile illness. After an incubation period of 3 to 6 days, patients present with an acute onset of fever, malaise, and headache. Occasional cases are associated with upper respiratory symptoms, and some cases include nausea and vomiting. Symptoms often last for 3 to 4 days, and most cases resolve in a week. While infections with other respiratory viruses...
Generalized Disease of the Newborn

Most serious enterovirus infections in infants develop during the first week of life, although severe disease can occur up to 3 months of age. Neonates often present with an illness resembling bacterial sepsis, with fever, irritability, and lethargy. Laboratory abnormalities include leukocytosis with a left shift, thrombocytopenia, elevated values in liver function tests, and CSF pleocytosis. The illness can be complicated by myocarditis and hypotension, fulminant hepatitis and disseminated intravascular coagulation, meningitis or meningoencephalitis, or pneumonia. It may be difficult to distinguish enterovirus infection from bacterial sepsis, although a history of a recent virus-like illness in the mother provides a clue.

Aseptic Meningitis and Encephalitis

Enteroviruses are the cause of up to 90% of cases of aseptic meningitis in children and young adults in which an etiologic agent can be identified. Patients with aseptic meningitis typically present with an acute onset of fever, chills, headache, photophobia, and pain on eye movement. Nausea and vomiting are also common. Examination reveals meningismus without localizing neurologic signs; drowsiness or irritability may also be apparent. In some cases, a febrile illness may be reported that remits but returns several days later in conjunction with signs of meningitis. Other systemic manifestations may provide clues to an enteroviral cause, including diarrhea, myalgias, rash, pleurodynia, myocarditis, and herpangina. Examination of the CSF invariably reveals pleocytosis; early in the course, polymorphonuclear leukocytes may be present or even predominant, raising the possibility of bacterial or other nonviral causes of meningitis. Partially treated bacterial meningitis may be particularly difficult to exclude in some instances. A useful rule is that the CSF cell count in enteroviral meningitis shows a shift to lymphocytic predominance within 24 h of presentation, and the total count generally does not exceed 1000 cells/μL. Additional CSF findings consist of a normal glucose content and a normal or only slightly elevated (by ≤100 mg/dL) level of protein. Enteroviruses and mumps virus may produce a similar picture of meningitis; a low CSF glucose level suggests mumps, whereas a normal CSF glucose level and transient CSF polymorphonuclear pleocytosis suggest enterovirus infection. Enteroviral meningitis is more frequent in summer and fall in temperate climates, while viral meningitis of other etiologies (e.g., mumps) is more common in winter and spring. Symptoms ordinarily resolve within a week, although CSF abnormalities can persist for several weeks. Enteroviral meningitis is often more severe in adults than in children. Neurologic sequelae are rare, and most patients have an excellent prognosis.

Enteroviral encephalitis is much less common than enteroviral aseptic meningitis. Occasional highly inflammatory cases of enteroviral meningitis may be complicated by a mild form of encephalitis that is recognized on the basis of progressive lethargy, disorientation, and sometimes seizures. Less commonly, severe primary encephalitis may develop. It is estimated that 10 to 20% of cases of viral encephalitis are due to enteroviruses. Immunocompetent patients generally have a good prognosis.

Patients with hypo- or agammaglobulinemia or severe combined immunodeficiency may develop chronic meningitis or encephalitis; about half of these patients have a dermatomyositis-like syndrome, with peripheral edema, rash, and myositis. They may also have chronic hepatitis. Patients may develop neurologic sequelae after receiving gamma globulin replacement therapy. Echoviruses (especially echovirus 11) are the most common pathogens in this situation.

Aseptic Meningitis and Encephalitis

Enteroviruses are the cause of up to 90% of cases of aseptic meningitis in children and young adults in which an etiologic agent can be identified. Patients with aseptic meningitis typically present with an acute onset of fever, chills, headache, photophobia, and pain on eye movement. Nausea and vomiting are also common. Examination reveals meningismus without localizing neurologic signs; drowsiness or irritability may also be apparent. In some cases, a febrile illness may be reported that remits but returns several days later in conjunction with signs of meningitis. Other systemic manifestations may provide clues to an enteroviral cause, including diarrhea, myalgias, rash, pleurodynia, myocarditis, and herpangina. Examination of the CSF invariably reveals pleocytosis; early in the course, polymorphonuclear leukocytes may be present or even predominant, raising the possibility of bacterial or other nonviral causes of meningitis. Partially treated bacterial meningitis may be particularly difficult to exclude in some instances. A useful rule is that the CSF cell count in enteroviral meningitis shows a shift to lymphocytic predominance within 24 h of presentation, and the total count generally does not exceed 1000 cells/μL. Additional CSF findings consist of a normal glucose content and a normal or only slightly elevated (by ≤100 mg/dL) level of protein. Enteroviruses and mumps virus may produce a similar picture of meningitis; a low CSF glucose level suggests mumps, whereas a normal CSF glucose level and transient CSF polymorphonuclear pleocytosis suggest enterovirus infection. Enteroviral meningitis is more frequent in summer and fall in temperate climates, while viral meningitis of other etiologies (e.g., mumps) is more common in winter and spring. Symptoms ordinarily resolve within a week, although CSF abnormalities can persist for several weeks. Enteroviral meningitis is often more severe in adults than in children. Neurologic sequelae are rare, and most patients have an excellent prognosis.

Enteroviral encephalitis is much less common than enteroviral aseptic meningitis. Occasional highly inflammatory cases of enteroviral meningitis may be complicated by a mild form of encephalitis that is recognized on the basis of progressive lethargy, disorientation, and sometimes seizures. Less commonly, severe primary encephalitis may develop. It is estimated that 10 to 20% of cases of viral encephalitis are due to enteroviruses. Immunocompetent patients generally have a good prognosis.

Patients with hypo- or agammaglobulinemia or severe combined immunodeficiency may develop chronic meningitis or encephalitis; about half of these patients have a dermatomyositis-like syndrome, with peripheral edema, rash, and myositis. They may also have chronic hepatitis. Patients may develop neurologic sequelae after receiving gamma globulin replacement therapy. Echoviruses (especially echovirus 11) are the most common pathogens in this situation.

Paralytic disease due to enteroviruses other than poliovirus occurs sporadically and is usually less severe than poliomyelitis. Most cases are due to enterovirus 70 or 71 or to coxsackievirus A7 or A9. Guillain-Barré syndrome is also associated with enterovirus infection. While some studies have suggested a link between enteroviruses and the chronic fatigue syndrome, most recent studies have not demonstrated such an association.

Pleurodynia (Bornholm Disease)

Patients with pleurodynia present with an acute onset of fever and spasms of pleuritic chest or upper abdominal pain. Chest pain is more common in adults, and abdominal pain is more common in children. Paroxysms of severe, knife-like pain usually last 15 to 30 min and are associated with diaphoresis and tachypnea. Fever peaks within an hour after the onset of paroxysms and subsides when pain resolves. The involved muscles are tender to palpation, and a pleural rub may be detected. The white blood cell count and chest x-ray are usually normal. Most cases are due to coxsackievirus B and occur during epidemics. Symptoms resolve in a few days, and recurrences are rare. Treatment includes the administration of nonsteroidal anti-inflammatory agents or the application of heat to the affected muscles.

Myocarditis and Pericarditis

Enteroviruses are estimated to cause up to one-third of cases of acute myocarditis. Coxsackievirus B and its RNA have been detected in pericardial fluid and myocardial tissue in some cases of acute myocarditis and pericarditis. Most cases of enteroviral myocarditis or pericarditis occur in newborns, adolescents, or young adults. More than two-thirds of patients are male. Patients often present with an upper respiratory tract infection that is followed by fever, chest pain, dyspnea, arrhythmias, and occasionally heart failure. A pericardial friction rub is documented in half of cases, and the electrocardiogram shows ST segment elevations or ST- and T-wave abnormalities. Serum levels of myocardial enzymes are often elevated. Neonates commonly have severe disease, while most older children and adults recover completely. Up to 10% of cases progress to chronic dilated cardiomyopathy. Chronic constrictive pericarditis may also be a sequela.

Exanthems

Enterovirus infection is the leading cause of exanthems in children in the summer and fall. While exanthems are associated with many enteroviruses, certain types have been linked to specific syndromes. Echoviruses 9 and 16 have frequently been associated with exanthem and fever. Rashes may be discrete (rubelliform) or confluent (morbilliform), beginning on the face and spreading to the trunk and extremities. Echovirus 9 is the most common cause of rubelliform rash. Unlike the rash of rubella, the enteroviral rash occurs in the summer and is not associated with lymphadenopathy. Roseola-like rashes develop after defervescence, with macules and papules on the face and trunk. The prodrome neuroton exhantem, caused by echovirus 16, is a roseola-like rash that often affects multiple members of a family. A variety of other rashes have been associated with enteroviruses, in-

---
cluding erythema multiforme and vesicular, urticarial, petechial, or purpuric lesions. Enanthems also occur, including lesions that resemble the Koplik’s spots seen with measles.

**Hand-Foot-and-Mouth Disease**  After an incubation period of 4 to 6 days, patients with hand-foot-and-mouth disease present with fever, anorexia, and malaise; these manifestations are followed by the development of sore throat and vesicles (Fig. 175-1) on the buccal mucosa and often on the tongue and then by the appearance of tender vesicular lesions on the dorsum of the hands, sometimes with involvement of the palms. The vesicles may form bullae and quickly ulcerate. About one-third of patients also have lesions on the palate, uvula, or tonsillar pillars, and one-third have a rash on the feet (including the soles) or on the buttocks. The disease is highly infectious, with attack rates of close to 100% among young children. The lesions usually resolve in 1 week. Most cases are due to coxsackievirus A16 or enterovirus 71.

An epidemic of enterovirus 71 infection in Taiwan in 1998 resulted in thousands of cases of hand-foot-and-mouth disease or herpangina. Severe complications included CNS disease, myocarditis, and pulmonary hemorrhage. About 90% of those who died were children ≤5 years old, and these deaths were associated with pulmonary edema or pulmonary hemorrhage. CNS disease included aseptic meningitis, flaccid paralysis (similar to poliomyelitis), or rhombencephalitis with myoclonus and tremor or ataxia. The mean age of patients with CNS complications was 2.5 years, and magnetic resonance imaging in cases with encephalitis usually showed brain-stem lesions.

**Herpangina**  Herpangina is usually caused by coxsackievirus A and presents as acute-onset fever, sore throat, dysphagia, and grayish-white papulovesicular lesions on an erythematous base that ulcerate. The lesions can persist for weeks; are present on the soft palate, anterior pillars of the tonsils, and uvula; and are concentrated in the posterior portion of the mouth. In contrast to herpetic stomatitis, enteroviral herpangina is not associated with gingivitis. Acute lymphonodular pharyngitis associated with coxsackievirus A10 presents as white or yellow nodules surrounded by erythema in the posterior oropharynx. The lesions do not ulcerate.

**Acute Hemorrhagic Conjunctivitis**  Patients with acute hemorrhagic conjunctivitis present with an acute onset of severe eye pain, blurred vision, photophobia, and watery discharge from the eye. Examination reveals edema, chemosis, and subconjunctival hemorrhage and often shows punctate keratitis and conjunctival follicles as well. Preauricular adenopathy is often found. Epidemics and nosocomial spread have been associated with enterovirus 70 and coxsackievirus A24. Systemic symptoms, including headache and fever, develop in 20% of cases, and recovery is usually complete in 10 days. The sudden onset and short duration of the illness help to distinguish acute hemorrhagic conjunctivitis from other ocular infections such as those due to adenovirus and Chlamydia. Paralysis has been associated with some cases of acute hemorrhagic conjunctivitis due to enterovirus 70 during epidemics.

**Other Manifestations**  Enteroviruses are an infrequent cause of childhood pneumonia and the common cold. Coxsackievirus B has been isolated at autopsy from the pancreas of a few children presenting with insulin-dependent diabetes mellitus; however, most attempts to isolate the virus have been unsuccessful. Other diseases that have been associated with enterovirus infection include parotitis, bronchitis, bronchiolitis, croup, infectious lymphocytosis, polyomyositis, acute arthritis, and acute nephritis.

**DIAGNOSIS**  Isolation of enterovirus in cell culture is the most common procedure for the diagnosis of infection. While cultures of stool, nasopharyngeal, or throat samples from patients with enterovirus diseases are often positive, isolation of the virus from these sites does not prove that it is directly associated with disease because these sites are frequently colonized for weeks in patients with subclinical infections. Isolation of virus from the throat is more likely to be associated with disease than isolation from the stool since virus is shed for shorter periods from the throat. Cultures of CSF, serum, fluid from body cavities, or tissues are positive less frequently, but a positive result is indicative of disease caused by enterovirus. In some cases the virus can be isolated only from the blood or only from the CSF; therefore, it is important to culture multiple sites. Cultures are more likely to be positive earlier than later in the course of infection. Most human enteroviruses can be detected within a week after inoculation of cell cultures. Cultures may be negative because of the presence of neutralizing antibody, lack of susceptibility of the cells used, or inappropriate handling of the specimen. Coxsackievirus A may require inoculation into special cell-culture lines or into suckling mice.

Identification of the serotype of an enterovirus is useful primarily for epidemiologic studies and, with a few exceptions, has little clinical utility. It is important to identify serious infections with enterovirus during epidemics and to distinguish the vaccine strain of poliovirus from the other enteroviruses in the throat or in the feces. Stool and throat samples for culture as well as acute- and convalescent-phase serum specimens should be obtained from all patients with suspected poliomyelitis. In the absence of a positive CSF culture, a positive culture of stool obtained within the first 2 weeks after the onset of symptoms is most often used to confirm the diagnosis of poliomyelitis. If poliovirus is isolated, it should be sent to the CDC in Atlanta for identification as either a wild-type or a vaccine virus.

The polymerase chain reaction (PCR) has been used to amplify viral nucleic acid from CSF, serum, urine, throat swabs, and tissues. A single pair of PCR primers can detect more than 92% of the serotypes that infect humans. With the proper controls, PCR of the CSF is highly sensitive (≥95%) and specific (>80%) and is more rapid than culture. PCR of serum is also highly sensitive and specific in the diagnosis of disseminated disease. PCR may be particularly helpful for the diagnosis and follow-up of enterovirus disease in immuno-deficient patients receiving immunoglobulin therapy, whose viral cultures may be negative. Antigen detection and hybridization of enterovirus sequences in human tissues with a specific probe are additional options, but these techniques are generally less sensitive than PCR.

Serologic diagnosis of enterovirus infection is limited by the large
Most enterovirus infections are mild and resolve spontaneously; however, intensive supportive care may be needed for cardiac, hepatic, or CNS disease. Intravenous, intrathecal, or intraventricular immunoglobulin has been used with apparent success for the treatment of chronic enterovirus meningoencephalitis and dermatomyositis in patients with hypo- or agammaglobulinemia. The disease may stabilize or resolve during therapy; however, some patients decline inexorably despite therapy. Intravenous administration of immunoglobulin with high titers of antibody to the infecting virus has been used in the treatment of some cases of life-threatening infection in neonates, who may not have maternally acquired antibody. In one trial involving neonates with enterovirus infections, immunoglobulin containing very high titers of antibody to the infecting virus reduced rates of viremia; however, the study was too small to show a substantial clinical benefit. The level of enteroviral antibodies varies with the immunoglobulin preparation. Oral pleconaril, which binds to the enterovirus capsid, reduced symptoms in a placebo-controlled trial of enteral aspecitic meningitis. In a review of compassionate-release pleconaril therapy in patients with potentially life-threatening enteroviral infections, ~75% of persons were judged to have a clinical response associated with therapy. These individuals included patients with chronic enteroviral meningoencephalitis, neonatal sepsis, myocarditis, and vaccine-associated paralytic poliomyelitis. Further study is needed to confirm these findings. Glucocorticoids are contraindicated.

Good hand-washing practices and the use of gowns and gloves are important in limiting nosocomial transmission of enteroviruses during epidemics. Enteric precautions are indicated for 7 days after the onset of enterovirus infections.

**PREVENTION AND ERADICATION OF POLIOVIRUS** (See also Chap. 107) After a peak of 57,879 cases of poliomyelitis in the United States in 1952, the introduction of inactivated vaccine in 1955 and of oral vaccine in 1961 ultimately eradicated disease due to wild-type poliovirus in the Western Hemisphere. Such disease has not been documented in the United States since 1979, when cases occurred among religious groups who had declined immunization. In the Western Hemisphere, paralysis due to wild-type poliovirus was last documented in 1991.

In 1988, the World Health Organization adopted a resolution to eradicate poliomyelitis by the year 2000. From 1988 to 2001, the number of cases worldwide decreased by >99%, with fewer than 1000 confirmed cases reported in 2001. In 2002, however, there were ~1900 cases of polio, with ~1500 reported in India. Wild-type poliovirus type 2 has not been detected in the world since 1999. The Americas were certified free of indigenous wild-type poliovirus transmission in 1994, the Western Pacific Region in 2000, and the European Region in 2002. In 2002, there were 8 countries in which indigenous wild-type poliovirus was still being transmitted (Table 175-3). Polio is a source of concern for unimmunized or partially immunized travelers to these regions. Outbreaks of polio in Europe and North America have been traced to cases imported from the Indian subcontinent. Clearly, global eradication of polio is necessary to eliminate the risk of importation of wild-type virus. Outbreaks are thought to have been facilitated by suboptimal rates of vaccination, isolated pockets of unvaccinated children, poor sanitation and crowding, improper vaccine-storage conditions, and a reduced level of response to one of the serotypes in the vaccine.

Outbreaks of poliomyelitis due to circulating vaccine-derived poliovirus have recently occurred. In the Dominican Republic and Haiti, 21 cases of vaccine-derived polio occurred in 2000 and 2001; 32 cases occurred in Egypt from 1988 to 1993, and 3 cases occurred in the Philippines in 2001. These OPV-derived viruses reverted to a more neurovirulent phenotype after undetected circulation (probably for >2 years). The epidemic in Hispaniola was rapidly terminated after intensive vaccination with OPV. These outbreaks emphasize the need for maintaining high levels of vaccine coverage and continued surveillance for circulating virus.

IPV is used in most industrialized countries and OPV in most developing countries, including those in which polio still is or recently was endemic. After several doses of OPV alone, the seropositivity rate for individual poliovirus serotypes may still be suboptimal for children in developing countries; one or more supplemental doses of IPV can increase the rate of seropositivity for these serotypes. While intramuscular injections of other vaccines (live or attenuated) can be given concurrently with OPV, unnecessary intramuscular injections should be avoided during the first month after vaccination because they increase the risk of vaccine-associated paralysis. Since 1988, an enhanced-potency inactivated poliovirus vaccine has been available in the United States.

OPV and IPV induce antibodies that persist for at least 5 years. Both vaccines induce IgG and IgA antibodies. Compared with recipients of IPV, recipients of OPV shed less virus and less frequently develop reinfection with wild-type virus after exposure to poliovirus. Although IPV is safe and efficacious, OPV offers the advantages of ease of administration, lower cost, and induction of intestinal immunity resulting in a reduction in the risk of community transmission of wild-type virus. Because of progress toward global eradication of polio (with a reduced risk of imported cases) and the continued occurrence of cases of vaccine-associated polio, an all-IPV regimen was recommended in 2000 for childhood poliovirus vaccination in the United States, with vaccine administration at 2, 4, and 6 to 18 months and 4 to 6 years of age. OPV will be used only in special circumstances: (1) for mass immunization campaigns to control outbreaks of polio; (2) for vaccination of unimmunized children who will be traveling to a polio-endemic area within 4 weeks; and (3) for children whose parents do not accept an all-IPV regimen. The latter children should receive at least two doses of IPV before receiving OPV. The risk of vaccine-associated polio should be discussed before administering OPV. Recommendations for vaccination of adults are listed in Table 175-4.

While it is hoped that endemic spread of poliovirus may be eliminated during the first decade of the 21st century, there are concerns about stopping vaccination. These include the observations that poliovirus is shed from some immunocompromised persons for several years, that vaccine-derived poliovirus can circulate and cause disease, and that wild-type poliovirus is present in a large number of laboratories. A national survey began in October 2002 to encourage laboratories to dispose of all unneeded wild-type poliovirus materials and to identify laboratories that have wild-type poliovirus or specimens (e.g., feces) that may contain the virus.
**TABLE 175-4  Recommendations for Poliovirus Vaccination of Adults**

1. Routine primary poliovirus vaccination is not indicated for unvaccinated adults residing in the United States, except for:
   a. travelers to areas where poliovirus is or may be epidemic or endemic;
   b. members of communities or population groups with disease caused by wild-type polioviruses;
   c. laboratory workers handling specimens that may contain wild-type polioviruses;
   d. health care workers in close contact with patients who may be excreting wild-type polioviruses.
2. Three doses of IPV are recommended for adults who need to be immunized. The second dose should be given 1 to 2 months after the first dose; the third dose should be given 6 to 12 months after the second dose.
3. Adults who are at increased risk of exposure to wild-type poliovirus and who have previously completed primary immunization should receive a single dose of IPV.

**REOVIRUSES**

Reoviruses are double-stranded RNA viruses encompassing three serotypes. Serologic studies indicate that most humans are infected with reoviruses during childhood; however, it has been difficult to establish a definite link of reovirus infection with a particular disease. It is likely that most infections either are asymptomatic or cause very mild disease. One outbreak of reovirus infection in children resulted in minor upper respiratory tract symptoms. Reovirus is considered a rare cause of mild gastroenteritis in infants and children. Speculation regarding an association of reovirus type 3 with idiopathic neonatal hepatitis and extrahepatic biliary atresia is based on an elevated prevalence of antibody to reovirus among some of these patients, detection of viral RNA by PCR in hepatobiliary tissues in some studies, and detection of virus in the porta hepatis in one case.

**FURTHER READING**

**DEFINITION**

Measles (rubeola) is a highly contagious, acute, exanthematous respiratory disease with a characteristic clinical picture and a pathognomonic exanthem: Koplik’s spots, an eruption on the buccal mucous membranes (Fig. 176-1). A successful live attenuated measles vaccine became available in 1963 in the United States and elsewhere, and measles is now an unusual disease in most developed countries where this vaccine is widely used. However, measles continues to occur sporadically in miniepidemics in the United States, and major epidemics in developing nations make this disease a persistent cause of childhood morbidity and mortality.

**ETIOLOGIC AGENT**

Measles virus is the only member of the genus *Morbillivirus* that infects humans. Part of the family Paramyxoviridae, it is closely related to the viruses causing canine and porcine distemper, rinderpest of cattle, morbilli of certain aquatic mammals, and *peste des petits ruminants* of goats and sheep. There is only one antigenic type.

Measles virions are pleomorphic spherical structures having a diameter of 100 to 250 nm and consisting of six proteins. The inner capsid is composed of a coiled helix of RNA and three proteins, and the outer envelope consists of a matrix protein bearing two types of short surface-glycoprotein projections or peplomers. One peplomer is a conical hemagglutinin (H) and the other a dumbbell-shaped fusion (F) protein. Sequencing of the single-stranded genome has made it possible to distinguish vaccine-type measles virus from the wild type. The genetic variability of wild-type measles virus permits the identification of strains that are endemic within a given locale where measles cases have occurred. In all, 20 genotypes have been identified. The cellular receptors for measles virus are the CD46 and CD150 molecules expressed on human lymphocytes and many other human cell types.

**EPIDEMIOLOGY**

Measles has a worldwide distribution; humans are the only natural hosts, although other primates can be experimentally infected. During the prevaccination era in the United States, measles epidemics occurred every 2 to 5 years in the winter and spring. In an epidemic year, roughly half a million measles cases were reported; 99% of adults had serologic evidence of previous measles infection.

*FIGURE 176-1  Koplik’s spots, which manifest as white or bluish lesions with an erythematous halo differentiates Koplik’s spots from Fordyce’s spots (ectopic sebaceous glands), which occur in the mouths of healthy individuals.*

After the live attenuated vaccine became available, the number of cases reported to the Centers for Disease Control and Prevention (CDC) fell, with a nadir of 1497 cases in 1983. After an upsurge to more than 27,000 cases (with 89 deaths) in 1990, the disease was once more brought under control, in part through the routine administration of two doses of vaccine. The foremost reason for the resurgence of measles was failure to immunize infants and young children, especially in inner-city areas. Primary vaccine failure (documented in about 5% of individuals) and secondary vaccine failure or waning immunity accounted for some cases.

In recent years, the majority of cases of measles have involved preschool children. Between 1993 and 1996, fewer than 1000 cases were reported annually in the United States; 309 cases were reported...
in 1995 and 116 cases in 2001. Molecular studies indicated interruption of transmission of indigenous measles in 1993. Most cases have since resulted from international importations of the virus. Mortality is highest among children under 2 years of age and among adults. Patients with impaired cell-mediated immunity are at especially high risk for severe or even fatal measles. The measles-associated mortality rate in the United States is about 0.3%; in developing countries, mortality frequently exceeds 1% and sometimes approaches 10%.

Measles virus is transmitted by respiratory secretions, predominantly through exposure to aerosols but also through direct contact with larger droplets. Patients are contagious from 1 to 2 days before the onset of symptoms until 4 days after the appearance of the rash. Infectivity peaks during the prodromal phase. The mean intervals from infection to onset of symptoms and to appearance of rash are 10 and 14 days, respectively.

**PATHOGENESIS, IMMUNITY, AND PATHOLOGY** Measles virus invades the respiratory epithelium and spreads via the bloodstream to the reticuloendothelial system, from which it infects all types of white blood cells, thereby establishing infection of the skin, respiratory tract, and other organs. Both viremia and viruria develop. Multinucleated giant cells with inclusion bodies in the nucleus and cytoplasm (Warthin-Finkeldey cells) are found in respiratory and lymphoid tissues and are pathognomonic for measles. Direct invasion of T lymphocytes and increased levels of suppressive cytokines, such as interleukin 4, may play a role in the temporary depression of cellular immunity that accompanies and transiently follows measles. The major infected cell in the blood is the monocyte. Infection of the entire respiratory tract accounts for the characteristic cough and coryza of measles and for the less frequent manifestations of croup, bronchiolitis, and pneumonia. Generalized damage to the respiratory tract, with resultant loss of cilia, predisposes to secondary bacterial infections such as pneumonia and otitis media.

Specific antibodies are not detectable before the onset of rash. Cellular immunity (consisting of cytotoxic T cells and possibly natural killer cells) plays a prominent role in host defense, and patients who are deficient in cellular immunity are at high risk for severe measles. Children with isolated agammaglobulinemia are not at increased risk. Immune reactions to the virus in the endothelial cells of dermal capillaries play a substantial role in the development of Koplik's spots (the pathognomonic exanthem) as well as in that of rash; in immunodeficient hosts, measles may be severe despite the absence of these manifestations. Measles antigens have been demonstrated in involved skin during early stages of the illness.

Pathologic changes in measles encephalitis include focal hemorrhage, congestion, and perivascular demyelination. Measles virus is rarely isolated from cerebrospinal fluid (CSF) in cases of encephalitis, which are thought to be due to the interaction of virus-infected cells with local cellular immune factors.

**CLINICAL MANIFESTATIONS** Measles begins with a 2- to 4-day respiratory prodrome of malaise, cough, coryza, conjunctivitis with lacrimation, nasal discharge, and increasing fever [with temperatures as high as 40.6°C (105°F), probably reflecting secondary viremia]. At this stage of the illness, in which the rash has not yet developed, influenza may be suspected. Just before the onset of the rash, Koplik’s spots appear as 1- to 2-mm blue-white spots on a bright red background (Fig. 176-1). Without adequate illumination for examination, they may be overlooked. Koplik’s spots are typically located on the buccal mucosa alongside the second molars and may be extensive; they are not associated with any other infectious disease. The spots wane after the onset of rash and soon disappear. The entire buccal and inner labial mucosa may be inflamed, and the lips may be redden.

The characteristic erythematous, nonpruritic, maculopapular rash of measles begins at the hairline and behind the ears, spreads down the trunk and limbs to include the palms and soles, and often becomes confluent (Fig. 176-2). At this time, the patient is at the most severe point of the illness. By the fourth day, the rash begins to fade in the order in which it appeared. Brownish discoloration of the skin and desquamation may occur later. Fever usually resolves by the fourth or fifth day after the onset of rash; prolonged fever suggests a complication of measles. Lymphadenopathy, diarrhea, vomiting, and splenomegaly are common features. The chest x-ray may be abnormal, even in uncomplicated measles, because of the propensity of this virus to invade the respiratory tract. The entire illness usually lasts about 10 days. The disease tends to be more severe in adults than in children, with higher fever, more prominent rash, and a higher incidence of complications.

Milder forms of the illness with less intense symptoms and a milder rash, termed modified measles, may occur in individuals with preexisting partial immunity induced by active or passive vaccination. These patients include infants under 1 year of age who retain some proportion of passively acquired maternal antibodies. On occasion, individuals with a history of immunization may develop modified measles.

**COMPLICATIONS** The complications of measles (Table 176-1) can conveniently be divided into three groups, according to the site involved: the respiratory tract, the central nervous system (CNS), and the gastrointestinal tract. Respiratory tract involvement, manifested as laryngitis, croup, or bronchitis, occurs in the majority of cases of uncomplicated measles. In young children, otitis media is the most common complication. Pneumonia is a frequent reason for hospitalization, especially of adults. The pneumonia is of viral origin in the majority of cases, but secondary bacterial infection (most commonly caused by streptococci, pneumococci, or staphylococci) also develops with some frequency. Primary giant cell (Hecht’s) pneumonia is most often documented in immunocompromised and/or malnourished patients.

Encephalographic abnormalities in the absence of symptoms of CNS disease are extremely frequent in measles. Symptomatic CNS disease may present with fever, headache, drowsiness, coma, and/or seizures. Symptoms usually begin within days after the onset of rash but occasionally appear for the first time several weeks later. About 10% of patients do not survive acute measles encephalitis; a significant percentage of surviving patients develop permanent sequelae, such as mental retardation or epilepsy. Most cases appear to result from an immune-mediated response to myelin proteins (postinfectious encephalomyelitis) and not directly from viral infection of the CNS (Chap. 359). Rarely, transverse myelitis follows measles. Immunocompromised patients are at risk for progressive fatal encephalitis 1 to 6 months after measles; in some cases, even though prior measles has...
not been recognized, the virus is identified at autopsy. Subacute sclerosing panencephalitis (SSPE)—a protracted, chronic, extremely rare form of measles encephalitis—sometimes follows measles and is particularly common among children who have measles before the age of 2 years (Chap. 360). SSPE has virtually disappeared in the United States as a result of widespread vaccination. Typically, progressive dementia evolves over several months. SSPE is thought to be due to a complex interaction of the host with defective measles virus. It is associated with extremely high levels of antibodies to measles virus in the blood and CSF.

Gastrointestinal complications of measles include gastroenteritis, hepatitis, appendicitis, ileocolitis, and mesenteric adenitis. It is not uncommon to detect high levels of alanine and aspartate aminotransferases in the absence of gastrointestinal signs such as jaundice.

Other, rare complications include myocarditis, glomerulonephritis, and postinfectious thrombocytopenic purpura. Measles can exacerbate preexisting tuberculosis, presumably through depression of cellular immunity induced by the virus. Natural measles and immunization against measles can result in tuberculin skin-test anergy lasting for about 1 month.

**ATYPICAL MEASLES** An atypical form of measles has been reported in individuals who received formalin-inactivated measles vaccine (used in the United States from 1963 through 1967 and in Canada until 1970) and subsequently were exposed to measles virus. After a several-day prodrome of fever, myalgia, and headache, the rash appears (Fig. 176-3). Unlike the rash of typical measles, that of atypical measles begins peripherally and moves centrally; it can be urticarial, maculopapular, hemorrhagic, and/or vesicular. Fever is usually high and is accompanied by edema of the extremities, interstitial pulmonary infiltrates, hepatitis, and (on occasion) pleural effusion. The differential diagnosis often includes Rocky Mountain spotted fever, Henoch-Schönlein purpura, meningococcemia, drug allergy, toxic shock syndrome, and varicella. Despite the severity of atypical measles, patients invariably recover after a convalescence that may be prolonged. Measles virus is not isolated from these patients, and they do not spread the virus to others. This disease is believed to be due to hypersensitivity to measles virus induced by the inactivated vaccine. Formalin inactivation destroys the antigenicity of the F protein, antibodies to which are important in preventing spread of the virus from one cell to another. The role of cellular immunity in this process is unknown. Extremely high convalescent titers of antibody to measles virus (e.g., 1:1,000,000) are diagnostic of atypical measles. To prevent this syndrome, adults who received formalin-inactivated measles vaccine should be reimmunized with at least one dose of live attenuated measles vaccine. Because inactivated measles vaccine has not been available for more than 25 years, atypical measles has now virtually disappeared.

**MEASLES IN THE IMMUNOCOMPROMISED HOST** Patients with defects in cell-mediated immunity are at risk for severe protracted and fatal measles. Included in this category are patients with congenital cellular immune defects or malignancy, recipients of immunosuppressive therapy, or persons infected with HIV. In these patients, measles may not be accompanied by a rash. Complications are primary measles (giant cell) pneumonia, progressive encephalitis beginning weeks to months after initial infection, and (in HIV-infected patients) progression to AIDS.

**MEASLES IN ADULTS** Measles is naturally a disease of childhood and, like many other viral infections, is more severe in adults than in children. About 3% of young adults with measles develop primary viral pneumonia and require hospitalization. Hepatitis and bronchospasm are more common among adults with measles than among children, and the rash is more severe and more confluent in adults. Bacterial superinfection is more common among adults, more than one-third of whom develop respiratory complications such as otitis media, sinusitis, and pneumonia. Adults may develop measles because they were never immunized or (more rarely) because their vaccine-induced immunity has waned. Very low titers of antibody to measles virus have been associated with lack of protection.

**LABORATORY FINDINGS** Lymphopenia and neutropenia are common in measles and may be due to invasion of leukocytes by the virus, with subsequent cell death. Leukocytosis may herald a bacterial superinfection. Patients with measles encephalitis usually have an elevated protein concentration in CSF as well as lymphocytosis.

**DIAGNOSIS** A specific diagnosis of measles can be made quickly by immunofluorescent staining of a smear of respiratory secretions for measles antigen; monoclonal antibodies conjugated to fluorescein are commercially available for this purpose. Secretions can also be examined microscopically for multinucleated giant cells. Measles virus can be isolated from respiratory secretions or urine and rapidly identified in tissue culture with fluorescein-labeled monoclonal antibodies. The presence of measles virus RNA has been demonstrated by diagnostic reverse-transcription polymerase chain reaction. A number of serologic tests are available for the diagnosis of measles; however, a serologic diagnosis cannot necessarily be made quickly because both acute- and convalescent-phase sera are usually tested, ideally at the same time. The older hemagglutination inhibition test has been re-
placed by enzyme immunoassay (EIA), which is more sensitive and simpler to perform. EIA can be used to measure specific IgM and thus to diagnose measles on the basis of an acute-phase serum sample alone. Specific IgM antibodies are detectable within 1 to 2 days after the appearance of rash, and the IgG titer rises significantly after 10 days. As already mentioned, atypical measles and SSPE are associated with extremely high titers of antibody.

DIFFERENTIAL DIAGNOSIS Classic measles—with Koplik’s spots, cough, coryza, conjunctivitis, and a rash beginning on the head—is easily diagnosed on clinical grounds. Modified measles is more difficult to diagnose clinically because one or more characteristic signs may be lacking. The differential diagnosis of measles includes Kawasaki disease, scarlet fever, infectious mononucleosis, toxoplasmosis, drug eruption, and Mycoplasma pneumoniae infection. Most of these conditions can be identified by either culture or serologic assay. In the differential diagnosis of measles, attention should be paid to the current epidemiology of the disease in the community and to the patient’s history of measles vaccination and foreign travel.

PREVENTION The development of live attenuated measles vaccine by Enders and colleagues was a milestone in American medicine. This vaccine, used in the United States for the routine immunization of children since 1963, induces seroconversion in about 95% of recipients and probably confers lifelong protection. Waning immunity to measles after immunization has been documented only on rare occasions. For the past three decades, measles vaccine has been available as the combination vaccine measles-mumps-rubella (MMR); MMR vaccine should be administered to children between the ages of 12 and 15 months. (Vaccination at 12 months is preferred for infants whose mothers were immunized against measles in childhood. These mothers have lower antibody titers than women who have had natural measles, and their infants correspondingly have transplacental antibodies of lower titer and shorter duration.) A second dose of MMR vaccine is recommended for school-age children at 4 to 12 years of age. This two-dose policy was developed in the late 1980s in response to measles outbreaks in the United States. Since the institution of the two-dose regimen and the increased effort to immunize all children, measles has again become an unusual disease in the United States. Regional guidelines that reflect the current local epidemiology of measles should be followed.

Older susceptible persons should also be immunized. Individuals should be considered susceptible to measles unless they have documentation of physician-diagnosed measles or of the receipt of two doses of vaccine, have laboratory evidence of measles immunity, or were born before 1957. Rarely, individuals born before 1957 develop measles, and those who are at risk of exposure to measles (e.g., health care workers, teachers, and international travelers) should be tested for measles antibody and immunized if necessary. Approximately 10% of healthy vaccinees develop a fever, with temperatures up to 39.4°C (103°F), 5 to 7 days after vaccination; this fever lasts 1 to 5 days and is accompanied by a transient rash. Individuals previously immunized only with killed vaccine are considered susceptible and should receive at least one dose—preferably two doses—of MMR vaccine. Transient adverse reactions in these individuals include fever, malaise, and redness and swelling at the injection site.

Because of the severity of measles in this group and the lack of reported problems following vaccination, children with asymptomatic HIV infection should receive MMR vaccine; those with severe immunosuppression (<15% CD4 lymphocytes) should not. A case of fatal measles due to vaccine-type virus was reported in a college student with AIDS. Measles vaccine is contraindicated for persons with impaired cell-mediated immunity, for pregnant women, and for persons with a history of anaphylaxis due to egg protein or neomycin. Minor illnesses, with or without fever and a history of convulsions, are not contraindications to vaccination. Vaccination should be deferred for 6 to 11 months after the receipt of immune globulin or of blood products containing antibodies and for at least 3 months after the discontinuation of immunosuppressive treatment. Vaccine failures have been ascribed to faulty storage of the preparation used, immunization of infants with preexisting (maternally derived) antibodies, and simultaneous administration of measles vaccine and immune globulin.

The only temporally related apparent complications of measles vaccination that are thought to be causal are febrile seizures, which rarely have long-term sequelae; thrombocytopenia, which is self-limited; and anaphylaxis, which is very rare. An exhaustive analysis conducted in 2000 by a number of official committees, including those of the American Academy of Pediatrics and the Institute of Medicine, found no causal relationship between MMR vaccination and development of autism.

Children and adults who are susceptible to measles and are exposed to the disease should receive postexposure prophylaxis. Standard immune globulin, given intramuscularly within 6 days of exposure, can exert a protective or modifying effect; the earlier it is given, the better the outcome. The dose is 0.25 mL/kg for healthy persons and 0.5 mL/kg for immunocompromised persons, with a maximum dose of 15 mL. Immune globulin is particularly strongly indicated for susceptible household contacts, especially those <1 year of age, and for immunocompromised persons. HIV-infected persons, particularly those with severe immunosuppression, should be given immune globulin after exposure, regardless of their measles immune status and whether or not they are receiving intravenous immune globulin. Vaccination within 72 h of exposure may also provide protection against clinical measles, but this strategy is contraindicated as postexposure prophylaxis for immunocompromised individuals. Vaccine and immune globulin should not be given concurrently.
Rubella (German Measles)

**Definition**  
Rubella is an acute viral infection of children and adults that characteristically includes rash, fever, and lymphadenopathy and has a broad spectrum of other possible manifestations. However, a high percentage of rubella infections in both children and adults are subclinical. In addition, the illness can resemble a mild attack of measles (rubeola) and can cause arthritis, especially in adults. Rubella was formerly known as German measles because it was first described clinically as distinct from rubeola in Germany, where it generated much medical interest in the mid-eighteenth and early nineteenth centuries. Rubella during pregnancy can lead to fetal infection, with the production of a significant constellation of malformations (congenital rubella syndrome) in a high proportion of infected fetuses. Rubella virus was first isolated in cell culture just before the last pandemic of the disease began in 1962. Since the licensing of rubella vaccine in the United States in 1969, there have been no further epidemics in this country.

**Etiologic Agent**  
Rubella virus, a togavirus, is the only member of the Rubivirus genus and is closely related to the alphaviruses. Unlike these agents, however, it does not require a vector for transmission. Moreover, there is no RNA sequence homology between rubella virus and the alphaviruses.

The rubella virion is composed of an inner icosahedral capsid of RNA and protein that is surrounded by a lipid-containing envelope with glycoprotein spikes and a diameter of about 60 nm. The structural proteins associated with rubella virus are E1 and E2 (transmembrane envelope glycoproteins) and C (the capsid protein that surrounds the viral RNA). Only one serotype has been identified.

**Epidemiology**  
In the United States during the prevaccine era, rubella was most common in the spring and most often affected school-age children; only 80 to 90% of adults were immune; and major epidemics occurred every 6 to 9 years. The most recent epidemic in the United States occurred in 1964 to 1965, when more than 12 million cases of postnatal rubella and more than 20,000 cases of the congenital rubella syndrome were reported. Although there have been no epidemics since the introduction of live attenuated rubella vaccine in 1969, limited outbreaks have been reported in settings where susceptible individuals come into close contact with one another (e.g., schools and workplaces). In 2001, only 23 cases of postnatally acquired rubella—most of them in young adults—and 3 confirmed cases of congenital rubella syndrome were reported to the Centers for Disease Control and Prevention (CDC).

Whether symptomatic or subclinical, rubella is contagious, albeit less so than measles. Its incubation period is 18 days on average, with a range of 12 to 23 days. The virus, which is spread in droplets shed in respiratory secretions, infects the respiratory tract and then the bloodstream. In postnatally acquired infections, rubella virus is shed during the prodromal phase of the illness, and shedding from the pharynx can continue for about a week after onset. Despite high titers of specific neutralizing antibodies, infants with congenital rubella may excrete rubella virus from the respiratory tract and in the urine until the age of 2 years. This excretion raises important issues related to infection control in hospital and day-care settings. Persons recently immunized with live attenuated rubella vaccine do not transmit the vaccine virus to others, although low titers of rubella virus may be detected transiently in the pharynx.

After an attack of rubella, specific antibodies and cell-mediated immunity develop and probably play a significant role in protection against future disease. Asymptomatic reinfection at the level of the respiratory tract is common upon re-exposure to the virus but is rarely, if ever, associated with viremia.

Rubella virus has been cultured from respiratory secretions during reinfection. Fetal infection may occur during maternal reinfection but is acknowledged to be extremely rare because of the absence of maternal viremia under these circumstances. Viremia following reinfection of individuals immunized against rubella is also rare. Thus the current level of congenital rubella in the United States is exceedingly low. Recently, however, it has been observed that young immigrants to the United States from countries in Latin America and the Caribbean, where rubella vaccine is not routinely given to children, are at increased risk for rubella susceptibility. Because infants with the congenital rubella syndrome have been born to immigrant Hispanic women, increasing efforts are being made to identify and vaccinate such women before they become pregnant.

**Pathogenesis and Pathology**  
Little is known about the microscopic pathology of postnatally acquired rubella because the disease is invariably self-limited. Like that of measles, the rash of rubella is immunologically mediated; its onset coincides with the development of specific antibodies. Viremia can be demonstrated for about a week before and ends within a few days after the onset of rash.

The cause of the damage to cells and organs in congenital rubella is not well understood. Proposed mechanisms of fetal damage include mitotic arrest of cells, tissue necrosis without inflammation, and chromosomal damage. The growth of the fetus may be retarded. Other findings may include decreased numbers of megakaryocytes in the bone marrow, extramedullary hematopoiesis, and interstitial pneumonia.

**Clinical Manifestations**  
Postnatally Acquired Rubella  
Infection acquired after birth usually results in an extremely mild or subclinical illness. A prodromal phase is uncommon in children; adults may have more severe disease, with a brief prodrome of malaise, fever, and anorexia. The foremost symptoms of postnatally acquired rubella include posterior auricular, cervical, and suboccipital lymphadenopathy; fever; and rash. The rash often begins on the face (Fig. 177-1) and spreads down the body. It is maculopapular but not confluent, is sometimes accompanied by mild coryza and conjunctivitis, and generally lasts for 3 to 5 days. A petechial exanthem on the soft palate, designated Forschheimer spots, may occur but is not specific for rubella. Fever may be absent entirely or may be present for only several days in the early phase of the illness.

Complications of postnatally acquired rubella are uncommon; bacterial superinfection is rare. One particularly troublesome complication
is seen almost exclusively in women: arthritis, most frequently involving the fingers, wrists, and/or knees. Arthritis develops as the rash is appearing and may take several weeks to resolve. Chronic arthritis resulting from rubella is extremely rare. Rubella virus has been isolated from joint fluid during acute rubella arthritis and from peripheral blood in chronic rubella arthritis.

Another complication of postnatally acquired rubella is hemorrhage due to both thrombocytopenia and vascular damage; this complication occurs in 1 of every 3000 patients. Thrombocytopenia may last for weeks or months; it can have long-term consequences if there is bleeding into organs such as the eye or the brain.

Both children and adults may develop encephalitis after rubella; the incidence is about five times lower than that of encephalitis following measles. Adults are more likely than children to develop encephalitis: the mortality rate from this complication is 20 to 50%. Mild hepatitis is an unusual complication. Immunocompromised patients are not at increased risk for rubella as they are for measles.

**Congenital Rubella** Maternal infection in early pregnancy can lead to fetal infection, with resultant congenital rubella. The classic signs of congenital rubella are cataract, heart disease, deafness, and myriad other defects (Table 177-1). The most important factor in the pathogenicity of rubella virus for the fetus is gestational age at the time of infection. Maternal infection during the first trimester leads to fetal infection in about 50% of cases; maternal infection early in the second trimester leads to fetal infection in about one-third of cases. Fetal malformations not only are more common after maternal infection in the first trimester but also tend to be more severe and to involve more organ systems. Whereas a fetus infected in the fourth week of gestation may develop many problems, one infected later (e.g., in the twentieth week) may have isolated deafness as the only symptom.

**DIAGNOSIS** Because postnatally acquired rubella is often a mild disease and because many cases are subclinical, diagnosis on clinical grounds can be difficult. Other diseases that may mimic rubella include toxoplasmosis, scarlet fever, modified measles, roseola, fifth disease (erythema infectiousum due to parvovirus B19), and enteroviral infection. Routine laboratory tests usually reveal leukopenia and atypical lymphocytes.

The isolation of rubella virus in cell cultures of throat samples, urine, or other secretions is difficult and expensive but is sometimes undertaken. This technique is most useful when congenital rubella is suspected. A laboratory diagnosis is more often made serologically. The most commonly used test is an enzyme-linked immunosorbent assay (ELISA) for IgG and IgM antibodies. Acute rubella is diagnosed by the documentation of a fourfold or greater rise in the titer of IgG antibodies in paired acute- and convalescent-phase serum specimens or by the detection of rubella-specific IgM antibodies in one serum specimen. However, false-negative and false-positive IgM reactions are sometimes obtained. Moreover, true-positive IgM reactions can occur in both primary infection and reinfection. Congenital rubella is diagnosed by the isolation of rubella virus, the detection of IgM antibodies in a single serum sample, and/or the documentation of either the persistence of rubella antibodies in serum beyond 1 year of age or a rising antibody titer anytime during infancy in an unvaccinated child. Biopsied tissues and/or blood and cerebrospinal fluid have also been used for the demonstration of rubella antigens with monoclonal antibodies and for the detection of rubella RNA by in situ hybridization and polymerase chain reaction.

**PREVENTION** Live attenuated rubella vaccine was licensed in 1969. 7 years after the virus was first isolated in culture. This vaccine was developed as a strategy to prevent congenital rubella by ensuring that very few pregnant women would be susceptible and that there would be little circulating wild-type virus. Rubella vaccine induces seroconversion in more than 95% of recipients. Since its licensure, there have been no major epidemics in the United States, and the number of cases has declined by 98%. The vaccine currently licensed in the United States, RA 27/3, is propagated in human diploid cells and is more immunogenic (particularly with regard to the stimulation of secretory immunity) than previously licensed vaccines. The present vaccination strategy, developed in part when measles was not being adequately controlled, is to immunize all infants at 12 to 15 months of age with measles-mumps-rubella (MMR) vaccine and to administer a second dose in early childhood. Rubella vaccine may also be administered to anyone who is thought to be susceptible to the infection and is not pregnant; it is particularly important that hospital workers of either sex receive vaccination. However, rubella vaccination results in chronic arthritis; however, even cases of frank arthritis in vaccinees are self-limited, lasting only about 1 week.

After investigation of a series of more than 400 women who were inadvertently immunized during pregnancy and who carried their infants to term, the CDC has concluded that vaccine-type rubella virus either does not cause the congenital rubella syndrome at all or does so at an incidence too low to be detected. Nonetheless, rubella vaccination is contraindicated for use in pregnant women, and it is recommended that pregnancy be avoided for at least 3 months after rubella vaccination. It is acceptable for rubella-susceptible children whose mothers are also susceptible to be immunized, as vaccinated individuals do not shed rubella virus or transmit it to susceptible individuals. Although it is recommended that rubella vaccine not be given to immunosuppressed persons, the vaccine is given to children infected with HIV. No adverse effects of rubella vaccine have been reported in immunocompromised patients.

**TREATMENT** There is no specific therapy for rubella. At one time, immune globulin was used in an effort to prevent congenital rubella when pregnant women became infected. However, because administration of immune globulin did not prevent maternal viremia, this approach was discarded. Symptom-based treatment is given for manifestations such as fever, arthralgia, and arthritis.

and sublingual glands are involved less often than the parotid and are
so within the next 24 h but may be delayed for as long as a week; it
The prodrome of mumps consists of fever,
CLINICAL MANIFESTATIONS
and epithelial duct cells is evident in the salivary glands and in the
cases, often in association with submandibular adenitis.
Other than parotitis, orchitis is the most common manifestation of
mumps among postpubertal males, developing in about 20% of cases.
The testis is painful and tender and is enlarged to several times its
normal size; accompanying fever is common. Later, testicular atrophy
develops in half of the affected men. Since orchitis is bilateral in fewer
than 15% of cases, sterility after mumps is rare. Oophoritis in
women—for less common than orchitis in men—may cause lower
abdominal pain but does not lead to sterility.
Aseptic meningitis, which may develop before, during, after, or in the
absence of parotitis, is a common manifestation of mumps in both
children and adults. Symptoms include stiff neck, headache, and
drowsiness. Pleocytosis of the cerebrospinal fluid (CSF), with up to
1000 cells/μL, may develop in up to 50% of cases of clinical mumps,
but clinical signs of meningeal irritation are documented in only 5 to
25% of cases. Within the first 24 h, polymorphonuclear leukocytes
may predominate in CSF, but by the second day nearly all the cells
are lymphocytes. The glucose level in CSF may be abnormally low,
and this finding may arouse suspicion of bacterial meningitis. Aseptic
meningitis due to mumps without parotitis is indistinguishable clinically
from that caused by other viruses. Mumps meningitis is almost
invariably self-limiting, although cranial nerve palsies have occasionally
led to permanent sequelae, particularly deafness. More rarely,
mumps virus may cause encephalitis, which presents as high fever with
marked changes in the level of consciousness and frequently results in
permanent sequelae in survivors. Other CNS problems occasionally
associated with mumps include cerebellar ataxia, facial palsy, transverse
myelitis, Guillain–Barré syndrome, and aqueductal stenosis leading
to hydrocephalus.
Mumps pancreatitis, which may present as abdominal pain, is difficult to diagnose because an elevated serum amylase level can be associated with either parotitis or pancreatitis. Other unusual complications of mumps include myocarditis, mastitis, thyroiditis, nephritis, arthritis, and thrombocytopenic purpura. An excessive number of spontaneous abortions are associated with gestational mumps when the disease occurs during the first trimester. Mumps in pregnancy does not lead to premature birth or fetal malformations.
DIFFERENTIAL DIAGNOSIS
The diagnosis of mumps is made easily in patients with acute bilateral parotitis and a history of recent exposure, but mumps is currently a rare disease in the United States due to widespread vaccination. When parotitis is unilateral or absent or when sites other than the parotid gland are involved, laboratory diagnosis may be required. The differential diagnosis of parotitis is presented in Table 178-1. Other entities should be considered when manifestations consistent with mumps appear in organs other than the parotid. Testicular torsion may produce a painful scrotal mass resembling that seen in mumps
**Rabies Virus and Other Rabdoviruses**

**Definition**  Rabies is an invariably lethal, acute viral disease of the central nervous system (CNS) that affects all mammals and that is transmitted by infected secretions. Most commonly, transmission to humans takes place through exposure to saliva during a bite by an infected animal.

**Etiology**  The rabies and rabies-related viruses are in the family Rhabdoviridae, with at least seven distinct types within the genus Lyssa-

orchitis. Other viruses (e.g., enteroviruses) may cause aseptic meningitis that is clinically indistinguishable from that due to mumps virus.

Myocarditis as a severe but usually self-limited complication of mumps has been described. Molecular diagnostic assays have implicated mumps virus in some cases of endocardial fibroelastosis following myocarditis.

**Laboratory Diagnosis**  Mumps virus is readily isolated after inoculation of appropriate clinical specimens into a variety of host systems, such as rhesus monkey kidney cells and human embryonic lung fibroblasts. The virus can be rapidly identified by inoculation of cells grown in shell vials and subsequent staining with fluorescein-labeled monoclonal antibodies to detect viral growth. Mumps virus may be recovered from saliva, throat, and urine during the first few days of illness and from the CSF of patients with mumps meningitis. Shedding of virus in the urine may persist for as long as 2 weeks. PCR is also used to detect mumps virus in clinical specimens. No particular peripheral blood cell count is characteristic of mumps.

Highly sensitive enzyme-linked immunosorbent assays are useful for serologic diagnosis of mumps and for determination of susceptibility to the disease. Acute mumps can be diagnosed either by the examination of acute- and convalescent-phase sera for a significant increase in IgG antibody titer or by the demonstration of specific IgM in one serum specimen. Use of a skin-test antigen to assess immunity to mumps has been replaced by serologic testing.

**Prevention**  Live attenuated mumps vaccine (Jeryl Lynn strain) induces antibodies that protect the recipient against infection in more than 95% of cases. The subcutaneously administered vaccine may be given to children older than 1 year but is not recommended for younger infants because of the potential for interference by passive maternal antibodies. Mumps vaccine is usually administered as part of the measles-mumps-rubella (MMR) vaccine at the age of 12 to 15 months and again at 4 to 12 years of age. This MMR vaccine is also recommended for susceptible older children, adolescents, and adults, particularly adolescent males who have not had mumps. For these patients, either MMR or monovalent mumps vaccine may be given; two doses are preferred. Inadvertent immunization of individuals who are already immune is not associated with significant adverse reactions. Mumps vaccine is not recommended for pregnant women, for patients receiving glucocorticoids, or for other immunocompromised hosts. However, children with HIV infection who are not severely immunocompromised can safely be immunized against mumps; MMR vaccine is usually used for this purpose (Chap. 107). Occasionally, febrile reactions and parotitis have been reported soon after mumps vaccination. Allergic reactions after vaccination, such as rash and pruritus, occur uncommonly and are usually mild and self-limited. In the United States, the incidence of encephalitis during the month after mumps vaccination is no greater than the background incidence rate of encephalitis in the population.

**Treatment**  Therapy for parotitis and other manifestations of mumps is symptom-based. The administration of analgesics and the application of warm or cold compresses to the parotid area may be helpful. Mumps immune globulin is of no value in prophylaxis or treatment of established disease. Testicular pain may be minimized by the local application of cold compresses and gentle support for the scrotum. Anesthetic blocks may also be used. Neither the administration of glucocorticoids nor incision of the tunica albuginea is of proven value for the treatment of severe orchitis. Anecdotal information on a small number of patients with orchitis suggests that administration of interferon α may be helpful.

**Further Reading**  

CENTERS FOR DISEASE CONTROL AND PREVENTION: Notice to readers: Final 2001 reports of notifiable diseases. MMWR 51:710, 2002

Isolates of rabies virus from different animal species and locales differ in their antigenic and biologic properties. These variations may account for differences in virulence between isolates. The bullet-shaped, enveloped viruses are single-strand RNA viruses of negative polarity. The rabies virus genome encodes five proteins: the nucleoprotein, the matrix protein, the glycoprotein, the phosphorylated protein, and a large polymerase protein. In immunofluorescence and complement fixation studies, broadly cross-reacting antigenic sites on the nucleoprotein are used to determine placement within the genus. The relatedness of a viral isolate to rabies and rabies-related viruses is determined by the comparison of specific antigenic sites or, more recently, by examination of RNA sequences. Cross-neutralization by rabies virus antisera ranges from moderate to very low. Only one serogroup is recognized within the genus. Recently, four new lyssaviruses have been described that expand current knowledge, classification, and taxonomy of rabies and rabies-related viruses.

**Epidemiology**

An understanding of the epizootiology of rabies is necessary in evaluating the risk of exposure and the need for rabies post-exposure prophylaxis (PEP) in humans. Rabies is found in mammals in all regions of the world except Antarctica. The susceptibility of mammals varies greatly and most likely is related to differences in cell surface receptor characteristics (e.g., type and abundance) and the impact of these differences on receptor-virus interactions. Rabies exists in two forms: urban rabies, propagated chiefly by unimmunized domestic dogs, and sylvatic rabies, propagated by skunks, foxes, raccoons, mongooses, wolves, and bats. Infection in domestic animals usually represents a “spillover” from sylvatic reservoirs of infection. Human infection occurs through contact with unimmunized domestic animals or from exposure to wild animals in locales where rabies is enzootic or epizootic. The worldwide incidence of human rabies is estimated at more than 30,000 cases per year. Southeast Asia, the Philippines, Africa, the Indian subcontinent, and tropical South America are areas where the disease is especially common. In some endemic areas, 1 to 2% of autopsies yield evidence of rabies. Increased travel of humans, along with intentional and unintentional translocation of animals (including known potential rabies-reservoir species), has made the recognition of clinical rabies and its prevention of increasing importance.

Although there are island countries and whole continents that consider themselves rabies-free, the designation is relative and should take into account potential animal translocation events, the capacity of rabies reservoir hosts (e.g., bats) for long-distance flight, the lack of adequate rabies diagnostic capacity and expertise, and the reluctance of national authorities to change official designations despite the identification of lyssaviruses among volant hosts (i.e., those capable of flight) and the identification of associated human rabies deaths.

The main reservoir of rabies throughout the world is the domestic dog. In developed countries, control of stray dogs and mandatory vaccination of owned dogs have resulted in the virtual elimination of this problem across large geographic areas (e.g., most of North America). With the virtual elimination of dog rabies in the United States since the 1960s, a dog bite now poses a dramatically reduced risk of rabies exposure that is appropriately managed by a 10-day observation of the dog. Tremendous advances in the control of dog rabies have recently been made in Latin and South American countries. However, dog rabies remains largely uncontrolled in most of Asia and Africa.

In addition to rabies in dogs, diverse rabies virus variants occur among other mammalian hosts. For example, the disease is found in the several species of mongoose in Asia and Africa and has been translocated to several Caribbean Islands. In Canada, rabies occurs among skunks and foxes, and raccoon rabies has invaded Ontario from New York. In Eastern Europe, raccoons occur among raccoon dogs. Coyotes, jackals, and other wild canids may serve as reservoirs or vectors in North America, Asia, and Africa. The major rabies virus variants in the United States occur among raccoons, skunks, red and gray foxes, coyotes, and multiple insectivorous bat species. The most recent outbreak—and the most intense to date—affects raccoons in the eastern states from Florida to Maine and westward to the Appalachians and eastern Ohio. At the epizootic front in Ohio, New York, Pennsylvania, and West Virginia, the largest evaluation of oral rabies vaccination of free-ranging raccoons is in progress and represents an attempt to contain the westward spread of raccoon rabies. The vaccine, which is contained in baits and distributed primarily by air, is a vaccinia-rabies glycoprotein recombinant virus. Although highly attenuated by the lack of a critical enzyme (thymidine kinase), the vaccine is a live vaccinia virus and can infect humans, as demonstrated by at least one accidental human infection. In the United States, the domestic animal most commonly infected with rabies is the cat (~300 cases per year vs. 100 cases in dogs). All other domestic animals combined (i.e., cattle, horses, sheep, goats, and pigs) account for a total of 150 to 200 cases per year.

Rabies in insectivorous bats occurs in the United States, Canada, Europe, Asia, Australia, and Africa—i.e., in essentially every locality where these bats are found. The epidemiology of rabies in bats is not well understood. In the United States, multiple rabies virus variants are generally associated with particular bat species, but variants may infect bat species other than their primary reservoir and may also infect terrestrial mammals, including other wildlife, domestic animals, and humans. Because migratory bat species travel widely and aggregate in large numbers, the rabies virus variants associated with these species are relatively homogeneous. In contrast, variants associated with nonmigratory bat species may demonstrate more genetic variation, such that isolates from particular geographic areas form distinct lineages. In general, the rate of rabies among seemingly healthy captured bats is low (1 in 100 to 1000). However, the rate of rabies among dead and dying bats in high-density colonies may be >50%. Rabies cannot be ruled out definitively in an individual bat or in any other animal except by direct fluorescent antibody testing of brain tissue.

The “bat” category in rabies surveillance reports includes a wide variety of species as well as many individual bats whose species is never identified. For surveillance purposes, it is uninformative to lump all bats together by order, as is the current practice in many states. Nevertheless, the total of rabid bats is second only to the number of rabid raccoons and skunks. In contrast to a single human case due to the raccoon rabies virus variant, a single human case of skunk-associated rabies, and two human cases of dog/coyote-associated rabies since 1980, the 30 human rabies cases due to bats account for >90% of all human rabies cases in the United States since that date. It is intriguing that a particular bat-associated rabies virus is implicated in most human cases: Ln/Ps, which is associated with silver-haired and eastern pipistrelle bats. Several factors may be involved in this observation. One possibility is that the teeth of these bats are so small that a bite may be dismissed (e.g., if the victim is unaware of the potential for rabies in these animals) or even go unrecognized (e.g., if the victim is asleep or under the influence of drugs or alcohol). Another possibility is that this virus variant may be better than others at replicating in cells of epidermal origin and at cooler temperatures. Perhaps a unique viral adaptation coupled with a relatively nontraumatic bite introduction is facilitating the emergence of this source of rabies in humans in the United States.

Human rabies is rare in the United States. The disease can be prevented if the exposure is recognized and appropriate local wound care and human rabies PEP are administered. From 1980 to 2002, most human rabies cases in the United States were acquired indigenously, with no apparent geographic trends. Two indigenously acquired human cases were associated with a localized outbreak of rabies among coyotes and dogs at the U.S.–Mexico border; however, this was a small outbreak in terms of relative animal case numbers.

A comparison of the epidemiology of animal rabies, human rabies PEP, and human rabies cases in the United States presents an interesting conundrum. Raccoons are the leading rabies reservoir, but only one human death from the raccoon-associated rabies virus variant has been documented. Since human rabies PEP is not reportable, there are
PATHOGENESIS The first event in rabies is the inoculation of virus through the skin, usually through a bite that delivers virus-laden saliva. Initial viral replication appears to occur within striated muscle cells at the site of inoculation. The peripheral nervous system is exposed at the neuromuscular and/or neurotendinous spindles of unmyelinated sensory nerve cell endings, with neurotransmitter receptors such as acetylcholine implicated in viral attachment and internalization. The virus then spreads centripetally up the nerve to the CNS, probably via peripheral nerve axoplasm, at a rate of \( \sim 3 \, \text{mm/h} \). Viremia has been demonstrated in experimental conditions but is not thought to play a role in naturally acquired disease. Once the virus reaches the CNS, it replicates almost exclusively within the gray matter and then passes centrifugally along autonomic nerves to other tissues—the salivary glands, adrenal medulla, kidneys, lungs, liver, skeletal muscles, skin, and heart. Passage of the virus into the salivary glands and viral replication in mucogenic acinar cells facilitate further transmission via infected saliva. The incubation period of rabies is exceedingly variable, ranging from 7 days to \( > 1 \) year (mean, 1 to 2 months) and apparently depending on the amount of virus introduced, the amount of tissue involved, host defense mechanisms, and the actual distance that the virus has to travel from the site of inoculation to the CNS. Rates of infection and mortality are highest from bites on the face, intermediate from bites on the hands and arms, and lowest from bites on the legs. Cases of human rabies with an extended incubation period (2 to 7 years) have been reported, but they are rare. Host immune responses and viral strains also influence disease expression.

The neuropathology of rabies resembles that of other viral diseases of the CNS: hyperemia, varying degrees of chromatolysis, nuclear pyknosis, and neuronophagia of the nerve cells; infiltration by lymphocytes and plasma cells of the Virchow-Robin space; microglial infiltration; and parenchymal areas of nerve cell destruction. In experimental animal models, adenosynophsyeal infection with rabies virus, with reduction in growth hormone and vasopressin release, is common. The most characteristic pathologic finding of rabies in the CNS is the formation of cytoplasmic inclusions called Negri bodies within neurons. Each eosinophilic mass measures \( \sim 10 \, \text{mm} \) and is made up of a finely fibrillar matrix and rabies virus particles. Negri bodies are distributed throughout the brain, particularly in Ammon’s horn, the cerebral cortex, the brainstem, the hypothalamus, the Purkinje cells of the cerebellum, and the dorsal spinal ganglia. Negri bodies are not demonstrated in at least 20% of cases of rabies, and their absence from brain material does not rule out the diagnosis.

CLINICAL MANIFESTATIONS (See also Table 179-1) The clinical manifestations of rabies can be divided into four stages: (1) a nonspecific prodrome; (2) an acute encephalitis similar to other viral encephalitides; (3) a profound dysfunction of brainstem centers that produces the classic features of rabies encephalitis; and (4) death or, in rare cases, recovery.

The prodromal period usually lasts 1 to 4 days and is marked by fever, headache, malaise, myalgias, increased fatigability, anorexia, nausea and vomiting, sore throat, and a nonproductive cough. The prodromal symptom suggestive of rabies is the complaint of paresthesia and/or fasciculations at or around the site of inoculation of virus. These sensations, which may be related to the multiplication of virus in the dorsal root ganglion of the sensory nerve supplying the area of the bite, are reported by 50 to 80% of patients.

The encephalitic phase is usually ushered in by periods of excessive motor activity, excitement, and agitation. Confusion, hallucinations, combativeness, bizarre aberrations of thought, muscle spasms, meningismus, opisthotonic posturing, seizures, and focal paralysis soon appear. Characteristically, the periods of mental aberration are interspersed with completely lucid periods, but as the disease progresses the lucid periods get shorter until the patient lapses into coma. Hyperesthesia, with excessive sensitivity to bright light, loud noise, touch, and even gentle breezes, is very common. On physical examination, the temperature may be found to be as high as 40.6°C (105°F). Abnormalities of the autonomic nervous system include dilated irregular pupils; increased lacrimation, salivation, and perspiration; and postural hypotension. Evidence of upper motor neuron paralysis, with weakness, increased deep tendon reflexes, and extensor plantar responses, is the rule. Paralysis of the vocal cords is common. Unfortunately, the presenting signs and symptoms of rabies are indistinguishable from those of other viral and neurologic diseases. Thus delays in diagnosis are frequent. The presence of hydrophobia or aerophobia (seen in about two-thirds of recent cases) increases the likelihood of antemortem diagnosis.

The manifestations of brainstem dysfunction begin shortly after the onset of the encephalitic phase. Cranial nerve involvement causes diplopia, facial palsies, optic neuritis, and the characteristic difficulty with deglutition. The combination of excessive salivation and difficulty in swallowing produces the traditional picture of “foaming at the mouth.” Hydrophobia—the painful, violent, involuntary contraction of the diaphragmatic, accessory respiratory, pharyngeal, and laryngeal muscles initiated by swallowing liquids—is seen in \( \sim 50% \) of cases. Involvement of the amygdaloid nucleus may result in priapism and spontaneous ejaculation. The patient lapses into coma, and involvement of the respiratory center produces an apneic death. The prominence of early brainstem dysfunction distinguishes rabies from other viral encephalitides and accounts for the rapid downhill course. The median period of survival after the onset of symptoms is 4 days, with a maximum of 20 days, unless artificial supportive measures are instituted.

If intensive respiratory support is used, a number of late complications may appear. These include inappropriate secretion of antidiuretic hormone, diabetes insipidus, cardiac arrhythmias, vascular instability, adult respiratory distress syndrome, gastrointestinal bleeding, thrombocytopenia, and paralytic ileus. Recovery is very rare and, when it occurs, gradual.

Rabies may also present as an ascending paralysis resembling the Landry/Guillain-Barré syndrome (dumb rabies, rage tranquille). Ini-
tially, this clinical pattern was reported most frequently among persons given PEP after being bitten by vampire bats. Paralytic rabies also occurs in Southeast Asia among persons with canine exposures. The difficulty of diagnosing rabies associated with ascending paralysis is illustrated by cases of person-to-person transmission of the virus by tissue transplantation. Corneal transplants from donors who died of presumed Landry/Guillain-Barré syndrome produced clinical rabies in and caused the deaths of the recipients. Retrospective pathologic examinations of the brains of recipients demonstrated Negri bodies, and rabies virus was subsequently isolated from each donor’s frozen eye.

**LABORATORY FINDINGS**  
During the early clinical period of rabies infection, laboratory findings—like signs and symptoms—are nonspecific. Complete blood cell counts and differentials are compatible with an acute viral illness. As with encephalitis or meningitis of any viral etiology, there is mild pleocytosis (>5 cells/μL) in the cerebrospinal fluid (CSF), with lymphocytosis. The CSF protein level may be mildly elevated, but the glucose level is generally normal. A decreased level of glucose in the CSF suggests the possibility of fungal, tuberculous, parasitic, leptospiral, syphilitic, sarcoid, or neoplastic meningitis. Severe pleocytosis (>1000 cells/μL) is compatible with nonviral and other inflammatory etiologies. The presence of large numbers of polymorphonuclear cells is indicative of bacterial infection, leptospirosis, amebic infection, and some noninfectious processes.

The most critical laboratory finding in suspected cases of human rabies are those that permit the exclusion of other etiologies (i.e., the most common sources of encephalitis) and that document a rapidly deteriorating clinical course compatible with rabies (see “Differential Diagnosis,” below). Antemortem diagnosis of human rabies can be arranged through consultation with the relevant state health department and the Centers for Disease Control and Prevention (CDC). Such a diagnosis requires samples of the patient’s CSF and serum (preferably paired), fresh saliva, and a full-thickness skin biopsy sample from the nape of the neck. If a patient dies during the effort to rule out rabies, fresh brain material is the optimal sample for a definitive postmortem diagnosis.

**Rabies Virus–Specific Antibodies in Serum and CSF**  
Since rabies virus remains in the “immunologically privileged” CNS (with no viremia), the infection is largely undetected by the immune system until late in the clinical course. Once encephalitis develops, immune surveillance within the CNS is substantially heightened and viral antigen is widespread, resulting in the development of an antibody response and the influx of cytotoxic T cells. Thus, rabies virus–specific antibodies in serum and CSF develop relatively late in the clinical course and, when the patient dies during the acute phase, may be undetectable.

Two laboratory methods are commonly used to detect rabies virus–specific antibodies. The indirect fluorescent antibody test involves the addition of dilutions of test serum to plates with wells containing rabies virus–infected cells. If rabies antigen–specific antibodies are present in the serum, they bind to infected cells. The bound antibody is then detected with fluorescein-tagged antihuman antibodies. This rapid test predominantly detects antibodies to the rabies virus nucleoprotein. The rapid fluorescent focus inhibition test (RFFIT) is a valuable but labor-intensive method that takes 1 day to complete. The RFFIT requires that a fixed amount of live rabies virus and dilutions of test serum be added to cell monolayers and allowed to incubate for 20 h. If neutralizing antibodies to the rabies virus glycoprotein are present in the patient’s serum, few or no infected foci are seen when the direct fluorescent antibody (DFA) test is applied to the cell monolayer, because the viral particles will have been neutralized by antibodies and prevented from infecting cells. Rabies virus–specific antibodies may be found in serum as a result of previous vaccination against rabies. In contrast, the occurrence of rabies virus antibodies in the CSF is diagnostic for rabies (or, in extremely rare cases, indicative of previous exposure to and survival of rabies virus), since antibodies from vaccination do not cross an intact blood-brain barrier.

**Reverse-Transcription Polymerase Chain Reaction (RT-PCR) on Fresh Saliva**  
Viral shedding in the saliva directly precedes and accompanies the development of clinical signs in animals and probably in humans as well. During early CNS infection, the host may appear normal, but virus may already be present in the saliva as a result of centrifugal spread. With the exquisitely sensitive RT-PCR, the presence of rabies virus nucleic acid in fresh saliva can be confirmed or ruled out. If testing is performed very early in the clinical course, additional samples may need to be evaluated, because viral shedding may be intermittent at this time.

**DFA Testing and RT-PCR on a Skin Biopsy Sample**  
As a result of widespread spread, the rabies virus genome and antigen may be detectable in a skin biopsy from the nape of the patient’s neck during the clinical course of suspected rabies. With the DFA test, viral antigen may be demonstrated in peripheral nerves associated with hair follicles in the skin sample. RT-PCR has shown greater sensitivity for detection of rabies genomic material in skin samples.

**Other Tests**  
Although patients with encephalitis are invariably evaluated with advanced tests (e.g., magnetic resonance imaging, computed tomography, electroencephalography, evoked response studies, electromyography, and nerve conduction studies), the results are nondiagnostic for rabies.

**DIFFERENTIAL DIAGNOSIS**  
The differential diagnosis in a case of suspected human rabies may initially include any cause of encephalitis, particularly infection with viruses such as herpesviruses, enteroviruses, and arboviruses (e.g., West Nile virus). The most important viruses to rule out are herpes simplex virus type 1, varicella-zoster virus, and (less commonly) enteroviruses, including coxsackieviruses, echoviruses, polioviruses, and human enteroviruses 68 to 71. A specific diagnosis may be made by a variety of diagnostic techniques, including CSF PCR testing, culture, and serology. In addition, consideration should be given to the local epidemiology of encephalitis caused by arboviruses belonging to several taxonomic groups, including eastern and western equine encephalitis viruses, St. Louis encephalitis virus, Powassan virus, the California encephalitis virus serogroup, and La Crosse virus.

New causes of viral encephalitis are also possible, as was evidenced by the recent outbreak in Malaysia of ~300 cases of encephalitis (mortality rate, 40%) caused by Nipah virus, a new paramyxovirus. Similarly, well-known viruses may be introduced into new locations, as is illustrated by the recent outbreak of encephalitis due to West Nile virus in the eastern United States. Epidemiologic factors (e.g., season, geographic location, and the patient’s age, travel history, and possible exposure to animal bites, rodents, and ticks) may help direct the diagnostic workup.

**TREATMENT**  
There is no specific treatment for clinical rabies. Death is virtually inevitable once clinical signs develop. Medical management is supportive and palliative.

**POSTEXPOSURE PROPHYLAXIS**  
When an exposure to rabies is recognized, immediate and thorough wound cleansing and the prompt administration of PEP (Table 179-2) are extremely effective in preventing infection. With regard to the prevention of human rabies in developed countries, recognition of a potential exposure and its distinction from circumstances in which no exposure has occurred are key steps in the judicious administration of rabies biologics. In developing countries, the prevention of rabies is hindered by economic conditions and inadequate access to modern biologics. Unprovoked bites, especially if severe and multiple, by a confirmed rabid animal constitute the most obvious and highest-risk route of exposure to rabies. As stated in the recommendations of the Advisory Committee on Immunization Practices (ACIP, Table 179-2), simply touching a rabid animal (or person) does not constitute an exposure to rabies. Rabies virus forms an infectious aerosol only under intentional
During the 10-day observation period, begin postexposure prophylaxis at the first sign
of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical
signs of rabies, it should be euthanized immediately and tested.

The animal should be euthanized and tested as soon as possible. Holding for observation
is not recommended. Discontinue vaccine if immunofluorescence test results of the an-
imal are negative.

Source: Human rabies prevention—United States, 1999. Recommendations of the Advi-
sory Committee on Immunization Practices (ACIP). MMWR Recom Rep 48(RR-1): 1-

or highly unnatural conditions. The only cases in which the aerosol
route has been implicated are laboratory accidents and the Frio cave
incidents of 50 years ago; in the latter situation, other routes of ex-
posure for the bat biologists (e.g., bat bites or— in one person—con-
tamination of an excoriated area of eczema) could not be ruled out.
Contamination of mucous membranes with infectious material is con-
sidered an exposure to rabies because of observations in various spe-
cies of occasional rabies cases resulting from intentional oral or intra-
nasal exposure to high titers of virus; however, the majority of animals
so exposed are unaffected, and a few such animals even develop immu-
nity to rabies. Limited laboratory experiments with direct ocular
exposure to rabies in one animal species did not result in viral infec-
tion; nevertheless, ocular contact with potentially contaminated ma-
terial is considered an exposure because of the historic occurrence of
human rabies cases after the transplantation of corneas from donors
retrospectively diagnosed with rabies. Contamination of a fresh wound
with infectious material (brain, salivary gland, or other innervated tis-
sue from a rabid animal) constitutes an exposure to rabies.

Once the possibility of exposure has been identified, the wound
should be thoroughly scrubbed with soap and then flushed with water.
Both mechanical cleansing and chemical cleansing are important. Qua-
ternary ammonium compounds such as 1 to 4% benzalkonium chlo-
ride, 1% cetrimide bromide, or povodine-iodine solutions should be
used. Tetanus toxoid and antibiotic prophylaxis should be admin-
istered as needed.

With an established exposure, the decision to administer human
rabies biologics is straightforward if the animal is available for rabies
diagnosis (i.e., euthanasia, brain removal, and laboratory testing). In
dogs, cats, and ferrets in the United States, the potential shedding
period indicates the adequacy of observation of the animal for 10 days
after a bite to a human. If the animal remains clinically normal, lab-
oratory and epidemiologic data indicate no risk of rabies exposure
through the bite (although clearly, if unvaccinated, the animal may
develop rabies in the future). If the animal develops signs suggestive
of rabies, it should be euthanized and tested immediately, and the
human victim should be treated according to the laboratory test result.
If the animal is unavailable, the decision to treat depends upon the risk
of rabies in the individual animal, the local epizootiology of rabies and
the consequent risk to the individual animal, the potential route of
exposure (i.e., multiple severe bites vs, potential contamination of
mucous membranes with infectious material), and other factors. This
decision may best be made in consultation with local, state, and federal
public health professionals who have specialized knowledge of these
variables.

Human rabies PEP consists of five doses of a modern cell culture
vaccine, of which two types are commonly available for use in the
United States (Table 179-3). The current cell culture vaccines are vir-
tually equivalent in their unfailing potency and relative paucity of
adverse effects. A reaction compatible with delayed-type hypersensi-
tivity may occur in up to 12% of patients receiving human diploid cell
vaccine; continuation of the pre- or postexposure series with an alter-
native vaccine may be sufficient for the resolution of this reaction.
Doses are administered on a schedule of 0, 3, 7, 14, and 28 days. In
addition to vaccine on day 0, one dose of human rabies immune glob-
ulin (20 IU/kg) should be given; as much of the dose as is anatomically
feasible should be administered at the site of the bite, with any excess
administered intramuscularly at a distant site—e.g., in the deltoid op-
oposite the vaccine site. Periodically, human rabies immune globulin is
in short supply. If it is not immediately available, the vaccine series
should be initiated and the rabies immune globulin may be added at
any point through day 7. After day 7, it is not necessary to add rabies
immune globulin to the patient’s regimen because endogenous anti-
bodies are being produced and exogenous antibodies may actually be
counterproductive. If a patient presents at a long interval after a po-
tential exposure, it is not too late to initiate full human PEP unless
clinical signs are present.

PREEXPOSURE RABBIES VACCINATION Preexposure rabies vaccination is
available to persons at risk of rabies exposure. The ACIP recommends
a series of 1-mL doses of modern cell culture vaccine administered
intramuscularly on days 0, 7, and 21 or 28. Once immunized against
rabies with potent vaccines, individuals are primed against rabies for
the rest of their lives. If an exposure occurs, a previously immunized

person should receive postexposure boosters consisting of two doses 3 days apart. Persons in the high-risk and moderate-risk rabies exposure categories should have their rabies virus–neutralizing antibody titers monitored every 6 months and every 2 years, respectively. Persons in the low-exposure category do not require serologic monitoring but, like all previously immunized persons, must receive the two booster vaccinations upon exposure to rabies. Moreover, appropriate wound care (i.e., copious flushing and the use of soap or detergent) remains critical.

**MOKOLA VIRUS**

Mokola virus was first isolated from wild shrews captured in Nigeria and was shown to be related morphologically and serologically to rabies virus. The subsequent isolation of the virus from cats in South Africa suggested a wider prevalence of the agent than had previously been expected. Only two cases of clinical infection have been reported; both were in children. One patient had a nonfatal illness characterized by fever, pharyngitis, and convulsions; Mokola virus was recovered from CSF. In the second patient, fever with cough and vomiting was followed within several days by drowsiness, confusion, and generalized flaccid weakness. The CSF was normal. The patient progressed to deep coma and died within 10 days of onset. Mokola virus was isolated from the brain, and examination of histopathologic sections revealed finely granular cytoplasmic inclusions that were distinguishable from Negri bodies in many neurons.

**VESICULAR STOMATITIS VIRUS**

Vesicular stomatitis is a viral illness of animals that occasionally affects humans. It presents as an acute, self-limited, influenza-like disease. The disease in animals is found in the United States and South America and affects chiefly domestic cattle, horses, swine, wild deer, raccoons, skunks, and bobcats.

In animals, vesicular stomatitis is characterized by the development of vesicles on the oral mucosa, particularly the tongue; the udders; and the heels. The mode of spread is probably by direct contact; however, epidemics tend to occur in warm weather, and isolation of the virus from *Phlebotomus* sandflies in Panama and *Aedes* mosquitoes in New Mexico suggests that these insects may be vectors. Two distinct types, New Jersey and Indiana, have been recognized, and most outbreaks in North America have been attributed to the New Jersey strain.

In humans, vesicular stomatitis is most common among laboratory workers. In one report, three-fourths of laboratory personnel handling experimentally infected animals or manipulating the virus developed neutralizing antibodies. The disease is also transmissible, however, under natural conditions among workers having direct contact with infected animals, especially cattle. An incubation period ranging from 1 to 6 days is followed by the sudden onset of fever (with temperatures of up to 40°C [104°F]), chills, profuse sweating, myalgias, malaise, headache, and pain on ocular movement. One-third to one-half of patients have a sore throat and cervical and/or submandibular adenopathy. Small raised vesicular lesions may appear on the buccal mucosa. Conjunctivitis and coryza are evident in 20% of cases. Small subcorneal, intraepithelial vesicles occasionally appear on the fingers, usually in association with direct inoculation of the virus. Symptoms generally last 3 to 4 days, but occasionally the course is diphasic. Inapparent infection is common: among laboratory workers with serologic evidence of infection, only about one-half report symptoms. In some areas of Panama, 17 to 35% of the population have neutralizing antibodies to vesicular stomatitis virus.

The differential diagnosis includes hand-foot-and-mouth disease, herpangina, primary herpetic pharyngitis and other mucocutaneous syndromes, and influenza. The virus is not commonly isolated from patients. However, a rise in titer of complement-fixation and/or neutralizing antibody to vesicular stomatitis virus between acute- and convalescent-phase sera helps to confirm the diagnosis. Treatment is nonspecific.

**FURTHER READING**

Some viruses are transmitted in nature without regard to humans and only incidentally infect and produce disease in humans; in addition, a few agents are regularly spread among humans by arthropods. Most of these viruses either are maintained by arthropods or chronically infect rodents. Obviously, the mode of transmission is not a rational basis for taxonomic classification. Indeed, zoonotic viruses from at least seven virus families act as significant human pathogens (Table 180-1). The virus families differ fundamentally from one another in terms of morphology, replication mechanisms, and genetics. Information on a virus’s membership in a family or genus is enlightening with regard to maintenance strategies, sensitivity to antivirals, and some aspects of pathogenesis but does not necessarily predict which clinical syndromes—if any—the virus will cause in humans.

FAMILIES OF ARTHROPOD- AND RODENT-BORNE VIRUSES (Table 180-1)

The Arenaviridae The Arenaviridae are spherical, 110- to 130-nm particles that bud from the cell’s plasma membrane and utilize ambisense RNA genomes with two segments for replication. There are two main phylogenetic branches of Arenaviridae: the Old World viruses, such as Lassa fever and lymphocytic choriomeningitis (LCM) viruses, and the New World viruses, including those causing the South American hemorrhagic fevers (HF). Arenaviruses persist in nature by chronically infecting rodents with a striking one virus—one rodent species relationship. These rodent infections result in long-term virus excretion and perhaps in lifelong viremia; vertical infection is common with some arenaviruses. Humans become infected through the inhalation of aerosols containing arenaviruses, which are then deposited in the terminal air passages, and probably also through close contact with rodents and their excreta, which results in the contamination of mucous membranes or breaks in the skin.

The Bunyaviridae The family Bunyaviridae includes four medically significant genera. All of these spherical viruses have three negative-sense RNA segments maturing into 90- to 120-nm particles in the Golgi complex and exiting the cell by exocytosis. Viruses of the genus *Bunyavirus* are largely mosquito-borne and have a viremic vertebrate intermediate host; many are also transovarially transmitted in their specific mosquito host. One serologic group also uses biting midges as vectors. Sandflies or mosquitoes are the vectors for the genus *Phlebovirus* (named after phlebotomus fever or sandfly fever, the best-known disease associated with the genus), while ticks serve as vectors for the genus *Nairovirus*. Viruses of both of these genera are also associated with vertical transmission in the arthropod host and with horizontal spread through viremic vertebrate hosts. The genus *Hanta virus* is unique among the Bunyaviridae in that it is not transmitted by arthropods but is maintained in nature by rodent hosts that chronically shed virus. Like the arenaviruses, the hantaviruses usually display striking virus-rodent species specificity. Hantaviruses do not cause chronic viremia in their rodent hosts and are transmitted only horizontally from rodent to rodent.

Other Families The Flaviridae are positive-sense, single-strand RNA viruses that form particles of 40 to 50 nm in the endoplasmic reticulum. The flaviviruses discussed here are from the genus *Flavivirus* and make up two phylogenetically and antigenically distinct divisions transmitted among vertebrates by mosquitoes and ticks, respectively.

* The Filoviridae are discussed in Chap. 181.
* The Rhabdoviridae are discussed in Chap. 179.

**Note:** Abbreviations refer to the disease syndrome most commonly associated with the virus: FM, fever; myalgia; AR, arthritis, rash; E, encephalitis; HF, hemorrhagic fever.
The mosquito-borne viruses fall into phylogenetic groups that include yellow fever virus, the four dengue viruses, and encephalitis viruses, while the tick-borne group encompasses a geographically varied spectrum of species, some of which are responsible for encephalitis or for hemorrhagic disease with encephalitis. The Reoviridae are double-strand RNA viruses with multisegmented genomes. These 80-nm particles are the only viruses discussed in this chapter that do not have a lipid envelope and thus are insensitive to detergents. The Togaviridae have a single positive-strand RNA genome and bud particles of ~60 to 70 nm from the plasma membrane. The togaviruses discussed here are all members of the genus Alphavirus and are transmitted among vertebrates by mosquitoes in their natural cycle. –The Filoviridae and the Rhabdoviridae are discussed in Chaps. 181 and 179, respectively.

**Prominent Features of Arthropod- and Rodent-Borne Viruses** Although this chapter discusses the major features of selected arthropodand rodent-borne viruses, it does not deal with >500 other distinct recognized zoonotic viruses, about one-fourth of which infect humans. Zoonotic viruses are undergoing genetic evolution, “new” zoonotic viruses are being discovered, and the epidemiology of zoonotic viruses is continuing to evolve through environmental changes affecting vectors, reservoirs, and humans. These zoonotic viruses are most numerous in the tropics but are also found in temperate and frigid climates. Their distribution and seasonal activity may be variable and often depend largely on ecologic conditions such as rainfall and temperature, which in turn affect the density of vectors and reservoirs and the development of infection therein.

**Maintenance and Transmission** Arthropod-borne viruses infect their vectors after the ingestion of a blood meal from a viremic vertebrate. The vectors then develop chronic, systemic infection as the viruses penetrate the gut and spread throughout the body. The viruses eventually reach the salivary glands during a period that is referred to as *extrinsic incubation* and that typically lasts 1 to 3 weeks in mosquitoes. At this point an arthropod is competent to continue the chain of transmission by infecting another vertebrate when a subsequent blood meal is taken.

The arthropod generally is unharmed by the infection, and the natural vertebrate partner usually has only transient viremia with no overt disease. An alternative mechanism for virus maintenance in its arthropod host is transovarial transmission, which is common among members of the family Bunyaviridae.

Rodent-borne viruses such as the hantaviruses and arenaviruses are maintained in nature by chronic infection transmitted between rodents. As in arthropod-borne virus cycles, there is usually a high degree of rodent-virus specificity, and there is no overt disease in the reservoir/vector.

**Epidemiology** The distribution of arthropod- and rodent-borne viruses is restricted by the areas inhabited by their reservoir/vectors and provides an important clue in the differential diagnosis. Table 180-2 shows the approximate geographic distribution of the most important of these viruses. Members of each family, each genus, and even each serologically related group usually occur in each area but may not be pathogenic in all areas or may not be a commonly recognized cause of disease in all areas and so may not be included in the table.

Most of these diseases are acquired in a rural setting; a few have urban vectors. Seoul, sandfly fever, and Oropouche viruses are examples of urban viruses, but the most notable are yellow fever, dengue, and chikungunya viruses. A history of mosquito bite has little diagnostic significance in the individual; a history of tick bite is more diagnostically specific. Rodent exposure is often reported by persons infected with an arenavirus or a hantavirus but again has little specificity. Indeed, aerosols may infect persons who have no recollection of having even seen rodents.

** Syndromes** Human disease caused by arthropod- and rodent-borne viruses is often subclinical. The spectrum of possible responses to infection is wide, and our knowledge of the outcome of most of these infections is limited. The usual disease syndromes associated with these viruses have been grouped into four categories: fever and myalgia, arthritis and rash, encephalitis, and hemorrhagic fever. Although for the purposes of this discussion most viruses have been placed in a single group, the categories often overlap. For example, West Nile and Venezuelan equine encephalitis viruses are discussed as encephalitis viruses, but during epidemics they may cause many cases of milder

*Note: HF, hemorrhagic fever.*
febrile syndromes and relatively uncommon cases of encephalitis. Similarly, Rift Valley fever virus is best known as a cause of HF, but the attack rates for febrile disease are far higher, and encephalitis is occasionally seen as well. LCM virus is classified as a cause of fever and myalgia because this syndrome is its most common disease manifestation and because, even when central nervous system (CNS) disease occurs, it is usually mild and is preceded by fever and myalgia. Dengue virus infection is considered as a cause of fever and myalgia (dengue fever) because this is by far the most common manifestation worldwide and is the syndrome most likely to be seen in the United States; however, dengue HF is also discussed in the HF section because of its complicated pathogenesis and importance in pediatric practice in certain areas of the world.

**Diagnosis** Laboratory diagnosis is required in any given case, although epidemics occasionally provide clinical and epidemiologic clues on which an educated guess as to etiology can be based. For most arthropod- and rodent-borne viruses, acute-phase serum samples (collected within 3 or 4 days of onset) have yielded isolates, and paired sera have been used to demonstrate rising antibody titers by a variety of tests. Intensive efforts to develop rapid tests for HF have resulted in an antigen-detection enzyme-linked immunosorbent assay (ELISA) and an IgM-capture ELISA that can provide a diagnosis based on a single serum sample within a few hours and are particularly useful in severe cases. More sensitive reverse-transcription polymerase chain reaction (RT-PCR) tests may yield diagnoses based on samples without detectable antigen and may also provide useful genetic information about the virus. Hantavirus infections differ from others discussed here in that severe acute disease is immunopathologic; patients present with serum IgM that serves as the basis for a sensitive and specific test.

At diagnosis, patients with encephalitis are generally no longer viremic or antigenemic and usually do not have virus in cerebrospinal fluid (CSF). In this situation, the value of serologic methods and RT-PCR is being validated. IgM capture is increasingly being used for the simultaneous testing of serum and CSF. IgG ELISA or classic serology is useful in the evaluation of past exposure to the viruses, many of which circulate in areas with a minimal medical infrastructure and sometimes cause mild or subclinical infection.

The remainder of this chapter offers general descriptions of the broad syndromes caused by arthropod- and rodent-borne viruses. Most of the diseases under consideration have not been studied in detail with modern medical approaches; thus available data may be incomplete or biased.

**FEVER AND MYALGIA**

Fever and myalgia constitute the syndrome most commonly associated with zoonotic virus infection. Many of the numerous viruses belonging to the families listed in Table 180-1 probably cause this syndrome, but several viruses have been selected for inclusion in the table because of their prominent associations with the syndrome and their biomedical importance.

The syndrome typically begins with the abrupt onset of fever, chills, intense myalgia, and malaise. Patients may also report joint pains, but no true arthritis is detectable. Anorexia is characteristic and may be accompanied by nausea or even vomiting. Headache is common and may be severe, with photophobia and retroorbital pain. Physical findings are minimal and are usually confined to conjunctival injection with pain on palpation of muscles or the epigastrium. The duration of symptoms is quite variable but generally is 2 to 5 days, with a biphasic course in some instances. The spectrum of disease varies from subclinical to temporarily incapacitating.

Less constant findings include a maculopapular rash. Epistaxis may occur but does not necessarily indicate a bleeding diathesis. A minority of the cases caused by some viruses are known or suspected to include aseptic meningitis, but this diagnosis is difficult in remote areas, given the patients’ photophobia and myalgia as well as the lack of opportunity to examine the CSF. Although pharyngitis may be noted or radiographic evidence of pulmonary infiltrates found in some cases, these viruses are not primary respiratory pathogens. The differential diagnosis includes anicteric leptospirosis, rickettsial diseases, and the early stages of other syndromes discussed in this chapter. These diseases are often described as “flu-like,” but the usual absence of cough and coryza makes influenza an unlikely confounder except at the earliest stages.

Complete recovery is generally the outcome in this syndrome, although prolonged asthenia and nonspecific symptoms have been described in some cases, particularly after infection with LCM or dengue virus. Treatment is supportive, with aspirin avoided because of the potential for exacerbated bleeding and Reye’s syndrome. Efforts at prevention are best based on vector control, which, however, may be expensive or impossible. For mosquito control, destruction of breeding sites is generally the most economically and environmentally sound approach. Measures taken by the individual to avoid the vector can be valuable. Avoiding the vector’s habitat and times of peak activity, preventing the vector from entering dwellings by using screens or other barriers, judiciously applying arthropod repellents such as diethyltoluamide (DEET) to the skin, and wearing permethrin-impregnated clothing are all possible approaches, depending on the vector and its habits.

**LYMPHOCYTIC CHORIOMENINGITIS** LCM is transmitted from the common house mouse (*Mus musculus*) to humans by aerosols of excreta and secreta. LCM virus, an arenavirus, is maintained in the mouse mainly by vertical transmission from infected dams. The vertically infected mouse remains viremic for life, with high concentrations of virus in all tissues. Infected colonies of pet hamsters have also served as a link to humans. LCM virus is widely used in immunology laboratories as a model of T cell function and can silently infect cell cultures and passaged tumor lines, resulting in infections among scientists and animal caretakers. Patients with LCM may have a history of residence in rodent-infested housing or other exposure to rodents. An antibody prevalence of ~5 to 10% has been reported among adults from the United States, Argentina, and endemic areas of Germany.

LCM differs from the general syndrome of fever and myalgia in that its onset is gradual. Among the conditions occasionally associated with LCM are orchitis, transient alopecia, arthritis, pharyngitis, cough, and maculopapular rash. An estimated one-fourth of patients or fewer suffer a febrile phase of 3 to 6 days and then, after a brief remission, develop renewed fever accompanied by severe headache, nausea and vomiting, and meningeal signs lasting for about a week. These patients virtually always recover fully, as do the uncommon patients with cutaneous signs of encephalitis. Recovery may be delayed by transient hydrocephalus.

During the initial febrile phase, leukopenia and thrombocytopenia are common and virus can usually be isolated from blood. During the CNS phase of the illness, virus may be found in the CSF, but antibodies are present in blood. The pathogenesis of LCM is thought to resemble that following direct intracranial inoculation of the virus into adult mice; the onset of the immune response leads to T cell-mediated immunopathologic meningitis. During the meningeal phase, CSF mononuclear-cell counts range from the hundreds to the low thousands per microliter, and hypoglycorrhachia is found in one-third of cases. The IgM-capture ELISA of serum and CSF is usually positive; RT-PCR assays have been developed for application to CSF.

Infection with LCM virus should be suspected in acutely ill febrile patients with marked leukopenia and thrombocytopenia. In cases of aseptic meningitis, any of the following should suggest LCM: well-marked febrile prodrome, adult age, autumn seasonality, low CSF glucose levels, or CSF mononuclear cell counts of >1000/µL.

In pregnant women, LCM virus infection may lead to fetal invasion with consequent congenital hydrocephalus and chorioretinitis. Since the maternal infection may be mild, consisting of only a short febrile illness, exposed mothers should be sought in both the mother and the fetus in suspicious circumstances, particularly TORCH-negative neonatal hydrocephalus. [TORCH is a battery of tests encompassing...
Increasingly common. Conditions favorable to dengue transmission exist and spread of the vector mosquito throughout the tropics and subtropics, seen in the Caribbean region, including Puerto Rico. With increasing are thought to have taken place in the United States. Dengue fever is and seasonal forays of the viruses to points as far north as Philadelphia and the incidence continues to be low. A common pattern of disease in endemic areas consists of high attack rates among travelers and military personnel with little or no disease in the local population, who are protected after childhood infection. More than 30 related phleboviruses are transmitted by sandflies and mosquitoes, but most are of unknown significance in terms of human health.

**DENGUE FEVER** All four distinct dengue viruses (dengue 1–4) have *Aedes aegypti* as their principal vector, and all cause a similar clinical syndrome. In rare cases, second infection with a serotype of dengue virus different from that involved in the primary infection leads to dengue HF with severe shock (see below). Sporadic cases are seen in the settings of endemic transmission and epidemic disease. Year-round transmission between latitudes 25°N and 25°S has been established, and seasonal forays of the viruses to points as far north as Philadelphia are thought to have taken place in the United States. Dengue fever is seen in the Caribbean region, including Puerto Rico. With increasing spread of the vector mosquito throughout the tropics and subtropics, large areas of the world have become vulnerable to the introduction of dengue viruses, particularly through air travel by infected humans, and both dengue fever and the related dengue HF are becoming increasingly common. Conditions favorable to dengue transmission exist in the southern United States, and bursts of dengue fever activity are to be expected in this region, particularly along the Mexican border, where water may be stored in containers and *A. aegypti* numbers may therefore be greatest: this mosquito, which is also an efficient vector of the yellow fever and chikungunya viruses, typically breeds near human habitation, using relatively fresh water from sources such as water jars, vases, discarded containers, coconut husks, and old tires. *A. aegypti* usually inhabits dwellings and bites during the day.

After an incubation period of 2 to 7 days, the typical patient experiences the sudden onset of fever, headache, retroorbital pain, and back pain along with the severe myalgia that gave rise to the colloquial designation “break-bone fever.” There is often a macular rash on the first day as well as adenopathy, palatal vesicles, and scleral injection. The illness may last a week, with additional symptoms usually including anorexia, nausea or vomiting, marked cutaneous hypersensitivity, and—near the time of defervescence—a maculopapular rash beginning on the trunk and spreading to the extremities and the face. Epistaxis and scattered petechiae are often noted in uncomplicated dengue, and preexisting gastrointestinal lesions may bleed during the acute illness.

Laboratory findings include leukopenia, thrombocytopenia, and, in many cases, serum aminotransferase elevations. The diagnosis is made by IgM ELISA or paired serology during recovery or by antigen-detection ELISA or RT-PCR during the acute phase. Virus is readily isolated from blood in the acute phase if mosquito inoculation or mosquito cell culture is used.

**COLORADO TICK FEVER** Several hundred cases of Colorado tick fever are reported annually in the United States. The infection is acquired between March and November through the bite of an infected *Dermacentor andersoni* tick in mountainous western regions at altitudes of 1200 to 3000 m (4000 to 10,000 ft). Small mammals serve as the amplifying host. The most common presentation consists of fever and myalgia; meningoencephalitis is not uncommon, and hemorrhagic disease, pericarditis, myocarditis, orchitis, and pulmonary presentations are also reported. Rash develops in a substantial minority of cases. The disease usually lasts 7 to 10 days and is often biphasic. The most important differential diagnostic considerations since the beginning of the twentieth century have been Rocky Mountain spotted fever and tularemia. In Colorado, Colorado tick fever is much more common than Rocky Mountain spotted fever.

Infection of erythroblasts and other marrow cells by Colorado tick fever virus results in the appearance and persistence (for several weeks) of erythrocytes containing the virus. This feature, detected in smears stained by immunofluorescence, can be diagnostically helpful. The clinical laboratory detects leukopenia and thrombocytopenia.

**OTHER VIRUSES CAUSING FEVER AND MYALGIA** For a discussion of additional zoonotic viral infections presenting with fever and myalgia, see Chap. 180 in Harrison’s Online (www.harrisonsonline.com).

**ENCEPHALITIS** Arboviral encephalitis is a seasonal disease, commonly occurring in the warmer months. Its incidence varies markedly with time and place, depending on ecologic factors. The causative viruses differ substantially in terms of case-infection ratio (i.e., the ratio of clinical to subclinical infections), mortality, and residua (Table 180-3). Humans are not an important amplifier of these viruses.

All the viral encephalitides discussed in this section have a similar pathogenesis as far as is known. An infected arthropod ingests a blood meal from a human and infects the host. The initial period of viremia is thought to originate most commonly from the lymphoid system. Viremia leads to CNS invasion, presumably through infection of olfactory neuroepithelium with passage through the cribriform plate or through infection of brain capillaries and multifocal entry into the CNS. During the viremic phase, there may be little or no recognized disease except in the case of tick-borne flaviviral encephalitis, in which there may be a clearly delineated phase of fever and systemic illness. The disease process in the CNS arises partly from direct neuronal infection and subsequent damage and partly from edema, inflammation, and other indirect effects. The usual pathologic picture is one of focal necrosis of neurons, inflammatory glial nodules, and perivascular lymphoid cuffing; the severity and distribution of these abnormalities vary with the infecting virus. Involved areas display the “luxury perfusion” phenomenon, with normal or increased total blood flow and low oxygen extraction.

The typical patient presents with a prodrome of nonspecific constitutional symptoms, including fever, abdominal pain, vertigo, sore throat, and respiratory symptoms. Headache, meningeal signs, photophobia, and vomiting follow quickly. Involvement of deeper structures may be signaled by lethargy, somnolence, and intellectual deficit (as disclosed by the mental status examination or failure at serial 7 subtraction); more severely affected patients will be obviously disoriented and may be comatose. Tremors, loss of abdominal reflexes, cranial nerve palsies, hemiparesis, monoparesis, difficulty in swallowing, and frontal lobe signs are all common. Spinal and motor neuron diseases are documented with West Nile and Japanese encephalitis viruses. Convulsions and focal signs may be evident early or may appear during the course of the disease. Some patients present with an abrupt onset of fever, convulsions, and other signs of CNS involvement. The results of human infection range from no significant symptoms through febrile headache to aseptic meningitis and finally to
full-blown encephalitis; the proportions and severity of these manifestations vary with the infecting virus.

The acute encephalitis usually lasts from a few days to as long as 2 to 3 weeks, but recovery may be slow, with weeks or months required for the return of maximal recoupable function. Common complaints during recovery include difficulty concentrating, fatigability, tremors, and personality changes. The acute illness requires management of a comatose patient who may have intracranial pressure elevations, inappropriate secretion of antidiuretic hormone, respiratory failure, and convulsions. There is no specific therapy for these viral encephalitides. The only practical preventive measures are vector management and personal protection against the arthropod transmitting the virus; for Japanese encephalitis or tick-borne encephalitis, vaccination should be considered in certain circumstances (see relevant sections below).

The diagnosis of arboviral encephalitis depends on the careful evaluation of a febrile patient with CNS disease, with rapid identification of treatable herpes simplex encephalitis, ruling out of brain abscess, exclusion of bacterial meningitis by serial CSF examination, and performance of laboratory studies to define the viral etiology. Leptospirosis, neurosyphilis, Lyme disease, cat-scratch fever, and newer viral encephalitides such as Nipah virus infection from Malaysia should be considered. The CSF examination usually shows a modest cell count—in the tens or hundreds or perhaps a few thousand. Early in the process, a significant proportion of these cells may be polymorphonuclear leukocytes, but usually there is a mononuclear cell predominance. CSF glucose levels are usually normal. There are exceptions to this pattern of findings. In eastern equine encephalitis, for example, polymorphonuclear leukocytes may predominate during the first 72 h of disease and hypoglycorrhachia may be detected. In LCM, lymphocyte counts may be in the thousands, and the glucose concentration may be diminished. Experience with imaging studies is still evolving; clearly, however, both computed tomography (CT) and magnetic resonance imaging (MRI) may be normal, except for evidence of preexisting conditions, or sometimes may suggest diffuse edema. Several patients with eastern equine encephalitis have had focal abnormalities, and individuals with severe Japanese encephalitis have presented with bilateral thalamic lesions that have often been hemorrhagic. Electroencephalography usually shows diffuse abnormalities and is not directly helpful.

A humoral immune response is usually detectable at or near the onset of disease. Both serum and CSF should be examined for IgM antibodies. Virus generally cannot be isolated from blood or CSF, although Japanese encephalitis virus has been recovered from CSF in severe cases. Virus can be obtained from and viral antigen is present in brain tissue, although its distribution may be focal.

</table>

The isolation of California encephalitis virus established the California serogroup of viruses as a cause of encephalitis, and its use as a diagnostic antigen led to the description of many cases of “California encephalitis.” In fact, however, this virus has been implicated in only a few cases of encephalitis, and the serologically related La Crosse virus is the major cause of encephalitis among viruses in the California serogroup. “California encephalitis” due to La Crosse virus infection is most commonly reported from the upper Midwest but is also found in other areas of the central and eastern United States, most often in West Virginia, Tennessee, North Carolina, and Georgia. The serogroup includes 13 other viruses, some of which may also be involved in human disease that is misattributed because of the complexity of the group’s serology; these viruses include the Jamestown Canyon, snowshoe hare, Inkoo, and Trivittatus viruses, all of which have *Aedes* mosquitoes as
their vector and all of which have a strong element of transovarial transmission in their natural cycles.

The mosquito vector of La Crosse virus is *A. triseriatus*. In addition to a prominent transovarial component of transmission, a mosquito can also become infected through feeding on viremic chipmunks and other mammals as well as through venereal transmission from another mosquito. The mosquito breeds in sites such as tree holes and abandoned tires and bites during daylight hours; these findings correlate with the risk factors for cases: recreation in forested areas, residence at the forest’s edge, and the presence of abandoned tires around the home. Intensive environmental modification based on these findings has reduced the incidence of disease in a highly endemic area in the Midwest. Most cases occur from July through September. The Asian tiger mosquito, *A. albopictus*, efficiently transmits the virus to mice and also transmits the agent transovarily in the laboratory; this aggressive anthropophilic mosquito has the capacity to urbanize, and its possible impact on transmission to humans is of concern.

An antibody prevalence of $\geq 20\%$ in endemic areas indicates that infection is common, but CNS disease has been recognized primarily in children $<15$ years of age. The illness varies from a picture of aseptic meningitis accompanied by confusion to severe and occasionally fatal encephalitis. Although there may be prodromal symptoms, the onset of CNS disease is sudden, with fever, headache, and lethargy often joined by nausea and vomiting, convulsions (in one-half of patients), and coma (in one-third of patients). Focal seizures, hemiparesis, tremor, aphasia, chorea, Babinski’s sign, and other evidence of significant neurologic dysfunction are common, but residua are not. Perhaps $10\%$ of patients have recurrent seizures in the succeeding months. Other serious sequelae are rare, although a decrease in scholastic standing has been reported and mild personality change has occasionally been suggested. Treatment is supportive over a 1- to 2-week acute phase during which status epilepticus, cerebral edema, and inappropriate secretion of antidiuretic hormone are important concerns. Ribavirin has been used in severe cases, and a clinical trial of this drug is under way.

The blood leukocyte count is commonly elevated, sometimes reaching levels of $20,000/\mu\text{L}$, and there is usually a left shift. CSF cell counts are typically 30 to $500/\mu\text{L}$ with a mononuclear cell predominance (although $25$ to $90\%$ of cells are polymorphonuclear in some cases). The protein level is normal or slightly increased, and the glucose level is normal. Specific virologic diagnosis based on IgM-capture assays of serum and CSF is efficient. The only human anatomical site from which virus has been isolated is the brain.

Jamestown Canyon virus has been implicated in several cases of encephalitis in adults; in these cases the disease was usually associated with a significant respiratory illness at onset. Human infection with this virus has been documented in New York, Wisconsin, Ohio, Michigan, Ontario, and other areas of North America where the vector mosquito, *A. stimulans*, feeds on its main host, the white-tailed deer.

**ST. LOUIS ENCEPHALITIS** St. Louis encephalitis virus is transmitted between *Culex* mosquitoes and birds. This virus causes low-level endemic infection among rural residents of the western and central United States, where *C. tarsalis* is the vector (see “Western Equine Encephalitis,” below), but the more urbanized mosquito species *C. pipiens* and *C. quinquefasciatus* have been responsible for epidemics resulting in hundreds or even thousands of cases in cities of the central and eastern United States. Most cases occur in June through October. The urban mosquitoes breed in accumulations of stagnant water and sewage with high organic content and readily bite humans in and around houses at dusk. The elimination of open sewers and trash-filled drainage systems is expensive and may not be possible, but screening of houses and implementation of personal protective measures may be an effective approach for individuals. The rural vector is most active at dusk and outdoors; its bites can be avoided by modification of activities and use of repellents.

Disease severity increases with age: infections that result in aseptic meningitis or mild encephalitis are concentrated in children and young adults, while severe and fatal cases primarily affect the elderly. Infection rates are similar in all age groups; thus the greater susceptibility of older persons to disease is a biologic consequence of aging. The disease has an abrupt onset, sometimes following a prodrome, and begins with fever, lethargy, confusion, and headache. In addition, nuchal rigidity, hypotonia, hyperreflexia, myoclonus, and tremor are common. Severe cases can include cranial nerve palsies, hemiparesis, and convulsions. Patients often complain of dysuria and may have viral antigen in urine as well as pyuria. The overall mortality is generally $\sim 7\%$ but may reach $20\%$ among patients over the age of 60. Recovery is slow. Emotional lability, difficulties in concentration and memory, astasia, and tremor are common in older patients.

The CSF of patients with St. Louis encephalitis usually contains tens to hundreds of cells, with a lymphocytic predominance and a normal glucose level. Leukocytosis with a left shift is often documented.

**JAPANESE ENCEPHALITIS** Japanese encephalitis virus is found throughout Asia, including far eastern Russia, Japan, China, India, Pakistan, and Southeast Asia, and causes occasional epidemics on western Pacific islands. The virus has been detected in the Torres Strait islands, and a human encephalitis case has been identified on the nearby Australian mainland. This flavivirus is particularly common in areas where irrigated rice fields attract the natural avian vertebrate hosts and provide abundant breeding sites for mosquitoes such as *C. tritaeniorhyncus*, which transmit the virus to humans. Additional amplification by pigs, which suffer abortion, and horses, which develop encephalitis, may be significant as well. Vaccination of these additional amplifying hosts may reduce the transmission of the virus. An effective, formalin-inactivated vaccine purified from mouse brain is produced in Japan and licensed for human use in the United States. It is given on days 0, 7, and 30 or—with some sacrifice in serum neutralizing titer—on days 0, 7, and 14. Vaccination is indicated for summer travelers to rural Asia, where the risk of clinical disease may be 0.05 to 2.1/10,000 per week (Table 107-5). The severe and often fatal disease reported in expatriates must be balanced against the 0.1 to 1% chance of a late systemic or cutaneous allergic reaction. These reactions are rarely fatal but may be severe and have been known to begin 1 to 9 days after vaccination, with associated pruritus, urticaria, and angioedema. Live attenuated vaccines are being used in China but are not recommended in the United States at this time.

**WEST NILE VIRUS INFECTION** West Nile virus is transmitted among wild birds by *Culex* mosquitoes in Africa, the Middle East, southern Europe, and Asia. It is a frequent cause of febrile disease without CNS involvement, but it occasionally causes aseptic meningitis and severe encephalitis; these serious infections are particularly common among the elderly. The febrile-myalgic syndrome caused by West Nile virus differs from many others by the frequent appearance of a maculopapular rash concentrated on the trunk and lymphadenopathy. Headache, ocular pain, sore throat, nausea and vomiting, and arthralgia (but not arthritis) are common accompaniments. In addition, the virus has been implicated in severe and fatal hepatic necrosis in Africa.

In 1996 West Nile virus caused $\geq 300$ cases of CNS disease, with $10\%$ mortality, in the Danube flood plain, including Bucharest. In 1999 the virus appeared in New York City and other areas of the north-eastern United States, causing $\geq 60$ cases of aseptic meningitis or encephalitis among humans as well as die-offs among crows, exotic zoo birds, and other avians. The encephalitis was most severe among the elderly and was often associated with notable muscle weakness and even with flaccid paralysis. The virus, thought to have been transmitted in New York City by the ubiquitous *C. pipiens* mosquito, spread as far west as Minnesota and Texas as well as north into Canada by 2002. It seems likely that further spread will occur, and involvement of new vectors may enhance transmission to humans.

West Nile virus falls into the same phylogenetic group of flaviviruses as St. Louis and Japanese encephalitis viruses, as do Murray...
Valley and Rocío viruses. The latter two viruses are both maintained in mosquitoes and birds and produce a clinical picture resembling that of Japanese encephalitis. Murray Valley virus has caused occasional epidemics and sporadic cases in Australia. Rocío virus caused recurrent epidemics in a focal area of Brazil in 1975 to 1977 and then virtually disappeared.

**CENTRAL EUROPEAN TICK-BORNE ENCEPHALITIS AND RUSSIAN SPRING-SUMMER ENCEPHALITIS** A spectrum of tick-borne flaviviruses has been identified across the Eurasian land mass. Many are known mainly as agricultural pathogens (e.g., louping ill virus in the United Kingdom). From Scandinavia to the Urals, central European tick-borne encephalitis is transmitted by *Ixodes ricinus*. Human cases occur between April and October, with a peak in June and July. A related and more virulent virus is that of Russian spring-summer encephalitis, which is associated with *I. persulcatus* and is distributed from Europe across the Urals to the Pacific Ocean. The ticks transmit the disease primarily in the spring and early summer, with a lower rate of transmission later in summer. Small mammals are the vertebrate amplifiers for both viruses. The risk varies by geographic area and can be highly localized within a given area; human cases usually follow outdoor activities or consumption of raw milk from infected goats or other infected animals.

After an incubation period of 7 to 14 days or perhaps longer, the central European viruses classically result in a febrile-myalgic phase that lasts for 2 to 4 days and is thought to correlate with viremia. A subsequent remission for several days is followed by the recurrence of fever and the onset of meningeal signs. The CNS phase varies from mild aseptic meningitis, which is more common among younger patients, to severe encephalitis with coma, convulsions, tremors, and motor signs lasting for 7 to 10 days before improvement begins. Spinal and medullary involvement can lead to typical limb-girdle paralysis and to respiratory paralysis. Most patients recover, only a minority with significant deficits. Infections with the far eastern viruses generally run a more abrupt course. The encephalitic syndrome caused by these viruses sometimes begins without a remission and has more severe manifestations than the European syndrome. Mortality is high, and major sequelae—most notably, lower motor neuron paralyses of the proximal muscles of the extremities, trunk, and neck—are common.

In the early stage of the illness, virus may be isolated from the blood. In the CNS phase, IgM antibodies are detectable in serum and/or CSF. Thrombocytopenia sometimes develops during the initial febrile illness, which resembles the early hemorrhagic phase of some other tick-borne flaviviral infections, such as Kyasanur Forest disease. Other tick-borne flaviviruses are less common causes of encephalitis, including louping ill virus in the United Kingdom and Powassan virus.

There is no specific therapy for infection with these viruses. However, effective alum-adjuncted, formalin-inactivated vaccines are produced in Austria, Germany, and Russia. Two doses of the Austrian vaccine separated by an interval of 1 to 3 months appear to be effective in the field, and antibody responses are similar when vaccine is given on days 0 and 14. Other vaccines have elicited similar neutralizing antibody titers. Since rare cases of postvaccination Guillain-Barré syndrome have been reported, vaccination should be reserved for persons likely to experience rural exposure in an endemic area during the season of transmission. Cross-neutralization for the central European and far eastern strains has been established, but there are no published field studies on cross-protection of formalin-inactivated vaccines. Because 0.2 to 4% of ticks in endemic areas may be infected, tick bites raise the issue of immunoglobulin prophylaxis. Prompt administration of high-titered specific preparations should probably be undertaken, although no controlled data are available to prove the efficacy of this measure. Immunoglobulin should not be administered late because of the risk of antibody-mediated enhancement.

**POWASSAN ENCEPHALITIS** Powassan virus is a member of the tick-borne encephalitis virus complex and is transmitted by *I. cookei* among small mammals in eastern Canada and the United States, where it has been responsible for 20 recognized cases of human disease. Other ticks may transmit the virus in a wider geographic area, and there is some concern that *I. scapularis* (also called *I. dammini*), a competent vector in the laboratory, may become involved as it becomes more prominent in the United States. Patients with Powassan encephalitis—often children—present in May through December after outdoor exposure and an incubation period thought to be ~1 week. Powassan encephalitis is severe, and sequelae are common.

**EASTERN EQUINE ENCEPHALITIS** Eastern equine encephalitis is found primarily within endemic swampy foci along the eastern coast of the United States, with a few inland foci as far removed as Michigan. Human cases present from June through October, when the bird—*Culiseta* mosquito cycle spills over into other mosquito species such as *A. sollicitans* or *A. vexans*, which are more likely to bite mammals. There is concern over the potential role of the introduced anthropophilic mosquito species *A. albopictus*, which has been found to be naturally infected and is an effective vector in the laboratory. Horses are a common target for the virus; contact with unvaccinated horses may be associated with human disease, but horses probably do not play a significant role in amplification of the virus.

Eastern equine encephalitis virus is one of the most destructive of the arboviral conditions, with a brusque onset, rapid progression, high mortality, and frequent residua. This severity is reflected in the extensive necrotic lesions and polymorphonuclear infiltrates found at postmortem examination of the brain and the acute polymorphonuclear CSF pleocytosis often occurring during the first 1 to 3 days of disease. In addition, leukocytosis with a left shift is a common feature. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

**WESTERN EQUINE ENCEPHALITIS** The primary maintenance cycle for western equine encephalitis virus in the United States is between *C. tarsalis* and birds, principally sparrows and finches. Equines and humans become infected, and both species suffer encephalitis without amplifying the virus in nature. St. Louis encephalitis is transmitted in a similar cycle in the same region but causes human disease a month earlier than the period (July through October) in which western equine encephalitis virus is active. Large epidemics of western equine encephalitis took place in the western and central United States and Canada during the 1930s to 1950s, but in recent years the disease has been uncommon. There were 41 reported cases in the United States in 1987 but only 5 reported cases from 1988 to 2001. This decline in incidence may reflect in part the integrated approach to mosquito management that has been employed in irrigation projects and the increasing use of agricultural pesticides; it almost certainly reflects the increased tendency for humans to be indoors behind closed windows at dusk, the peak period of biting by the major vector.

Western equine encephalitis virus causes a typical diffuse viral encephalitis with an increased attack rate and increased morbidity in the young, particularly children <2 years old. In addition, mortality is high among the young and the very elderly. One-third of individuals who have convulsions during the acute illness have subsequent seizure activity. Infants <1 year old—particularly those in the first months of life—are at serious risk of motor and intellectual damage. Twice as many males as females develop clinical encephalitis after 5 to 9 years of age; this difference may be related to greater outdoor exposure of boys to the vector but is also likely to be due in part to biologic differences. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

**VENEZUELAN EQUINE ENCEPHALITIS** There are six known types of virus in the Venezuelan equine encephalitis complex. An important distinction is between the “epizootic” viruses (subtypes IAB and IC) and the “enzyootic” viruses (subtypes ID to IF and types II to VI). The epizootic viruses have an unknown natural cycle but periodically cause extensive epidemics in equines and humans in the Americas. These epidemics rely on the high-level viremia in horses and mules that results in the infection of several species of mosquitoes, which in turn infect
humans and perpetuate virus transmission. Humans also have high-level viremia but probably are not important in virus transmission. Enzootic viruses are found primarily in humid tropical forest habitats and are maintained between *Culex* mosquitoes and rodents; these viruses cause human disease but are not pathogenic for horses and do not cause epizootics.

Epizootics of Venezuelan equine encephalitis occurred repeatedly in Venezuela, Colombia, Ecuador, Peru, and other South American countries at intervals of 10 years from the 1930s until 1969, when a massive epizootic spread throughout Central America and Mexico, reaching southern Texas in 1972. Genetic sequencing of the virus from the 1969 to 1972 outbreak suggested that it originated from residual "un-inactivated" virus in veterinary vaccines. The outbreak was terminated in Texas with the use of a live attenuated vaccine (TC-83) originally developed for human use by the U.S. Army; this virus was then used for further production of inactivated veterinary vaccines. No further epizootic disease was identified until 1995 and subsequently, when additional epizootics took place in Colombia, Venezuela, and Mexico. The viruses involved in these epizootics as well as previously epizootic subtype IC viruses have been shown to be close phylogenetic relatives of known enzootic subtype ID viruses. This finding suggests that active evolution and selection of epizootic viruses are under way in northern South America.

During epizootics, extensive human infection is the rule, with clinical disease in 10 to 60% of infected individuals. Most infections result in notable acute febrile disease, while relatively few result in encephalitis. A low rate of CNS invasion is supported by the absence of encephalitis among the many infections resulting from exposure to aerosols in the laboratory or from vaccine accidents. The most recent large epizootic of Venezuelan equine encephalitis occurred in Colombia and Venezuela in 1995; of the 85,000 clinical cases, 4% (with a higher proportion among children than adults) included neurologic symptoms and 300 ended in death.

Enzootic strains of Venezuelan equine encephalitis virus are common causes of acute febrile disease, particularly in areas such as the Florida Everglades and the humid Atlantic coast of Central America. Encephalitis has been documented only in the Florida infections; the three cases were caused by type II enzootic virus, also called *Everglades virus*. All three patients had preexisting cerebral disease. Extrapolation from the rate of genetic change suggests that Everglades virus may have been introduced into Florida <200 years ago and that it is most closely related to the ID subtypes that appear to have given evolutionary rise to the epizootic strains active in South America.

The prevention of epizootic Venezuelan equine encephalitis depends on vaccination of horses with the attenuated TC-83 vaccine or with an inactivated vaccine prepared from that strain. Humans can be protected with similar vaccines, but the use of such products is restricted to laboratory personnel because of reactogenicity and limited availability. In addition, wild-type virus and perhaps TC-83 vaccine persists to laboratory personnel because of reactogenicity and limited availability. In addition, wild-type virus and perhaps TC-83 vaccine may have some degree of fetal pathogenicity. Enzootic viruses are genetically and antigenically different from epizootic viruses, and protection against the former with vaccines prepared from the latter is relatively ineffective.

**ARTHRITIS AND RASH**

True arthritis is a common accompaniment of several viral diseases, such as rubella (caused by a non-alphavirus togavirus), parvovirus B19 infection, and hepatitis B; it is an occasional accompaniment of infection due to mumps virus, enteroviruses, herpesviruses, and adenoviruses. It is not generally appreciated that the alphaviruses are also common causes of arthritis. In fact, the alphaviruses discussed below all cause acute febrile diseases accompanied by the development of true arthritis and a maculopapular rash. Rheumatic involvement includes arthritis (often migratory), pericarditis, pleuritis, and (less commonly) joint effusions. Most of these diseases are less severe and have fewer articular manifestations in children than in adults. In temperate climates, these are summer diseases. No specific therapy or licensed vaccines exist.

**SINDBIS VIRUS INFECTION**  Sindbis virus is transmitted among birds by mosquitoes. Infections with the northern European strains of this virus (which cause, for example, Pogosta disease in Finland, Karelian fever in the independent states of the former Soviet Union, and Okelbo disease in Sweden) and with the genetically related southern African strains are particularly likely to result in the arthritis-rash syndrome. Exposure to a rural environment is commonly associated with this infection, which has an incubation period of <1 week.

The disease begins with rash and arthralgia. Constitutional symptoms are not marked, and fever is modest or lacking altogether. The rash, which lasts about a week, begins on the trunk, spreads to the extremities, and evolves from macules to papules that often vesiculate. The arthritis of this condition is multiaxial, migratory, and incapacitating, with resolution of the acute phase in a few days. Wrist, ankles, phalangeal joints, knees, elbows, and—to a much lesser extent—proximal and axial joints are involved. Persistence of joint pains and occasionally of arthritis is a major problem and may go on for months or even years despite a lack of deformity.

**CHIKUNGUNYA VIRUS INFECTION**  It is likely that chikungunya virus (“that which bends up”) is of African origin and is maintained among non-human primates on that continent by *Aedes* mosquitoes of the subgenus *Steogomyia* in a fashion similar to yellow fever virus. Like yellow fever virus, chikungunya virus is readily transmitted among humans in urban areas by *A. aegypti*. The *A. aegypti*—chikungunya virus transmission cycle has also been introduced into Asia, where it poses a prominent health problem. The disease is endemic in rural areas of Africa, and intermittent epidemics take place in towns and cities of Africa and Asia. Chikungunya is one more reason (in addition to dengue and yellow fever) that *A. aegypti* must be controlled.

Full-blown disease is most common among adults, in whom the clinical picture may be dramatic. The abrupt onset follows an incubation period of 2 to 3 days. Fever and severe arthralgia are accompanied by chills and constitutional symptoms such as headache, photophobia, conjunctival injection, anorexia, nausea, and abdominal pain. Migratory polyarthritis mainly affects the small joints of the hands, wrists, ankles, and feet, with lesser involvement of the larger joints. Rash may appear at the outset or several days into the illness; its development often coincides with defervescence, which takes place around day 2 or day 3 of disease. The rash is most intense on the trunk and limbs and may desquamate. Petechiae are occasionally seen, and epistaxis is not uncommon, but this virus is not a regular cause of the HF syndrome, even in children. A few patients develop leukopenia. Elevated levels of aspartate aminotransferase (AST) and C-reactive protein have been described, as have mildly decreased platelet counts. Recovery may require weeks. Some older patients continue to suffer from stiffness, joint pain, and recurrent effusions for several years; this persistence may be especially common in HLA-B27 patients. An investigational live attenuated vaccine has been developed but requires further testing.

A related virus, O'nyong-nyong, caused a major epidemic of arthritis and rash involving at least 2 million people as it moved across eastern and central Africa in the 1960s. After its mysterious emergence, the virus virtually disappeared, leaving only occasional evidence of its persistence in Kenya until a transient resurgence of epidemic activity in 1997.

**EPIDEMIC POLYARTHRITIS (ROSS RIVER VIRUS INFECTION)**  Ross River virus has caused epidemics of distinctive clinical disease in Australia since the beginning of the twentieth century and continues to be responsible for thousands of cases in rural and suburban areas annually. The virus is transmitted by *A. vigilax* and other mosquitoes, and its persistence is thought to involve transovarial transmission. No definitive vertebrate host has been identified, but several mammalian species, including wallabies, have been suggested. Endemic transmission has also been documented in New Guinea, and in 1979 the virus swept through the eastern Pacific Islands, causing hundreds of thousands of illnesses.
The virus was carried from island to island by infected humans and was believed to have been transmitted among humans by A. polynesiensis and A. aegypti.

The incubation period is 7 to 11 days long, and the onset of illness is sudden, with joint pain usually ushering in the disease. The rash generally develops coincidentally or follows shortly but in some cases precedes joint pains by several days. Constitutional symptoms such as low-grade fever, asthenia, myalgia, headache, and nausea are not prominent and indeed are absent in many cases. Most patients are incapacitated for considerable periods by joint involvement, which interferes with sleeping, walking, and grasping. Wrist, ankle, metacarpophalangeal, interphalangeal, and knee joints are the most commonly involved, although toes, shoulders, and elbows may be affected with some frequency. Periarticular swelling and tenosynovitis are common, and one-third of patients have true arthritis. Only half of all arthritis patients can resume normal activities within 4 weeks, and 10% still must limit their activity at 3 months. Occasional patients are symptomatic for 1 to 3 years but without progressive arthropathy. Aspirin and nonsteroidal anti-inflammatory drugs are effective for the treatment of symptoms.

Clinical laboratory values are normal or variable in Ross River virus infection. Tests for rheumatoid factor and antinuclear antibodies are negative, and the erythrocyte sedimentation rate is acutely elevated. Joint fluid contains 1000 to 60,000 mononuclear cells per microliter, and Ross River virus antigen is demonstrable in macrophages. IgM antibodies are valuable in the diagnosis of this infection, although they occasionally persist for years. The isolation of the virus from blood by mosquito inoculation or mosquito cell culture is possible early in the illness. Because of the great economic impact of annual epidemics in Australia, an inactivated vaccine is being developed and has been found to be protective in mice.

Perhaps because of the local interest in arboviruses in general and in Ross River virus in particular, other arthritogenic arboviruses have been identified in Australia, including Gan Gan virus, a member of the family Bunyaviridae; Kokobera virus, a flavivirus; and Barmah Forest virus, an alphavirus. The last virus is a common cause of infection and must be differentiated from Ross River virus by specific testing.

**HEMORRHAGIC FEVERS**

The viral HF syndrome is a constellation of findings based on vascular instability and decreased vascular integrity. An assault, direct or indirect, on the microvasculature leads to increased permeability and (particularly when platelet function is decreased) to actual disruption and local hemorrhage. Blood pressure is decreased, and in severe cases shock supervenes. Cutaneous flushing and conjunctival suffusion are examples of common, observable abnormalities in the control of local circulation. The hemorrhage is inconstant and is in most cases an indication of widespread vascular damage rather than a life-threatening loss of blood volume. Disseminated intravascular coagulation (DIC) is occasionally found in any severely ill patient with HF but is thought to occur regularly only in the early phases of HF with renal syndrome, Crimean-Congo HF, and perhaps some cases of filovirus HF. In some viral HF syndromes, specific organs may be particularly impaired, such as the kidney in HF with renal syndrome, the lung in hantavirus pulmonary syndrome, or the liver in yellow fever, but in all these diseases the generalized circulatory disturbance is critically important.

The pathogenesis of HF is poorly understood and varies among the viruses regularly implicated in the syndrome, which number more than a dozen. In some cases direct damage to the vascular system or even to parenchymal cells of target organs is important, whereas in others soluble mediators are thought to play the major role. The acute phase in most cases of HF is associated with ongoing virus replication and viremia. Exceptions are the hantavirus diseases and dengue HF/dengue shock syndrome (DHF/DSS), in which the immune response plays a major pathogenic role.

The HF syndromes all begin with fever and myalgia, usually of abrupt onset. Within a few days the patient presents for medical attention because of increasing prostration that is often accompanied by severe headache, dizziness, photophobia, hyperesthesia, abdominal or chest pain, anorexia, nausea or vomiting, and other gastrointestinal disturbances. Initial examination often reveals only an acutely ill patient with conjunctival suffusion, tenderness to palpation of muscles or abdomen, and borderline hypotension or postural hypotension, perhaps with tachycardia. Petechiae (often best visualized in the axillae), flushing of the head and thorax, periorbital edema, and proteinuria are common. Levels of AST are usually elevated at presentation or within a day or two thereafter. Hemoconcentration from vascular leakage, which is usually evident, is most marked in hantavirus diseases and in DHF/DSS. The seriously ill patient progresses to more severe symptoms and develops shock and other findings typical of the causative virus. Shock, multifocal bleeding, and CNS involvement (encephalopathy, coma, convulsions) are all poor prognostic signs.

One of the major diagnostic clues is travel to an endemic area within the incubation period for a given syndrome (Table 180-4). Except for Seoul, dengue, and yellow fever virus infections, which have urban vectors, travel to a rural setting is especially suggestive of a diagnosis of HF.

Early recognition is important because of the need for virus-specific therapy and supportive measures, including prompt, atrumatic hospitalization; judicious fluid therapy that takes into account the patient’s increased capillary permeability; administration of cardiotonic drugs; use of pressors to maintain blood pressure at levels that will support renal perfusion; treatment of the relatively common secondary bacterial infections; replacement of clotting factors and platelets as indicated; and the usual precautionary measures used in the treatment of patients with hemorrhagic diatheses. DIC should be treated only if clear laboratory evidence of its existence is found and if laboratory monitoring of therapy is feasible; there is no proven benefit of such therapy. The available evidence suggests that HF patients have a decreased cardiac output and will respond poorly to fluid loading as it is often practiced in the treatment of shock associated with bacterial sepsis. Specific therapy is available for several of the HF syndromes. In addition, several diseases considered in the differential diagnosis—malaria, shigellosis, typhoid, leptospirosis, relapsing fever, and ricketsial disease—are treatable and potentially lethal. Strict barrier nursing and other precautions against infection of medical staff and visitors are indicated in HF except that due to hantaviruses, yellow fever, Rift Valley fever, and dengue.

**LASSA FEVER** Lassa virus is known to cause endemic and epidemic disease in Nigeria, Sierra Leone, Guinea, and Liberia, although it is probably more widely distributed in West Africa. This virus and its relatives exist elsewhere in Africa, but their health significance is unknown. Like other arenaviruses, Lassa virus is spread to humans by small-particle aerosols from chronically infected rodents and may also be acquired during the capture or eating of these animals. It can be transmitted by close person-to-person contact. The virus is often present in urine during convalescence and is suspected to be present in seminal fluid early in recovery. Nosocomial spread has occurred but is uncommon if proper sterile parenteral techniques are used. Individuals of all ages and both sexes are affected; the incidence of disease is highest in the dry season, but transmission takes place year-round. In countries where Lassa virus is endemic, Lassa fever can be a prominent cause of febrile disease. For example, in one hospital in Sierra Leone, laboratory-confirmed Lassa fever is consistently responsible for one-fifth of admissions to the medical wards. There are probably tens of thousands of Lassa fever cases annually in West Africa alone.

The average case has a gradual onset (among the HF agents, only the arenaviruses are typically associated with a gradual onset) that gives way to more severe constitutional symptoms and prostration. Bleeding is seen in only ~15 to 30% of cases. A maculopapular rash is often noted in light-skinned Lassa patients. Effusions are common,
and male-dominant pericarditis may develop late. The fetal death rate is 92% in the last trimester, when maternal mortality is also increased from the usual 15% to 30%; these figures suggest that interruption of the pregnancy of infected women should be considered. White blood cell counts are normal or slightly elevated, and platelet counts are normal or somewhat low. Deafness coincides with clinical improvement in ~20% of cases and is permanent and bilateral in some. Reinfection may occur but has not been associated with severe disease.

High-level viremia or a high serum concentration of AST statistically predicts a fatal outcome. Thus patients with an AST level of >150 IU/mL should be treated with intravenous ribavirin. This antiviral nucleoside analogue appears to be effective in reducing mortality from rates among retrospective controls, and its only major side effect is reversible anemia that usually does not require transfusion. The drug should be given by slow intravenous infusion in a dose of 32 mg/kg; this dose should be followed by 16 mg/kg every 6 h for 4 days and then by 8 mg/kg every 8 h for 6 days.

**SOUTH AMERICAN HF SYNDROMES (ARGENTINE, BOLIVIAN, VENEZUELAN, AND BRAZILIAN)** These diseases are similar to one another clinically, but their epidemiology differs with the habits of their rodent reservoirs and the interactions of these animals with humans (Table 180-4). Person-to-person or nosocomial transmission is rare but has occurred.

The basic disease resembles Lassa fever, with two marked differences. First, thrombocytopenia—often marked—is the rule, and bleeding is quite common. Second, CNS dysfunction is much more common than in Lassa fever and is often manifest by marked confusion, tremors of the upper extremities and tongue, and cerebellar signs. Some cases follow a predominantly neurologic course, with a poor prognosis. The clinical laboratory is helpful in diagnosis since thrombocytopenia, leukopenia, and proteinuria are typical findings.

**Argentine HF** is readily treated with convalescent-phase plasma given within the first 8 days of illness. In the absence of passive antibody therapy, intravenous ribavirin in the dose recommended for Lassa fever is likely to be effective in all the South American HF syndromes. The transmission of the disease from men convalescing from Argentine HF to their wives suggests the need for counseling of arenavirus HF patients concerning the avoidance of intimate contacts for several weeks after recovery. A safe, effective, live attenuated vaccine exists for Argentine HF. In experimental animals, this vaccine is cross-protective against the Bolivian HF virus.

**RIFT VALLEY FEVER** The mosquito-borne Rift Valley fever virus is also a pathogen of domestic animals such as sheep, cattle, and goats. It is maintained in nature by transovarial transmission in floodwater *Aedes* mosquitoes and presumably also has a vertebrate amplifier. Epizootics and epidemics occur when sheep or cattle become infected during particularly heavy rains; developing high-level viremia, these animals infect many different species of mosquitoes. <sup>a</sup> Figure is for HF cases only. Most infections with Rift Valley fever virus result in fever and myalgia rather than HF.
This severe HF syndrome has a wide geographic distribution, potentially being found wherever ticks of the genus *Hyalomma* occur (Table 180-4). The propensity of these ticks to feed on domestic livestock and certain wild mammals means that veterinary serosurveys are the most effective mechanism for the surveillance of virus circulation in a region. Human infection is acquired via a tick bite or during the crushing of infected ticks. Domestic animals do not become ill but do develop viremia; thus there is danger of infection at the time of slaughter and for a brief interval thereafter (through contact with hides or carcasses). Cases have followed sheep shearing. An epidemic in South Africa was associated with slaughter of tick-infested ostriches. Nosocomial epidemics are common and are usually related to extensive blood exposure or needle sticks.

Although generally similar to other HF syndromes, Crimean-Congo HF causes extensive liver damage, resulting in jaundice in some cases. Clinical laboratory values indicate DIC and show elevations in AST, creatine phosphokinase, and bilirubin. Patients with fatal cases generally have more marked changes, even in the early days of illness, and also develop leukocytosis rather than leukopenia. Thrombocytopenia is also more marked and develops earlier in cases with a fatal outcome.

No controlled trials have been performed with intravenous ribavirin, but clinical experience and retrospective comparison of patients with ominous clinical laboratory values suggest that ribavirin is efficacious and should be given. No human or veterinary vaccines are recommended.

HF WITH RENAL SYNDROME This disease, the first to be identified as an HF, is widely distributed over Europe and Asia; the major causative viruses and their rodent reservoirs on these two continents are Puuma virus (bank vole, *Clethrionomys glareolus*) and Hantaan virus (striped field mouse, *Apodemus agrarius*), respectively. Other potential causative viruses exist, including Dobrava virus (yellow-necked field mouse, *A. flaviollus*), which causes severe HF with renal syndrome in the Balkans. Seoul virus is associated with the Norway or sewer rat, *Rattus norvegicus*, and has a worldwide distribution through the migration of the rodent; it is associated with mild or moderate HF with renal syndrome in Asia, but in many areas of the world the human disease has been difficult to identify. Most cases occur in rural residents or vacationers; the exception is Seoul virus disease, which may be acquired in an urban or rural setting or from contaminated laboratory rat colonies. Classic Hantaan disease in Korea (Korean HF) and in rural China (epidemic HF) is most common in spring and fall and is related to rodent density and agricultural practices. Human infection is acquired primarily through aerosols of rodent urine, although virus is also present in saliva and feces. Patients with hantavirus diseases are not infectious. HF with renal syndrome is the most important form of HF today, with >1,000,000 cases of severe disease in Asia annually and milder Puuma infections numbering in the thousands as well.

Severe cases of HF with renal syndrome caused by Hantaan virus evolve in identifiable stages: the febrile stage with myalgia, lasting 3 to 4 days; the hypotensive stage, often associated with shock and lasting from a few hours to 48 h; the oliguric stage with renal failure, lasting 3 to 10 days; and the polyuric stage with diuresis and hypostenuria.

The febrile period is initiated by the abrupt onset of fever, headache, severe myalgia, thirst, anorexia, and often nausea and vomiting. Photophobia, retroorbital pain, and pain on ocular movement are common, and the vision may become blurred with ciliary body inflammation. Flushing over the face, the V area of the neck, and the back are characteristic, as are pharyngeal injection, periorbital edema, and conjunctival suffusion. Petechiae often develop in areas of pressure, the conjunctivae, and the axillae. Back pain and tenderness to percussion at the costovertbral angle reflect massive retroperitoneal edema. Laboratory evidence of mild to moderate DIC is present. Other laboratory findings include proteinuria and an active urinary sediment.

The hypotensive phase is ushered in by falling blood pressure and sometimes by shock. The relative bradycardia typical of the febrile phase is replaced by tachycardia. Kinin activation is marked. The rising hematocrit reflects increasing vascular leakage. Leukocytosis with a left shift develops, and thrombocytopenia continues. Atypical lymphocytes—which in fact are activated CD8 T cells—circulate. Proteinuria is marked, and the urine’s specific gravity falls to 1.010. The renal circulation is congested and compromised from local and systemic circulatory changes resulting in necrosis of tubules, particularly at the corticomedullary junction, and oliguria.

During the oliguric phase, hemorrhagic tendencies continue, probably in large part because of uremic bleeding defects. The oliguria persists for 3 to 10 days before renal function returns and marks the onset of the polyuric stage, which carries the danger of dehydration and electrolyte abnormalities.

Mild cases of HF with renal syndrome may be much less stereotypical. The presentation may include only fever, gastrointestinal abnormalities, and transient oliguria followed by hypostenuria.

HF with renal syndrome should be suspected in patients with rural exposure in an endemic area. Prompt recognition of the disease will permit rapid hospitalization and expectant management of shock and
renal failure. Useful clinical laboratory parameters include leukocytosis, which may be leukemoid and is associated with a left shift; thrombocytopenia; and proteinuria. Mainstays of therapy are the management of shock, reliance on pressors, modest crystalloid infusion, intravenous use of human serum albumin, and treatment of renal failure with prompt dialysis for the usual indications. Hydration may result in pulmonary edema, and hypertension should be avoided because of the possibility of intracranial hemorrhage. Use of intravenous ribavirin has reduced mortality and morbidity in severe cases provided treatment is begun within the first 48 days of illness. The case-fatality ratio may be as high as 15% but with proper therapy should be <5%. Sequela have not been definitely established, but there is a correlation in the United States between chronic hypertensive renal failure and the presence of antibodies to Seoul virus.

Infections with Puumala virus, the most common cause of HF with renal syndrome in Europe, result in a much attenuated picture but the same general presentation. The syndrome may be referred to by its former name, nephropathia epidemica. Bleeding manifestations are found in only 10% of cases, hypotension rather than shock is usually seen, and oliguria is present in only about half of patients. The dominant features may be fever, abdominal pain, proteinuria, mild oliguria, and sometimes blurred vision or glaucoma followed by polyuria and hyposthenuria in recovery. Mortality is <1%.

The diagnosis is readily made by IgM-capture ELISA, which should be positive at admission or within 24 to 48 h thereafter. The isolation of virus is difficult, but RT-PCR of a blood clot collected early in the clinical course or of tissues obtained postmortem will give positive results. Such testing is usually undertaken only if definitive identification of the infecting viral species is required or if molecular epidemiologic questions exist.

HANTAVIRUS PULMONARY SYNDROME Hantavirus pulmonary syndrome was discovered in 1993, but retrospective identification of cases by immunohistochemistry (1978) and serology (1959) support the idea that it is a recently discovered rather than a truly new disease. The causative viruses are hantaviruses of a distinct phylogenetic lineage that is associated with the rodent subfamily Sigmodontinae. Sin Nombre virus chronically infects the deer mouse (Peromyscus maniculatus) and is the most important virus causing hantavirus pulmonary syndrome in the United States. The disease is also caused by a Sin Nombre virus variant from the white-footed mouse (P. leucopus), by Black Creek Canal virus (Sigmodon hispidus, the cotton rat), and by Bayou virus (Oryzomys palustris, the rice rat). Several other related viruses cause the disease in South America, but Andes virus is unusual in that its home range of the deer mouse and in atypical cases.

A specific diagnosis is best made by IgM testing of acute-phase serum, which has yielded positive results even in the prodrome. Tests using a Sin Nombre virus antigen detect the related hantaviruses causing the pulmonary syndrome in the Americas. Occasionally, heterologous viruses will react only in the IgG ELISA, but this finding is highly suspicious given the very low seroprevalence of these viruses in normal populations. RT-PCR is usually positive when used to test blood clots obtained in the first 7 to 9 days of illness as well as tissues; this test is useful in identifying the infecting virus in areas outside the home range of the deer mouse and in atypical cases.

YELLOW FEVER Yellow fever virus caused major epidemics in the Americas, Africa, and Europe before the discovery of mosquito transmission in 1900 led to its control through attacks on its urban vector, A. aegypti. Only then was it found that a jungle cycle also existed in Africa, involving other Aedes mosquitoes and monkeys, and that colonization of the New World with A. aegypti, originally an African species, had established urban yellow fever as well as an independent sylvatic yellow fever cycle in American jungles involving Haemagogus mosquitoes and New World monkeys. Today, urban yellow fever transmission occurs only in some African cities, but the threat exists in the great cities of South America, where reinfestation by A. aegypti has taken place and dengue transmission by the same mosquito is common. As late as 1905, New Orleans suffered >3000 cases with 452 deaths from “yellow jack.” Despite the existence of a highly effective and safe vaccine, several hundred jungle yellow fever cases occur annually in South America, and thousands of jungle and urban cases occur each year in Africa.

Y fever is a typical HF accompanied by prominent hepatic necrosis. A period of viremia, typically lasting 3 or 4 days, is followed by a period of “intoxication.” During the latter phase in severe cases,
the characteristic jaundice, hemorrhages, black vomit, anuria, and terminal delirium occur, perhaps related in part to extensive hepatic involvement. Blood leukocyte counts may be normal or reduced and are often high in terminal stages. Albuminuria is usually noted and may be marked; as renal function fails in terminal or severe cases, the level of blood urea nitrogen rises proportionately. Abnormalities detected in liver function tests range from modest elevations of AST levels in mild cases to severe derangement.

Urban yellow fever can be prevented by the control of A. aegypti. The continuing sylvatic cycle requires vaccination of all visitors to areas of potential transmission. With few exceptions (in the very young and the elderly), reactions to vaccine are minimal; immunity is provided within 10 days and lasts for at least 10 years. An egg allergy dictates caution in vaccine administration. Although there are no documented harmful effects of the vaccine on the fetus, pregnant women should be immunized only if they are definitely at risk of yellow fever exposure. Since vaccination has been associated with several cases of encephalitis in children <6 months of age, it should be delayed until after 12 months of age unless the risk of exposure is very high. Timely information on changes in yellow fever distribution and yellow fever vaccine requirements can be obtained from Health Information for Travelers, Centers for Disease Control and Prevention, Atlanta, GA 30333; by fax request (404-332-4565; document number 220022#); by phone (404-332-4559); or via the Internet (www.cdc.gov).

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME A syndrome of HF noted in the 1950s among children in the Philippines and Southeast Asia was soon associated with dengue virus infections, particularly those occurring against a background of previous exposure to another serotype. The transient heterotypic protection after dengue virus infection is replaced within several weeks by the potential for heterotypic infection resulting in typical dengue fever (see above) or—uncommonly—for enhanced disease (secondary DHF/DSS). In rare instances, primary dengue infections lead to an HF syndrome, but much less is known about pathogenesis in this situation. In the past 20 years, A. aegypti has progressively reinvaded Latin America and other areas, and frequent travel by infected individuals has introduced multiple strains of dengue virus from many geographic areas. Thus the pattern of hyperendemic transmission of multiple dengue serotypes has now been established in the Americas and the Caribbean and has led to the emergence of DHF/DSS as a major problem there as well. Millions of dengue infections, including many thousands of cases of DHF/DSS, occur annually. The severe syndrome is unlikely to be seen in U.S. citizens since few children have the dengue antibodies that can trigger the pathogenetic cascade when a second infection is acquired.

Macrophage/monocyte infection is central to the pathogenesis of dengue fever and to the origin of DHF/DSS. Previous infection with a heterologous dengue-virus serotype may result in the production of nonprotective antiviral antibodies that nevertheless bind to the virion’s surface and through interaction with the Fc receptor focus secondary dengue viruses on the target cell, the result being enhanced infection. The host is also primed for a secondary antibody response when viral antigens are released and immune complexes lead to activation of the classic complement pathway, with consequent phlogistic effects. Cross-reactivity at the T cell level results in the release of physiologically active cytokines, including interferon γ and tumor necrosis factor α. The induction of vascular permeability and shock depends on multiple factors, including the following:

1. Presence of enhancing and nonneutralizing antibodies—Transplacental maternal antibody may be present in infants <9 months old, or antibody elicited by previous heterologous dengue infection may be present in older individuals. T cell reactivity is also intimately involved.
2. Age—Susceptibility to DHF/DSS drops considerably after 12 years of age.
3. Sex—Females are more often affected than males.

Dengue HF is identified by the detection of bleeding tendencies (tourniquet test, petechiae) or overt bleeding in the absence of underlying causes such as preexisting gastrointestinal lesions. Dengue shock syndrome, usually accompanied by hemorrhagic signs, is much more serious and results from increased vascular permeability leading to shock. In mild DHF/DSS, restlessness, lethargy, thrombocytopenia (<100,000/µL), and hemocoagulation are detected 2 to 5 days after the onset of typical dengue fever, usually at the time of defervescence. The maculopapular rash that often develops in dengue fever may also appear in DHF/DSS. In more severe cases, frank shock is apparent, with low pulse pressure, cyanosis, hepatomegaly, pleural effusions, ascites, and in some cases severe ecchymoses and gastrointestinal bleeding. The period of shock lasts only 1 or 2 days, and most patients respond promptly to close monitoring, oxygen administration, and infusion of crystalloid or—in severe cases—colloid. The case-fatality rates reported vary greatly with case ascertainment and the quality of treatment; however, most DHF/DSS patients respond well to supportive therapy, and overall mortality in an experienced center in the tropics is probably as low as 1%. A virologic diagnosis can be made by the usual means, although multiple flavivirus infections lead to a broad immune response to several members of the group, and this situation may result in a lack of virus specificity of the IgM and IgG immune responses. A secondary antibody response can be sought with tests against several flavivirus antigens to demonstrate the characteristic wide spectrum of reactivity.

The key to control of both dengue fever and DHF/DSS is the control of A. aegypti, which also reduces the risk of urban yellow fever and chikungunya virus circulation. Control efforts have been handicapped by the presence of nondegradable tires and long-lived plastic containers in trash repositories, insecticide resistance, urban poverty, and an inability of the public health community to mobilize the populace to respond to the need to eliminate mosquito breeding sites. Live attenuated dengue vaccines are in the late stages of development and have produced promising results in early tests. Whether vaccines can provide safe, durable immunity to an immunopathologic disease such as DHF/DSS in endemic areas is an issue that will have to be tested, but it is hoped that vaccination will reduce transmission to negligible levels.

EBOLA AND MARBURG VIRUSES

Clarence J. Peters

DEFINITION

Both Marburg virus and Ebola virus cause an acute febrile illness associated with high mortality. This illness is characterized by multisystem involvement that begins with the abrupt onset of headache, myalgias, and fever and proceeds to prostration, rash, and shock and often to bleeding manifestations. Epidemics usually begin with a single case acquired from an unknown reservoir in nature and spread mainly through close contact with sick persons or their body fluids, either in the home or at the hospital.

ETIOLOGY

The family Filoviridae comprises two antigenically and genetically distinct viruses: Marburg virus and Ebola virus. Ebola virus has four readily distinguishable subtypes named for their original sites of recognition (Zaire, Sudan, Cote d’Ivorie, and Reston). Except for Ebola virus subtype Reston, all the Filoviridae are African viruses that cause severe and often fatal disease in humans. The Reston virus, which has been exported from the Philippines on several occasions, has caused fatal infections in monkeys but only subclinical infections in humans. Different isolates of the four Ebola subtypes made over time and space exhibit remarkable sequence conservation, indicating marked genetic stability in their selective niche. Typical filovirus particles contain a single linear, negative-sense, single-stranded RNA arranged in a helical nucleocapsid. The virions are 790 to 970 nm in length; they may also appear in elongated, contorted forms. The lipid envelope confers sensitivity to lipid solvents and common detergents. The viruses are largely destroyed by heat (60°C, 30 min) and by acidity but may persist for weeks in blood at room temperature. The surface glycoprotein self-associates to form the virion surface spikes, which presumably mediate attachment to cells and fusion. The glycoprotein’s high sugar content may contribute to its low capacity to elicit neutralizing antibodies. A smaller form of the glycoprotein, bearing many of its antigenic determinants, is produced in vitro–infected cells and is found in the circulation in human disease; it has been speculated that this circulating soluble protein may suppress the immune response to the virion surface protein or block antiviral effector mechanisms. Both Marburg virus and Ebola virus are biosafety level 4 pathogens because of their high associated mortality rate and aerosol infectivity.

EPIDEMIOLOGY

Marburg virus was first identified in Germany in 1967, when infected African green monkeys (Cercopithecus aethiops) imported from Uganda transmitted the agent to vaccine-laboratory workers. Of the 25 human cases acquired from monkeys, 7 ended in death. The six secondary cases were associated with close contact or parenteral exposure. Secondary spread to the wife of one patient was documented, and virus was isolated from the husband’s semen despite the presence of circulating antibodies. Subsequently, isolated cases of Marburg virus infection have been reported from eastern and southern Africa, with limited spread.

In 1999, repeated transmission of Marburg virus to workers in a gold mine in eastern Democratic Republic of Congo was documented. The secondary spread of the virus among patients’ families was more extensive than previously noted, resembling that of Ebola virus and emphasizing the importance of hygiene and proper barrier nursing in the epidemiology of these viruses in Africa.

In 1976, epidemics of severe hemorrhagic fever (550 human cases) occurred simultaneously in Zaire and Sudan, and Ebola virus was found to be the etiologic agent. Later, it was shown that different subtypes of virus—associated with 90 and 50% mortality, respectively—caused the two epidemics. Both epidemics were associated with interhuman spread (particularly in the hospital setting) and the use of unsterilized needles and syringes, a common practice in developing-country hospitals. The epidemics dwindled as the clinics were closed and people in the endemic area increasingly shunned affected persons and avoided traditional burial practices.

The Zaire subtype of Ebola virus occurred in a major epidemic (317 cases, 88% mortality) in Democratic Republic of Congo in 1995 and in smaller epidemics in Gabon in 1994–1996. Mortality was high, transmission to caregivers and others who had direct contact with body fluids was common, and poor hygiene in hospitals exacerbated spread. In the Congo epidemic, an index case was infected in Kikwit in January 1995. The epidemic smoldered until April, when intense nosocomial transmission forced closure of the hospitals; samples were finally sent to the laboratory for Ebola testing, which yielded positive results within a few hours. International assistance, with barrier nursing instruction and materials, was provided; nosocomial transmission ceased, hospitals reopened, and patients were segregated to prevent intrafamilial spread. The last case was reported in June 1995.

Separate emergences of Ebola virus (subtype Zaire) were detected in Gabon from 1994 through 2003, usually in association with deep forest exposure and subsequent familial and nosocomial transmission. Nonhuman primates sometimes exhibited die-offs, and Ebola infection was confirmed in at least some animals. In a 1996 episode, a physician exposed to Ebola-infected patients traveled to South Africa with a fever; a nurse who assisted in a cooldown on the physician developed Ebola hemorrhagic fever and died despite intensive care. The index patient was identified retrospectively on the basis of serum antibodies and virus isolation from semen. Thus, distant transport of Ebola virus is an established risk, but limited nosocomial spread occurs under proper hygienic conditions.

In 2000–2001, an indolent outbreak of the Sudan subtype claimed the lives of 224 (53%) of 425 patients with presumptive cases in Uganda.

The Reston subtype of Ebola virus was first seen in the United States in 1989, when it caused a fatal, highly transmissible disease among cynomolgus macaques imported from the Philippines and quarantined in Reston, VA, pending distribution to biomedical researchers. This and other appearances of the Reston virus have been traced to a single export facility in the Philippines, but no source in nature has been established.

Epidemiologic studies (including a specific search in the Kikwit epidemic) have failed to yield evidence for an important role of airborne particles in human disease. This lack of epidemiologic evidence is surprising and seems to conflict with the viruses’ classification as biosafety level 4 pathogens based in part on their aerosol infectivity and with formal laboratory assessments showing a high degree of aerosol infectivity for monkeys. Sick humans apparently do not usually generate sufficient amounts of infectious aerosols to pose a significant hazard to those around them.

Available evidence points to a nonprimate reservoir for these viruses, but an intensive search has failed to elucidate what this reservoir might be. Speculation has centered on a possible role for bats, but that
hypothesis has risen in part merely because of the ubiquity of bats when sought in affected areas and the frustration of researchers in identifying a source of virus.

PATHOLOGY AND PATHOGENESIS In humans and in animal models, Ebola and Marburg viruses replicate well in virtually all cell types, including endothelial cells, macrophages, and parenchymal cells of multiple organs. The earliest involvement is that of the mononuclear phagocyte system, and this is responsible for initiation of the disease process. Viral replication is associated with cellular necrosis both in vivo and in vitro. Significant findings at the light-microscopic level include liver necrosis with Councilman bodies (intracellular inclusions that correlate with extensive collections of viral nucleocapsids), interstitial pneumonitis, cerebral glial nodules, and small infarcts. Antigen and virosomes are abundant in fibroblasts, interstitium, and (to a lesser extent) the appendages of the subcutaneous tissues in fatal cases; escape through small breaks in the skin or possibly through sweat glands may occur and, if so, may be correlated with the established epidemiologic risk of close contact with patients and the touching of the deceased. Inflammatory cells are not prominent, even in necrotic areas.

In addition to sustaining direct damage from viral infection, patients infected with Ebola virus (Zaire subtype) have high circulating levels of proinflammatory cytokines, which presumably contribute to the severity of the illness. In fact, the virus interacts intimately with the cellular cytokine system. It is resistant to the antiviral effects of interferon α, although this mediator is amply induced. Viral infection of endothelial cells selectively inhibits the expression of MHC class I molecules and blocks the induction of several genes by the interferons. In addition, glycoprotein expression inhibits αV integrin expression, an effect that has been shown in vitro to lead to detachment and subsequent death of endothelial cells.

Acute infection is associated with high levels of circulating virus and viral antigen. Clinical improvement takes place when viral titers decrease concomitantly with the onset of a virus-specific immune response, as detected by enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody test. In fatal cases, there is usually little evidence of an antibody response and there is extensive depletion of spleen and lymph nodes. Recovery is apparently mediated by the cellular immune response; convalescent-phase plasma has little in vitro virus-neutralizing capacity and is not protective in passive transfer experiments in monkey and guinea pig models.

CLINICAL MANIFESTATIONS After an incubation period of ~7 to 10 days (range, 3 to 16 days), the patient abruptly develops fever, severe headache, malaise, myalgia, nausea, and vomiting. Continued fever is joined by diarrhea (often severe), chest pain (accompanied by cough), prostration, and depressed mentation. In light-skinned patients (and less often in dark-skinned individuals), a maculopapular rash appears around day 5 to 7 and is followed by desquamation. Bleeding may begin about this time and is apparent from any mucosal site and into the skin. In some epidemics, fewer than half of patients have had overt bleeding, and this manifestation has been absent even in some fatal cases. Additional findings include edema of the face, neck, and/or scrotum; hepatomegaly; flushing; conjunctival injection; and pharyngitis. Around 10 to 12 days after the onset of disease, the sustained fever may break, with improvement and eventual recovery of the patient. Recrudescence of fever may be associated with secondary bacterial infections or possibly with localized virus persistence. Late hepatitis, uveitis, and orchitis have been reported, with isolation of virus from semen or detection of polymerase chain reaction (PCR) products in vaginal secretions for several weeks.

LABORATORY FINDINGS Leukopenia is common early on; neutrophilia has its onset later, Platelet counts fall below (sometimes much below) 50,000/μL. Laboratory evidence of disseminated intravascular coagulation may be found, but its clinical significance and the need for therapy are controversial. Serum levels of alanine and aspartate aminotransferases (particularly the latter) rise progressively, and jaundice develops in some cases. The serum amylose level may be elevated, and this elevation may be associated with abdominal pain suggesting pancreatitis. Proteinuria is usual; decreased kidney function is proportional to shock.

DIAGNOSIS Most patients acutely ill as a result of infection with Ebola or Marburg viruses have high concentrations of virus in blood. Antigen-detection ELISA is a sensitive, robust diagnostic modality. Virus isolation and reverse-transcriptase PCR are also effective and provide additional sensitivity in some cases. Patients who are recovering develop IgM and IgG antibodies that are best detected by ELISA but are also reactive in the less specific fluorescent antibody test. Skin biopsies are an extremely useful adjunct in postmortem diagnosis of Ebola (and, to a lesser extent, Marburg) virus infections because of the presence of large amounts of viral antigen, the relative safety of obtaining the sample, and the freedom from cold-chain requirements for formalin-fixed tissues.

TREATMENT No virus-specific therapy is available, and, given the extensive viral involvement in fatal cases, supportive treatment may not be as useful as was once hoped. However, recent studies in rhesus monkeys have shown improved survival among animals treated with an inhibitor of factor VIIa/tissue factor. Vigorous treatment of shock should take into account the likelihood of vascular leak in the pulmonary and systemic circulation and of myocardial functional compromise. The membrane fusion mechanism of Ebola resembles that of retroviruses, and the identification of “fusogenic” sequences suggests that inhibitors of cell entry may be developed. Despite the poor neutralizing capacity of monoclonal convalescent-phase sera, plage display of immunoglobulin mRNA from convalescent bone marrow has produced monoclonal antibodies that have in vitro neutralizing capacity and mediate protection in guinea pig—but, unfortunately, not in monkey—models.

PREVENTION No vaccine or antiviral drug is currently available, but barrier nursing precautions in African hospitals can greatly decrease the spread of the virus beyond the index case and thus prevent epidemics of filoviruses and other agents as well. An adenovirus-vectored Ebola glycoprotein gene has proved protective in nonhuman primates and is undergoing phase 1 trials in humans.

FURTHER READING

Fungi can appear microscopically as either rounded, budding forms (yeast-like organisms) or hyphae (molds). Yeast-like colonies are smooth, while mold colonies are fuzzy; fungi that grow as yeasts include species of *Candida* and *Cryptococcus*, while fungi that grow as molds include species of *Aspergillus*, *Rhizopus*, and *dermatophytes* (ringworm fungi). The fungi that cause histoplasmosis, blastomycosis, sporotrichosis, coccidiodomycosis, and paracoccidioidomycosis are called *dimorphic* (“having two forms”) because they are spherical in tissue but grow like molds when cultured at room temperature. *Candida* species other than *Candida glabrata* appear in tissue as both budding yeasts and tubular elements called *pseudo hyphae*. Pseudo hyphae, unlike true hyphae, have constrictions in the cell wall where septa are located and have septa at branching points. *Pneumocystis* (Chap. 191) is closer to fungi than to parasites by ribosomal sequences. Because the drugs used to treat *Pneumocystis* pneumonia are also used to treat parasitic or bacterial infections (see Chaps. 118 and 193), those drugs will not be discussed in this chapter.

Many fungi can form two different types of spores and are given different names, depending on the spore-bearing structures. When the spores are produced by mitosis, the fungus is said to be an *anamorph*, or to be in the imperfect state. Many fungi can have different sporing structures in which genetic recombination occurs, often as a result of coculture with a strain of the opposite mating type. A fungus producing those distinctive spores is said to be a *teleomorph*, or to be in the perfect state. Diagnostic laboratories usually use the name of the anamorph because they do not use culture conditions that would produce the teleomorph. One exception is *Scedosporium apiospermum*, which is often observed as a teleomorph in the diagnostic laboratory and identified as *Pseudallescheria boydii*.

Most fungi that are pathogenic for humans are saprophytes in nature; they cause infection when airborne spores reach the lung or paranasal sinus or when hyphae or spores are accidentally inoculated into the skin or cornea. Acquisition of infection from another person or an animal has been reported in the case of ringworm but is very rare in other mycoses. Thus, hospitalized patients with fungal infections do not require special isolation. Most fungi infect hosts preferentially by one route and only infrequently by other routes. For example, the agents of ringworm, pityriasis versicolor, and piedra infect the epidermis and its appendages. Sporotrichosis and mycetoma usually arise from subcutaneous inoculation. Inhalation is the route of inoculation for the agents of most deep mycoses. Ingestion of fungi rarely causes infection; *Candida albicans*, a normal commensal in the mouth and intestine, reaches deeper tissues only when mucosal or cutaneous barriers are breached by disease, surgery, trauma, or catheterization. Histoplasmosis, blastomycosis, coccidiodomycosis, and paracoccidioidomycosis have been called “endemic” mycoses to emphasize their restricted geographic distribution. Some fungi, such as *Aspergillus* and *Fusarium*, are said to be opportunists in that they usually infect hosts with compromised immunity. This distinction is relative, not absolute.

Immunity after exposure to fungi may confer partial protection against reinfection. Residents of areas in which mycoses are endemic are less subject to infection than are newcomers. Predisposing factors are helpful in defining host defense. Immunoglobulin deficiencies do not appear to predispose to any mycosis, whereas neutropenia is common among patients who develop invasive mold infections or deep candidiasis. Cell-mediated immunity appears to be of paramount importance in cryptococcosis, histoplasmosis, and coccidioidomycosis.

**Diagnosis**

Many fungi can be identified to the genus or even the species level by microscopic examination of smears or biopsy specimens. Calcofluor white staining with fluorescence microscopy is a sensitive technique for smears of sputum, bronchoalveolar lavage fluid, or pus. India ink smear remains the method of choice for detecting cryptococci in cerebrospinal fluid (CSF). *Candida* yeast cells and pseudohyphae are the only fungi that are usually gram-positive on smears. For other fungi, Gram’s staining is distinctly suboptimal. For histopathology slides, Gram or methenamine silver and a neutral counterstain are preferred.

The method used has a marked effect on the rapidity and sensitivity of blood cultures for fungi except in the case of *Candida* species, which are relatively easy to grow. For most other fungi, concentration of the blood by lysis centrifugation and culture on solid medium constitute the optimal technique. Commercially available nucleic acid hybridization techniques can speed the identification of slow-growing molds, such as *Histoplasma capsulatum* and *Coccidioides immitis*. Serology has limited value, but testing of serum or CSF for cryptococcal antigen or antibody to *C. immitis* can be diagnostic. Detection of *Histoplasma* antigen in urine or serum is helpful in diagnosis and in following the results of treatment for disseminated histoplasmosis. Skin testing with fungal antigens is not useful in detecting active infection.

**Antifungal Therapy**

### Imidazoles and Triazoles

(*See also “Systemic Antifungals”*) These synthetic compounds act by inhibiting ergosterol synthesis in the fungal cell wall and, when given topically, may cause direct damage to the fungal cytoplasmic membrane. The imidazoles available for cutaneous application include clotrimazole, econazole, ketoconazole, sulconazole, oxiconazole, and miconazole. Vaginal formulations include four imidazoles (miconazole, clotrimazole, toconazole, and butoconazole) and one triazole (terconazole). As yet, no substantial differences in the efficacy of or local intolerance to the various topical azoles have become apparent. All are effective in the treatment of cutaneous candidiasis, tinea (pityriasis) versicolor, and mild to moderately severe ringworm of the glabrous skin. Vaginal formulations are effective for vulvovaginal candidiasis. Clotrimazole is poorly absorbed from the gastrointestinal tract, but the oral troche is useful as a topical treatment for oral and esophageal candidiasis.

### Polycyclic Macrolide Antibiotics

These broad-spectrum antifungal agents combine with sterol in the fungal cytoplasmic membrane, increasing membrane permeability. Topically, they are not active against ringworm but are effective against candidiasis of the skin and mucous membranes. Nystatin and amphotericin B suspensions are effective in oral thrush, and vaginal troches are effective in vulvovaginal candidiasis. Both nystatin and amphotericin B are available in topical preparations for cutaneous candidiasis.

### Other Topical Antifungals

Ciclopirox olamine, haloprogin, terbinfine, and naftifine have the same clinical spectrum among the cutaneous mycoses as the imidazoles. Tolnaftate and undecylenic acid are effective against ringworm but not candidiasis. Keratolytic agents, such as salicylic acid, are helpful as accessory drugs for some hyperkeratotic skin lesions.

### Systemic Antifungals

**Griseofulvin** Griseofulvin is a useful drug in the treatment of certain kinds of ringworm; however, it is ineffective in the treatment of candidiasis. The microcrystalline and ultramicrocrystalline preparations differ in dose but not in efficacy. Absorption of both is enhanced when the drug is ingested with fat-containing foods. Griseofulvin interacts with phenobarbital and warfarin.
Terbinafine  Oral terbinafine (250 mg once daily) is at least as effective as itraconazole and more effective than griseofulvin in onychomycosis and ringworm. Treatment duration ranges from 3 months for fingernails to 6 months for toenails. Gastrointestinal distress is the most common side effect. Rash, hepatitis, and pancycopenia have occurred, but serious adverse effects have been uncommon. Terbinafine decreases cyclosporine levels. Ciclmidine increases and rifampin decreases terbinafine levels in blood.

Imidazoles and Triazoles  

**GENERAL FEATURES**  
The azole antifungals include imidazoles and triazoles. Fluconazole, itraconazole, voriconazole, and the investigational azoles posaconazole and ravuconazole are all triazoles, so named because they have three nitrogens in the ring structure. This class has less impact on human hormonal synthesis and less hepatotoxicity than the only widely used systemic imidazole, ketoconazole. Itraconazole has many structural features in common with ketoconazole; however, it has a broader spectrum of activity and has largely replaced ketoconazole.

Interactions between azoles and other drugs can increase the plasma concentrations of the other drugs to toxic levels or decrease the azole plasma concentrations to subtherapeutic levels. A few drugs can increase the plasma concentrations of azoles, but the effect is modest. Drug-drug interactions are most numerous with itraconazole and ketoconazole; some drugs are contraindicated for concomitant use with these agents. Azole interactions with any one class of drugs, such as benzodiazepines, HMG-CoA reductase inhibitors, or drugs that decrease gastric acidity, should be considered to apply to all drugs of that class until proven otherwise. Fluconazole differs substantially from itraconazole: unlike that of itraconazole, the absorption of fluconazole is independent of food or gastric acid, and fluconazole has much less effect on the hepatic metabolism of other drugs than does itraconazole. High fluconazole blood levels engendered by azotemia is not necessary, but the doseshould be reduced by half in patients whose CD4 cell counts were <200/μL and was particularly effective among those with counts of <50/μL. However, this regimen is not recommended because it does not reduce mortality, is expensive, and can lead to drug resistance.

**FLUCONAZOLE**  
This triazole can be administered in tablet form, as a suspension, or as an intravenous infusion. With a half-life of about 31 h, fluconazole can be given once a day. Approximately 80% of the drug is excreted unchanged in the urine. Patients with creatinine clearance rates of 21 to 50 mL/min and 11 to 20 mL/min should have their fluconazole doses reduced by 50 and 75%, respectively. The drug penetrates the CSF and other body fluids very well.

Nausea and abdominal distress are the most common forms of drug-related fluconazole toxicity. An allergic rash may develop and is particularly common among patients infected with HIV. Fatal cases of Stevens-Johnson syndrome have been described in the HIV-infected population. Alopecia commonly follows prolonged administration of 400 mg daily but resolves when therapy is discontinued. Rare cases of anaphylaxis, hepatic necrosis, and neutropenia have been described.

Fluconazole is useful in the treatment of oropharyngeal and esophageal candidiasis in adults. A single 150-mg tablet is effective in vulvovaginal candidiasis. Catheter-acquired candidemia in the immunocompetent host responds to 400 mg of fluconazole daily in conjunction with the removal of the infected catheter. Treatment should be continued for 10 to 14 days after the patient has become afebrile. Fluconazole is also effective in initial and maintenance therapy for cryptococcal meningitis in patients with AIDS, although most of these patients should initially receive a 2-week course of intravenous amphotericin B. Fluconazole is the drug of choice for coccidioidal meningitis.

The incidence of deep candidiasis among recipients of allogeneic bone marrow transplants can be reduced by the administration of fluconazole (400 mg daily) for 75 days after initiation of the transplantation-preparative regimen. Prophylaxis in other neutropenic patients has not appeared useful. Fluconazole (200 mg daily) reduced the incidence of cryptococcosis and mucosal candidiasis among AIDS patients whose CD4+ cell counts were <200/μL and was particularly effective among those with counts of <50/μL. However, this regimen is not recommended because it does not reduce mortality, is expensive, and can lead to drug resistance.

Fluconazole is less effective than itraconazole in blastomycosis, histoplasmosis, and sporotrichosis. The drug is not active in aspergillosis, pseudallescheriasis, or mucormycosis.

**VORICONAZOLE**  
This recently marketed triazole is available as 50- and 200-mg tablets and as vials of 200 mg for intravenous administration. The average-sized adult is given 6 mg/kg intravenously every 12 h for 2 doses followed by maintenance doses of 4 mg/kg intravenously every 12 h. Patients whose condition is improving, the regimen can be changed to 200 mg twice daily by mouth. Up to 300 mg twice daily by mouth can be given to patients who do not respond adequately to the lower dose.

Voriconazole is well absorbed from the gastrointestinal tract and is metabolized completely by the liver by way of CYP2C9, CYP2C19, and CYP3A4. Genetic polymorphisms in CYP2C19 activity cause substantial variation in voriconazole metabolism. Dose adjustment for azotemia is not necessary, but the dose should be reduced by half in continued for 6 to 12 months. Itraconazole blood levels (see above) are helpful in documenting absorption when the oral drug is used for the treatment of deep mycoses. The commercially available intravenous formulation should be considered for initial therapy in hospitalized patients whose itraconazole absorption from the gastrointestinal tract may be suboptimal and whose creatinine clearance rate exceeds 30 mL/min. The dose is 200 mg twice daily for 4 doses followed by 200 mg daily for up to 2 weeks. Intravenous itraconazole, followed by the oral solution, is approved for the treatment of fever of unknown origin in neutropenic patients not responding to at least 96 h of therapy with antibacterial antibiotics.

Except for gastrointestinal distress from the oral solution, the toxicity of itraconazole is generally low, although life-threatening hepatotoxicity, congestive heart failure, edema, cardiac dysrhythmias, and peripheral neuropathy have been reported.
patients with moderate liver disease. Because the cyclosporine used in the intravenous formulation is renally excreted, oral—not intravenous—voriconazole should be used in patients with creatinine clearance rates below 50 mL/min. Penetration into the CSF is good. Concurrent use of sirolimus is contraindicated because its serum levels are markedly increased in the presence of voriconazole. Until more complete data are available, the drug interactions for voriconazole should be considered to be similar to those for itraconazole. The toxic effects of voriconazole include transient visual disturbances (color changes, blurring) in 30% of patients, hepatotoxicity in 10%, and rash in 5%. The spectrum of voriconazole includes all the fungi against which itraconazole and fluconazole are active. Voriconazole is indicated for initial treatment of invasive aspergillosis, pseudallescheriasis, and fusariosis. The drug is also useful as empirical therapy in febrile neutropenic patients who do not respond to at least 96 h of treatment with antibacterial antibiotics and who are at high risk of invasive mold infections.

**Investigational Triazoles**

Posaconazole and ravuconazole, which are undergoing early clinical trials, have antifungal spectra similar to that of voriconazole. Ravuconazole is notable for a half-life of ~1 week.

**Echinocandins**

One echinocandin (caspofungin) is on the market, and two others (micafungin and anidulafungin) are being assessed in clinical trials. All are administered intravenously and act by inhibiting synthesis of (1,3)β-D-glucan in the cell wall. The in vitro activity of these drugs against nearly all Candida species is similar and is independent of azole resistance. The possible exception is Candida parapsilosis, a species whose susceptibility varies with the isolate and the particular echinocandin. Activity against Aspergillus species is more obvious in experimentally infected animals than in vitro, where changes in hyphal shape are more obvious than decreased growth. The recommended regimen is a 70-mg loading dose followed by 50 mg daily. Toxicity is low and includes histamine-like acute infusion reactions and hepatotoxicity. Cyclosporine elevates caspofungin blood levels, but other drug-drug interactions have been minor so far. No dosage adjustment is needed in patients with azotemia or hemodialysis, but the dose should be reduced for moderate hepatic insufficiency. Penetration into CSF is negligible. On the basis of an open trial in 63 patients, caspofungin has been approved for salvage therapy in aspergillosis. Data on candidemia in nonneutropenic patients indicate an efficacy equivalent to that of fluconazole or amphotericin B.

**Amphotericin B**

A colloidal deoxycholate complex of the polyene drug amphotericin B is available for intravenous or intrathecal administration. The catabolism of amphotericin B is extremely slow and is not influenced by renal failure, hepatic failure, or hemodialysis. The drug’s penetration into CSF and vitreous humor is poor; however, the concentrations in pleural, peritoneal, and articular exudates are adequate for many mycoses. Histoplasmosis, blastomycosis, paracoccidioidomycosis, candidiasis, and cryptococcosis are the most responsive mycoses; coccidioidomycosis, extracellular sporotrichosis, aspergillosis, and mucormycosis are less responsive; and chromoblastomycosis, mucormeta, and pseudallescheriasis respond little, if at all. The usual course is 0.5 to 0.7 mg/kg daily for 8 to 10 weeks. Infusions are generally given in 5% dextrose over 2 to 4 h.

Initial doses of amphotericin B occasionally cause marked febrile reactions that may be poorly tolerated by adult patients with limited cardiac or pulmonary function. It may be prudent to give such patients an initial 1-mg test dose followed by rapidly escalating doses, depending on tolerance. Premedication with aspirin or acetaminophen or the addition of hydrocortisone (25 mg) to the infusion decreases chills and fever. Azotemia during treatment is usual, the extent depending on the daily dose, underlying renal disease, and concomitant nephrotoxic agents. Saline infusions have been advocated to reduce azotemia. Continuous amphotericin B infusions may reduce nephrotoxicity, but the impact on efficacy is unknown. Other side effects include anemia, hypokalemia, renal tubular acidosis, nausea, anorexia, weight loss, phlebitis, and occasionally hypomagnesemia. Intrathecal amphotericin B has been used in coccidiodal meningitis and refractory cryptococcal meningitis, although this therapy is associated with transient fever, headache, nausea, and vomiting.

Three lipid formulations of intravenous amphotericin B are commercially available in the United States. These formulations and their usual once-daily doses are amphotericin B lipid complex (ABLC), 5 mg/kg; amphotericin B colloidal dispersion (ABCD), 6 mg/kg; and liposomal amphotericin B (L-AB), 4–5 mg/kg. The most nephrotoxic lipid formulation is ABLC; ABCD causes less azotemia; and L-AB is the least nephrotoxic. Acute, febrile, infusion-related reactions occur with all amphotericin B formulations; their degree of severity is greatest with ABCD and lesser with ABLC and L-AB. The recommended duration for initial infusions of ABCD is 6 h for 6 mg/kg, slower than the 2-h duration of ABLC or L-AB infusions. Infusions of ABCD given more rapidly than 1 mg/kg per hour have caused severe reactions with fever and hypoxia. Use of these remarkably expensive formulations should be restricted to patients who cannot tolerate the nephrotoxicity of the deoxycholate formulation (ABD). Although the lipid formulations are also approved for patients with mycoses failing to respond to ABD, there is no indication that these formulations are more effective than ABD for all mycoses. ABCD and L-AB are probably equivalent in efficacy to ABD for most mycoses. Data on the efficacy of ABCD are largely confined to aspergillosis, in which the efficacy of this lipid formulation was equivalent to that of conventional amphotericin B.

**Flucytosine**

Flucytosine (5-fluorocytosine) is a synthetic oral drug useful in cryptococcosis, candidiasis, and chromoblastomycosis. Within the fungal cell, flucytosine is converted to the antimetabolite 5-fluorouracil. Drug resistance appears rather rapidly when flucytosine is used alone. For this reason, the drug is generally used in combination with amphotericin B. The usual dose of flucytosine is 25 to 37.5 mg/kg every 6 h. Flucytosine is well absorbed from the gastrointestinal tract. The drug penetrates well into the CSF and is excreted unchanged in the urine. Even modest reductions in renal function may elevate flucytosine blood levels into the toxic range (≥100 to 125 μg/mL). Elevated levels are associated with a significant incidence of neutropenia and thrombocytopenia and also seem to predispose to colitis, the other major toxic effect of this drug. Hepatotoxicity is idiosyncratic and uncommon. An allergic rash may develop.

**HISTOPLASMOSIS**

John E. Bennett

**ETIOLOGIC AGENT** *Histoplasma capsulatum var. capsulatum* is a dimorphic fungus that grows as a mold in nature or on Sabouraud’s agar at room temperature. Hyphae bear both large and small spores, which are used for identification. Nucleic acid hybridization can also be used to identify the organism in culture. *H. capsulatum var. capsulatum* grows as a small budding yeast in host tissue and on enriched agar, such as blood cysteine glucose, at 37°C. Despite its name, the fungus is unencapsulated. Coculture of isolates with opposite mating types can produce different sporulating structures in which genetic recombination occurs. When these structures, referred to as a *teleomorph* or the *perfect state*, are seen in culture, the name *Ajellomyces capsulatus* is used. *H. capsulatum var. duboisii* is a rare cause of infection, with most cases originating in Africa. The yeast cells of the *duboisii* variant are larger than those of *H. capsulatum var. capsulatum*, but the mold forms of the two appear identical.

**EPIDEMIOLOGY** Infection with *H. capsulatum* has been encountered in many areas of the world but is much more frequent in certain areas. Within the United States, infection is most common in the southeastern, mid-Atlantic, and central states. Infection has been reported in travelers returning from Latin America and other endemic areas overseas. Endemicity is contingent on the availability of proper conditions in nature for growth of the fungus. *H. capsulatum* prefers moist surface soil, particularly soil enriched by droppings of certain birds and bats. The fungus persists in contaminated soil for years and becomes airborne when the soil is disturbed. Acute infection is usually recognized as case clusters occurring 5 to 18 days after the exposure of groups of people to dust while (for example) cleaning dirt-floored chicken coops; raking or rototilling soil; exploring caves; and cleaning, remodeling, or demolishing old buildings. Skin-test reactivity in many endemic areas indicates that >80% of residents over age 16 have been exposed.

**PATHOGENESIS AND PATHOLOGY** Microconidia, or small spores, of *H. capsulatum* are small enough to reach the alveoli on inhalation and are transformed there to budding forms. With time, an intense granulomatous reaction occurs. Caseation necrosis or calcification may result. In children, the primary infection usually heals completely but may leave spotty calcification in the hilar nodes or lung. Transient dissemination may leave calcified granulomas in the spleen. In adults, a rounded mass of scar tissue, with or without central calcification, may remain in the lung. This mass has been called a *histoplasmosa*. Previous exposure is thought to confer some protection against reinfection, but infection in persons with prior positive skin tests clearly has occurred.

In a small proportion of patients, histoplasmosis becomes a progressive, potentially fatal infection. The disease occurs either as chronic fibrocavitary pneumonia or, less commonly, as disseminated infection. Patients with either form lack a history of acute primary pulmonary histoplasmosis. Chronic pulmonary infection favors otherwise-healthy males over the age of 40. A history of cigarette use or the presence of emphysema is elicited from nearly all patients with chronic progressive pulmonary histoplasmosis. An acute, rapidly fatal disseminated infection is most likely to be encountered among young children and immunosuppressed patients, including those with AIDS. Use of tumor necrosis factor α antagonists, particularly infliximab, also appears to predispose to severe disseminated histoplasmosis. A more chronic but equally lethal disseminated infection is more common among previously healthy adults.

**CLINICAL MANIFESTATIONS** The vast majority of infections are either asymptomatic or mild, and the diagnosis is elusive. Cough, fever, malaise, and chest x-ray findings of hilar adenopathy with or without one or more areas of pneumonitis are typical features. Erythema nodosum and erythema multiforme have been reported in a few outbreaks. Hilar adenopathy may cause temporary compression of the right-middle lobe bronchus in children and young adults. Subacute pericarditis may develop, probably by extension from contiguous lymph nodes. Rarely, hilar nodes undergo a caseous, granulomatous reaction with perinodal fibrosis. Mediastinal structures become encased by progressive fibrosis, and compression of the pulmonary veins, superior vena cava, pulmonary arteries, and esophagus may take place over many years. Late involvement of mediastinal disease, only rare nonviable *Histoplasma* cells can be found in caseous residua of lymph nodes.

Chronic pulmonary histoplasmosis is characterized by a gradual onset (over weeks or months) of increasing productive cough, weight loss, and sometimes night sweats. Chest x-ray reveals uni- or bilateral fibronodular apical infiltrates. Approximately one-third of cases stabilize or improve spontaneously early in the course. The remainder progress insidiously. Retraction and cavitation of the upper lobes occur, with spread to the apex of the lower lobes and other areas of the lung. Emphysema and bulla formation further compromise pulmonary function. Death from cor pulmonale, bacterial pneumonia, or histoplasmosis occurs after months or years.

Disseminated histoplasmosis has many features in common with hematogenously disseminated tuberculosis (Chap. 150). Common findings include fever, emaciation, hepatosplenomegaly, lymphadenopathy, abnormal liver function, anemia, leukopenia, and thrombocytopenia. Although skin lesions are uncommon in histoplasmosis, patients with far-advanced HIV infection may present with one or more discrete erythematous skin papules. Diffuse pulmonary disease may be mistaken for *Pneumocystis* pneumonia in patients infected with HIV. HIV-infected patients responding to highly active antiretroviral therapy may experience a return of the symptoms of histoplasmosis as a result of immune reconstitution. Previously normal patients usually have a much more indolent disease that progresses over weeks or months. Disease tends to be more focal, with one or more indurated ulcers of the mouth, tongue, nose, or larynx in about one-fourth of cases. Other focal findings include granulomatous hepatitis, Addison’s disease, gastrointestinal ulcers, endocarditis, and chronic meningitis. Chest x-ray abnormalities are evident in half of cases and characteristically have a miliary pattern.

Infection with *H. capsulatum var. duboisii* is rare but should be considered in previous residents of Africa. Clinical manifestations resemble those of blastomycosis more than those of histoplasmosis in that skin and bone lesions are very common.

Presumed ocular histoplasmosis syndrome (POHS) is a clinical syndrome characterized by discrete atrophic choroidal scars in the macula or midperiphery, peripapillary atrophy, and choroidal neovascularization. These changes lead to a severe loss of central vision. It is unclear whether POHS represents an immune response to prior histoplasmosis, but there is no evidence of active infection. Susceptibility may be correlated with certain HLA types.

**DIAGNOSIS** Culture of the etiologic organism is the preferred method for diagnosis of histoplasmosis but is often difficult. Blood cultures are best performed by the lysis-centrifugation technique, with plates held at 30°C for at least 2 weeks. Approximately 15 mL of blood should be cultured from adults. Routine blood cultures in broth are generally unsuitable. Cultures of bone marrow, mucosal lesions, liver, and bronchoalveolar lavage fluid are diagnostically useful in disseminated histoplasmosis. Sputum culture is the preferred method for the diagnosis of chronic pulmonary histoplasmosis. However, growth may require 2 to 4 weeks to become visible, and other organisms may overgrow the plate. Diagnosis based on Giemsa-stained smears of blood or bronchoalveolar lavage fluid or on methenamine silver staining of infected lung, bone marrow, lymph node, or mucosal lesions requires considerable expertise, although these techniques yield results rapidly and provide specimens that can easily be sent to a referral laboratory. Organisms may be very scanty in lesions with marked caseous necrosis. An assay for *Histoplasma* antigen in blood or urine is commercially available and is useful both for diagnosis and for monitoring the response to therapy in patients with disseminated infection.
Antigen is detected occasionally in acute pulmonary histoplasmosis but rarely in chronic pulmonary disease. Diagnosis by antigen detection requires confirmation by culture or histopathology because false-positive results have occasionally been obtained. Tests for antibody to \textit{H. capsulatum} have been of limited value in diagnosis. Histoplasmin skin testing has proven useful in epidemiologic studies but is no longer commercially available.

**TREATMENT**

See also Table 183-1. Acute pulmonary histoplasmosis requires no therapy. Oral itraconazole (200 mg/d) can be given in the hope of shortening the course of illness, although this effect has not been proven. Patients with mediastinal fibrosis may benefit from vascular stent placement, but their ultimate prognosis is poor. All patients with disseminated or chronic pulmonary histoplasmosis should receive antifungal therapy. Intravenous amphotericin B (conventional or lipid formulation) is the drug of choice for the initial treatment of patients with disseminated histoplasmosis who are severely ill or immunosuppressed or whose infection involves the central nervous system; the regimen can be changed to itraconazole (200 mg twice daily) for life to prevent relapse. Lifelong maintenance therapy may not be necessary for HIV-infected patients who have received prolonged itraconazole treatment, have had a sustained response to highly active antiretroviral therapy, and no longer have detectable \textit{Histoplasma} antigen in serum.

Immunocompetent patients with disseminated or chronic pulmonary histoplasmosis are given itraconazole (200 mg twice daily) and are generally treated for 6 to 12 months. Alternatively, immunocompetent patients can be given a 10-week course of amphotericin B (0.5 mg/kg daily).

Long-term maintenance therapy with an azole is not recommended for patients other than those with AIDS. However, relapse of chronic pulmonary and disseminated histoplasmosis is not rare and warrants careful follow-up for 1 year after therapy.

\* Amphotericin B is given as 0.5 mg/kg daily for 10 to 12 weeks. Liposomal amphotericin B (3–5 mg/kg daily) can also be used. Itraconazole is given as 200 mg twice daily for 6 to 12 months except in AIDS patients, in whom therapy is lifelong.

**COCCIDIOIDOMYCOSIS**

**ETIOLOGIC AGENT** \textit{Coccidioides immitis} has two forms, growing as a white fluffy mold on most culture media but as a nonbudding spheroidal form (a sphere) in host tissue or under special conditions. Solely on the basis of DNA evidence, isolates from outside the San Joaquin Valley of California have been designated \textit{Coccidioides posadassi} by some authorities. \textit{C. immitis} reproduces in host tissue by forming small endospores within mature spherules. After rupture of the spherule, the released endospores enlarge, become spherules, and repeat the cycle. The fungus is identified by its appearance and by the formation of thick-walled, barrel-shaped spores, called \textit{arthrospores}, in the hyphae of the mold form. Nucleic acid hybridization is a highly accurate and relatively safe way to identify this biohazard level 3 fungus.

**EPIDEMIOLOGY, PATHOGENESIS, AND PATHOLOGY** \textit{C. immitis} is a soil saprophyte found in certain arid regions of the United States, Mexico, Central America, and South America. Within the United States, most cases of infection with \textit{C. immitis} are acquired in California, Arizona, and western Texas (Fig. 184-1). A few cases are acquired by exposure to spherules from endemic areas (e.g., in cotton bales). Use of \textit{C. immitis} by bioterrorists should be kept in mind should large outbreaks occur (Chap. 205).

Infection in humans and animals results from inhalation of wind-borne arthrospores from soil sites. This primary pulmonary infection is symptomatic in only 40% of cases, with symptoms ranging from a mild influenza-like illness to severe pneumonia. Mild self-limited infections may come to medical attention because of case clusters or outbreaks, or construction work. Windstorms can carry spores to adjacent nonendemic areas and cause case clusters. The usual course of primary pneumonia is complete healing, although an area of pneumonitis (detected on radiographs) may heal by the formation of a coin-like lesion called a \textit{coccidioidoma}. Less commonly, a single thin-walled cavity remains as a chronic sequela in the area of consolidation. Alternatively, an area of consolidation may persist as chronic pneumonia or progress to fibronodular cavitory disease.

Pleural effusion may be the only manifestation of primary infection. Spontaneous healing of this form is common.

An uncommon but dreaded complication of coccidioidomycosis is dissemination beyond the lung and hilar lymph nodes. Dissemination is especially frequent among blacks, Filipinos, Native Americans, Mexican Americans, pregnant women, and immunosuppressed patients, including those with AIDS.

\textit{C. immitis} incites a chronic pyogranuloma in host tissue, often with areas of caseation necrosis. Lung and hilar node lesions may show...
calcification. Both IgM and IgG antibodies to *C. immitis* are induced by infection, but neither type of antibody appears to be protective. The amount of specific IgG antibody is a rough measure of the antigenic mass (i.e., of the intensity of infection), and a high titer is a poor prognostic sign. Appearance of delayed hypersensitivity to antigens of *C. immitis* is most common in clinical forms of disease with a good prognosis, such as self-limited primary pulmonary disease.

**CLINICAL MANIFESTATIONS** Symptomatic primary pulmonary infection begins 10 to 14 days after exposure and is manifested by fever, cough, chest pain, malaise, and sometimes the hypersensitivity reactions listed above. Chest radiographs may show an infiltrate, hilar adenopathy, or pleural effusion. Mild peripheral-blood eosinophilia may be found. Spontaneous improvement begins after several days to 2 weeks of illness and usually culminates in complete recovery.

The symptoms of a chronic thin-walled cavity include cough or hemoptysis in half of cases; the other half are asymptomatic. The cavity contracts to a nodule during the first year in about half of cases. Chronic fibrocavitary pulmonary coccidioidomycosis causes cough, sputum production, variable degrees of fever, and weight loss. The first indications of dissemination usually appear during primary infection. Reactivation with dissemination in later years occurs occasionally, especially if Hodgkin’s disease, non-Hodgkin’s lymphoma, renal transplantation, AIDS, or immunosuppression of some other etiology has supervened. Dissemination should be suspected when fever, malaise, hilar or paratracheal lymphadenopathy, elevated sedimentation rate, and high complement fixation titers signal abnormal persistence in patients with primary pulmonary coccidioidomycosis. With time, lesions appear in the bone, skin, subcutaneous tissue, menses, joints, and other sites. Chronic meningitis presents as headache of indolent onset, with or without other signs of disseminated coccidioidomycosis. Cultures and smears of cerebrospinal fluid (CSF) are most often negative, but antibody is usually detectable in CSF by complement fixation. Skin lesions are indolent and maculopapular. Soft tissue and bony lesions contain pus and may present as a draining sinus. Without treatment, disseminated coccidioidomycosis progresses to death over weeks to years.

Disseminated coccidioidomycosis can progress rapidly in patients with advanced HIV infection. Fever with skin or bone lesions may be the first sign. Those who present with diffuse pulmonary infiltrates have a poor prognosis. Blood cultures are positive late in the disease, if at all.

**DIAGNOSIS** When coccidioidomycosis is suspected, sputum, urine, and pus should be examined for *C. immitis* by wet smear and culture. The laboratory request should indicate clearly that coccidioidomycosis is suspected, because the mold form must be handled with extreme care to prevent infection of laboratory personnel. On biopsy, smaller spherules must be distinguished from nonbudding forms of * Blastomyces* and *Cryptococcus*, but the appearance of the mature spherule is diagnostic.

Serologic tests are very helpful in the diagnosis of coccidioidomycosis. Latex agglutination and agar gel diffusion tests are useful in screening sera for antibody to *Coccidioides*. The complement fixation test is used for CSF determinations and for the confirmation and quantitation of serum antibody detected by screening tests.

The number of cases with a positive complement fixation test depends on the severity of disease and on the laboratory performing the test. Positive tests are least common among patients with solitary pulmonary cavities or primary pulmonary infection, while sera from patients with disseminated disease in multiple organs are nearly all positive. Seroconversion is helpful in diagnosing primary pulmonary coccidioidomycosis but may not occur for up to 8 weeks after onset. A positive complement fixation test of unconcentrated CSF is diagnostic of meningitis. Rarely, a paratricular focus causes a positive complement fixation test of CSF.

Conversion of the skin test from negative to positive (≥5 mm of induration at 24 or 48 h) with spherulin may take place between days 3 and 21 of symptoms in primary pulmonary coccidioidomycosis. Spherulin is not currently available commercially, but skin testing can be helpful in epidemiologic studies, such as investigations of case clusters or the definition of endemic areas. The utility of skin testing as a diagnostic tool is limited by the persistence of positive tests resulting from remote exposures to *Coccidioides* and by the frequency of negative skin tests among patients with either thin-walled cavities or disseminated coccidioidomycosis. A positive skin test has not predicted dissemination in HIV-infected patients. The presence of complement-fixing antibody to *C. immitis* in AIDS patients should prompt a search for active infection.

**TREATMENT**

See also Table 184–1. Primary pulmonary coccidioidomycosis usually resolves spontaneously. Some physicians give a few weeks of treatment with intravenous amphotericin B followed by oral itracona-

1. Itraconazole is given as 200 mg twice daily by mouth and fluconazole as 400 mg/d by mouth.
2. Amphotericin B is given as 0.5–0.7 mg/kg daily or as a lipid formulation (5 mg/kg daily).
3. Risk factors include HIV infection, organ transplantation, treatment with high-dose glucocorticoids, and pregnancy.
4. The optimal duration of therapy for disseminated infection is unclear but should probably be lifelong in both immunocompetent and immunocompromised patients.
5. Patients in whom fluconazole therapy fails at the 400-mg dose may be advanced to 600 or 800 mg daily. Lifelong therapy for meningitis is recommended.
azole or fluconazole to patients with unusually severe or protracted primary infection in the hope of aborting disseminated or chronic pulmonary disease. Solitary pulmonary cavities that do not close spontaneously over the first year can be excised electively, particularly if complicated by hemoptysis or recurrent bacterial infection. Response to systemic antifungal therapy is poor.

Patients with severe or rapidly progressing disseminated coccidioidomycosis are first given intravenous amphotericin B at a dose of 0.5 to 0.7 mg/kg daily. Patients whose condition improves after 2 to 3 months of amphotericin B treatment or who have more indolent disseminated infection are given itraconazole (200 mg twice daily) or fluconazole (400 mg/d). These oral agents are useful for long-term suppression of infection, and treatment should be continued for years. Patients with coccidioidal meningitis usually are initially given fluconazole (400 to 800 mg/d) but may require intrathecal amphotericin B. Hydrocephalus is a frequent complication of uncontrollable meningitis. Surgical debridement of bone lesions or drainage of abscesses can be helpful. The prognosis for ultimate cure of disseminated coccidioidomycosis is guarded.

**DIAGNOSIS** Infection may be confirmed by the presence of the fungus in a culture of sputum, pus, or urine. An expert can identify the fungus in a culture of sputum, pus, or urine. An expert can identify the fungus in a culture of sputum, pus, or urine. An expert can identify the fungus in a culture of sputum, pus, or urine.

**EPIDEMIOLOGY** The infection is restricted by geography and age. Blastomycosis is uncommon in any locality, but most cases occur in the southeastern, central, and mid-Atlantic areas of the United States and in the Canadian provinces of Ontario and Manitoba. In Florida, Kentucky, Arkansas, Tennessee, North Carolina, Wisconsin, and Illinois typically report the most cases. Cases have also been encountered in Africa, Mexico, Central America, and (rarely) South America. Most patients are between 20 and 69 years old. The male-to-female ratio is about 10:1. There is no occupational predisposition to the development of blastomycosis.

**PATHOGENESIS AND PATHOLOGY** Infection with *B. dermatitidis* appears to be acquired by inhalation of the fungus from soil, decomposed vegetation, or rotting wood. Several case clusters have resulted from participation in recreational activities in wooded areas along waterways. Infection is not transmissible from person to person. The initial pulmonary infection may either heal spontaneously or become chronic. Spread to other portions of the lung, cavitation, or endobronchial lesions may be found in patients with chronic disease. Whether or not the lung lesion resolves spontaneously, infection commonly spreads hematogenously to the skin, subcutaneous tissue, bone, prostate, epidiymis, or mucosa of the nose, mouth, or larynx. Less commonly, infection spreads to the brain, meninges, liver, lymph nodes, or spleen. Dissemination may not be evident for weeks or years after the appearance of the lung lesion. Progressive infection is only rarely attributable to an underlying disease, to HIV infection, or to immunosuppressive treatment. The inflammatory response includes lymphocytes, giant cells, and neutrophils. Pseudoepitheliomatous hyperplasia may be striking and may lead to a mistaken diagnosis of squamous cell carcinoma of the skin, lung, or larynx.

Resection of chronic progressive pulmonary lesions is a helpful adjunct to chemotherapy when infection is confined to the lung and to one lobe.

**FURTHER READING**

**CLINICAL MANIFESTATIONS** A few patients have acute, self-limited pneumonia. Fever, productive cough, myalgia, and malaise usually resolve within a month. Pulmonary infiltrates clear slowly as *B. dermatitidis* disappears from the sputum.

In the vast majority of patients, blastomycosis has an indolent onset and a chronically progressive course. Fever, cough, weight loss, lasitute, skin lesions, and chest ache are common. Skin lesions favor exposed areas and enlarge over many weeks from pimplles to well-circumscribed, verrucous, crusted, or ulcerated lesions. Pain and regional lymphadenopathy are minimal. Large chronic lesions may undergo central healing with scarring and contracture. Mucous membrane and laryngeal lesions present as an indurated, nontender, sharply circumscribed hypertrophic plaque, often mistaken for squamous cell carcinoma. Chest x-ray findings are abnormal in two-thirds of patients, with one or more densely consolidated areas of pneumonia or nodular infiltrates that occasionally include areas of cavitation. Pleural thickening or small pleural effusions develop occasionally, but large pleural effusions are rare, as is calcification of the lung or hilar nodes. Patients may present with an acute respiratory distress syndrome (ARDS), although indolent symptoms usually precede this syndrome. The lungs of ARDS patients are filled with myriad organisms, and the patient often dies within a few days of admission to the hospital. Calcification, hilar adenopathy, and large pleural effusions are rare. Osteolytic lesions occur in one-fourth of patients and may involve nearly any bone. Osseous lesions, which appear radiologically as circumscribed osteolytic areas, present clinically as a cold abscess or a draining sinus or extend to a contiguous joint and cause an indolent arthritis yielding pus on aspiration. Prostatic and epididymal lesions present as an indurated nontender mass. Hydrocele or a draining sinus may accompany blastomycotic epididymitis.

**DIAGNOSIS** The diagnosis of blastomycosis is made by demonstration of the fungus in a culture of sputum, pus, or urine. An expert can diagnose blastomycosis by the appearance of the organism in wet smear or histopathologic section. The fungus may be visible in a spumt cytology smear but is easily overlooked.

**TREATMENT** See Also Table 185-1. A few patients have developed only transitory lung lesions, but no guidelines are known to distinguish these patients from those whose disease will progress locally or disseminate. Therefore, every patient should receive treatment. Intravenous amphotericin B is the drug of choice for patients with rapidly progressive infections, severe illness, or central nervous system lesions. Because the clinical...
response to amphotericin B is more rapid than that to an azole, intravenous itraconazole is less appropriate. However, therapy may be switched to itraconazole when the patient’s condition stabilizes. Skin and noncavitary lung lesions should be treated for about 8 to 10 weeks when amphotericin B alone is used. The recommended total dose for an adult is ~2 g. Cavity lung disease or infection extending beyond the lung and skin is more likely to relapse after 10 weeks of amphotericin B administration at this total dose; thus it should be treated for about 10 to 12 weeks with a total dose of ≥2.5 g, or the patient should be switched to itraconazole for prolonged therapy. Experience with lipid amphotericin B formulations is limited, but they are likely to prove effective.

Oral itraconazole (200 mg daily with food) is the drug of choice for the treatment of patients who have indolent nonmeningeal blastomycosis of mild to moderate severity and who take the drug reliably. Therapy with itraconazole is continued for 6 to 12 months, whether given initially or after a short course of amphotericin B. HIV-infected patients should probably receive lifelong therapy, but relevant experience is limited. Fluconazole is less effective than itraconazole; however, because of its good penetration into the central nervous system, treatment with 400 to 800 mg daily may be considered to follow amphotericin B therapy in CNS blastomycosis. The mortality rate in appropriately treated cases of blastomycosis is ≤15% but exceeds 50% in cases presenting as ARDS.

**CRYPTOCOCCOSIS**

**Etiologic Agent** Cryptococcosis is an infection caused by the yeastlike fungus *Cryptococcus neoformans*. This fungus reproduces by budding and forms round, yeastlike cells. Within the host and on certain culture media, a large polysaccharide capsule surrounds each yeast cell. The fungus grows well in smooth, creamy-white colonies on Sabouraud’s or other simple media at 20° to 37°C. Identification of the organism is based on gross and microscopic appearance, biochemical test results, and growth at 37°C. The results of nucleic acid hybridization or the formation of brown pigment on Niger seed agar can also be used for identification.

The fungus has four capsular serotypes, designated A, B, C, and D. There are also two mating types. Coculture of opposite mating types creates a transient diploid state called *Filobasidiella neoformans* var. *neoformans* for serotypes A and D and *F. neoformans* var. *bacillispora* for serotypes B and C. Organisms not cultured under mating conditions are designated *C. neoformans* var. *neoformans* for serotypes A and D and *C. neoformans* var. *gattii* for serotypes B and C; a simple color medium distinguishes the two varieties. Some authorities have called serotype A *C. neoformans* var. *grubii*.

**Epidemiology** Weathered pigeon droppings commonly contain serotype A or D ( *C. neoformans* var. *neoformans*). *C. neoformans* var. *gattii* has been isolated from the litter around trees of the species *Eucalyptus camaldulensis* and *E. tereticornis*. Eucalyptus isolates have so far typed as serotype B. The distribution of these eucalyptus species in Australia corresponds to the distribution of infections due to *C. neoformans* var. *gattii* in that country. The high prevalence of these trees in other subtropical climates has been postulated to explain the relative restriction of such infections to warm climates. A notable exception is the cluster of clinical cases and environmental isolates not from eucalyptus trees on the eastern coast of Vancouver Island in British Columbia, Canada.

The most common predisposing factor to cryptococcosis worldwide is currently AIDS. CD4+ cell counts are usually below 200/μL in AIDS patients who develop cryptococcal infection. The incidence of cryptococcosis has been declining in the United States since the advent of highly active antiretroviral therapy (HAART). More than half of non-AIDS patients with cryptococcosis have been receiving glucocorticoids or other immunosuppressive drugs prior to the onset of the fungal infection. Solid organ transplantation, lymphoma, sarcoidosis, and idiopathic CD4+ lymphocytopenia also predispose to infection by *C. neoformans* var. *neoformans*. Most infections in immunocompromised patients are caused by serotype A, although serotype D occurs in up to 20% of cases in Western Europe. Infections with var. *gattii* have been rare among AIDS patients and other immunocompromised patients, even in subtropical climates where var. *gattii* infection occurs in previously healthy individuals.

Animals, particularly cats, can acquire cryptococcosis but have not been known to transmit the infection to other animals or to humans. The source from which humans acquire the infection is unknown, with the rare exception of cases acquired through a transplanted cornea, kidney, or other solid organ. Cryptococcosis is rare before puberty.

**Pathogenesis and Pathology** Cryptococcal infection is thought to be acquired by inhalation of the fungus into the lungs, although rare cases of cutaneous cryptococcosis appear to arise by minor trauma. Pulmonary infection has a tendency toward spontaneous resolution and is frequently asymptomatic. Silent hematogenous spread to the brain leads to clusters of cryptococci in the perivascular areas of cortical gray matter, in the basal ganglia, and, to a lesser extent, in other areas of the central nervous system. The inflammatory response around these foci is usually scant. In the more chronic cases, a dense basilar arachnoidal duralis is typical. Lung lesions are characterized by intense granulomatous inflammation. Cryptococci are best seen in tissue by staining

CLINICAL MANIFESTATIONS Most patients have meningococcal meningitis at the time of diagnosis. This form of cryptococcosis is invariably fatal without appropriate therapy; death occurs anytime from 2 weeks to several years after the onset of symptoms. Early manifestations include headache, nausea, staggering gait, dementia, irritability, confusion, and blurred vision. Both fever and nuchal rigidity are often mild or lacking. Papilledema is evident in one-third of cases at the time of diagnosis. Rapid and permanent loss of vision may occur, leaving a central scotoma or optic atrophy. Cranial nerve palsies, typically asymmetric, occur in about one-fourth of cases. Other lateralized signs are rare. With progression of the infection, deepening coma and signs of brainstem compression appear. Autopsy often reveals cerebral edema in more acute cases and hydrocephalus in more chronic cases. Neuroimaging is most often normal. Focal lesions called cryptococcomas are more common in previously normal patients, particularly those with var. gattii infections, than in immunosuppressed patients. These lesions are commonly located in the basal ganglia or the head of the caudate nucleus. Cryptococcomas are best seen on magnetic resonance imaging (MRI) with T2 or FLARE imaging and gadolinium enhancement. Edema around the mass disappears with successful therapy, but the cryptococcoma can persist for years.

Pulmonary cryptococcosis causes chest pain in ~40% of patients and cough in ~20%. Fever is modest or absent. The chest x-ray shows one or more dense infiltrates, which are often well circumscibed. Cavititation, pleural effusions, and hilar adenopathy are infrequent. Calcification is not evident, and fibrotic stranding is rarely noticeable.

Some 10% of patients with cryptococcosis have skin lesions, and the vast majority of patients with skin lesions have disseminated infection (Fig. 186-1). One or a few asymptomatic tiny papular lesions appear and slowly enlarge; they display a tendency toward central softening leading to ulceration. Osteolytic lesions occur in 4% of cases and usually present as a cold abscess. Rare manifestations of cryptococcosis include prostatitis, endophthalmitis, hepatitis, pericarditis, endocarditis, and renal abscesses.

Cryptococcosis in AIDS patients is notable for the relative paucity of symptoms and signs, even in severe disease. Headache is present in ~90% of cases and fever in ~75%. Blurred vision, cranial nerve palsies, lethargy, and confusion signal advanced infection. Cerebrospinal fluid (CSF) abnormalities in protein and glucose levels and in cell count are modest (see “Diagnosis”). A CSF leukocyte count of <10/µL and an opening pressure of >250 mm H2O are bad prognostic signs. Immune reconstitution during a response to HAART can lead to a return of fever and headache, suppuration of mediastinal lymph nodes, or meningeal enhancement on MRI.

DIAGNOSIS Fever and headache in a patient with AIDS or with risk factors for HIV infection suggest the possibility of cryptococcosis, toxoplasmosis, or central nervous system lymphoma. Evidence of a focal lesion on MRI is unusual in cryptococcosis. Most cryptococcal cerebral mass lesions occur in patients infected with C. neoformans var. gattii who also have meningitis. In patients without AIDS, meningitis due to C. neoformans resembles that due to Mycobacterium tuberculosis, Histoplasma capsulatum, Coccioidiodes immitis, or metastatic cancer. Lumbar puncture is the single most useful diagnostic test. An India ink smear of centrifuged CSF sediment reveals encapsulated yeast in more than half of cases, although artifacts can cause confusion. In patients without AIDS, levels of glucose in CSF are reduced in half of all cases; protein levels are usually increased; and lymphocytic pleocytosis is usually found. CSF abnormalities are less pronounced in patients with AIDS, although India ink smear and serum antigen tests are more often positive.

Approximately 90% of patients with cryptococcal meningoencephalitis, including all those with a positive CSF smear and nearly all AIDS patients, have capsular antigen detectable in CSF or serum by latex agglutination. An enzyme immunoassay for cryptococcal antigen does not offer useful quantitative results but more clearly establishes positivity. Occasional false-positive results in both antigen tests make culture the definitive diagnostic test and have prevented serum antigen from being a useful screening test in asymptomatic patients with AIDS. Testing for serum antigen in AIDS patients with headache or fever is helpful. C. neoformans can often be cultured from the urine of patients with meningoencephalitis. fungemia occurs in 10 to 30% of non-AIDS patients and in 60% of AIDS patients.

Pulmonary cryptococcosis appears on computed tomography (CT) as nodules with smooth or relatively undefined margins and homogeneous attenuation. In rare instances, ground-glass opacification is seen. Sputum culture is positive in only 10% of cases, and serum antigen tests are positive in only one-third. Occasionally, C. neoformans appears in one or more sputum specimens as an endobronchial saprophyte. Biopsy is usually required for diagnosis.

Cutaneous cryptococcosis may be mistaken for a comedo, basal cell carcinoma, or sarcoidosis. In patients with AIDS, skin lesions may be numerous and are sometimes mistaken for molluscum contagiosum (as shown for a liver transplant recipient in Fig. 186-1). Biopsy reveals myriad cryptococci. Osseous cryptococcosis is diagnosed by examination of bone or an adjacent soft tissue abscess.

**TREATMENT**

See also Table 186-1. Patients with AIDS and cryptococcosis are treated initially with intravenous amphotericin B (0.7 to 1.0 mg/kg daily) for at least 2 weeks and until their clinical condition is stable; thereafter, they receive fluconazole. The addition of flucytosine (25 mg/kg every 6 h) to amphotericin B for 2 weeks has minimal impact on morbidity and mortality. After treatment with amphotericin B, fluconazole (400 mg) is given once daily; daily doses of 800 mg have been used with marginal changes in toxicity or efficacy. The addition of flucytosine to fluconazole increases gastrointestinal intolerance. Serum and CSF antigen have not been helpful in determining the efficacy of therapy, but CSF cultures should convert to negative. After at least 10 weeks of treatment and when the patient is asymptomatic, treatment with fluconazole (200 mg/d) is continued indefinitely. Itraconazole is less effective than fluconazole in cryptococcal meningitis but can be used. Patients with incapacitating symptoms of immune reconstitution improve with glucocorticoid therapy; it is unclear whether amphotericin B should be restarted until the glucocorticoid dose has been ta-
pered. AIDS patients who have negative antigen and fungal cultures of CSF after prolonged fluconazole treatment and who have a sustained (≥6-month) CD4+ response to HAART (with counts of at least 100 to 200/μL) may be candidates for discontinuation of maintenance therapy. Should CD4+ cell counts fall again, resumption of maintenance therapy would be reasonable.

In patients without AIDS, the therapeutic goal is to cure cryptococcal meningitis, not merely to control its symptoms. A single intensive course of amphotericin B is given for at least 10 weeks until cultures from all previously positive sites (particularly CSF) become convincingly negative. Normalization of the glucose level in lumbar CSF is important. The CSF antigen titer should fall by the end of therapy, but complete clearance of CSF or serum antigen during therapy is not essential. Amphotericin B (0.6 to 0.7 mg/kg daily for 10 weeks) is the best-studied regimen, but liposomal amphotericin B (4 to 5 mg/kg daily) is probably equivalent. Amphotericin B lipid complex and amphotericin B colloidal dispersion are not recommended pending further study. Fluconosine has been added to amphotericin B to accelerate the culture response, but grave toxicity can result unless fluconosine blood levels are kept below 100 μg/mL. Fluconazone (400 mg daily), given initially or begun after a course of amphotericin B, has cured cryptococcal meningitis or pulmonary cryptococcosis in some less immunosuppressed patients. Useful parameters for deciding when to discontinue therapy are unknown, but culture conversion, normalization of CSF glucose levels, and a fall in CSF antigen titer are minimal end points. A 6- to 12-month course of treatment is often used. Routine follow-up CSF cultures for the next year are useful in detecting relapse before symptoms supervene. Lung lesions on CT may take 6 weeks to improve and many months to resolve, if they ever do. Some immunosuppressed patients are treated as described above for AIDS patients, with indefinite fluconazole maintenance therapy.

Hydrocephalus may be the presenting manifestation or a later complication of cryptococcosis. Blindness, dementia, and personality change are among the other sequelae. Cerebral edema (in the absence of a cryptococcoma) causing headache, confusion, or blurred vision should be treated by daily lumbar puncture or CSF shunting to avert blindness. The shunt does not act as a nidus of persistent infection.

* CSF culture should be negative, antigen titer falling, and glucose level normal.

**PROPHYLAXIS** Fluconazone (200 mg/d) has been shown to decrease the incidence of cryptococcosis in HIV-infected patients with CD4+ cell counts of <200/μL and particularly in those with counts of <50/μL. Weekly fluconazone has not provided this protection. Daily fluconazone has not conferred a survival advantage; in light of its cost and the currently low incidence of cryptococcosis in patients with AIDS in the United States, prophylaxis is strongly discouraged.

LILJANG P et al: Use of ventriculoperitoneal shunts to treat uncontrollable intracranial hypertension in patients who have cryptococcal meningitis without hydrocephalus. Clin Infect Dis 34:E64, 2002

**ETIOLOGIC AGENTS** *Candida albicans* is the most common cause of mucosal candidiasis and is responsible for about half of all cases of candidemia in hospitalized patients. A small proportion of isolates previously identified as *C. albicans* have been transferred to a new species, *C. dubliniensis*. *C. tropicalis*, *C. parapsilosis*, *C. guilliermondii*, *C. glabrata* (formerly *Torulopsis glabrata*), *C. krusei*, and a few other *Candida* species account for the other half of candidemia cases; all can cause potentially lethal septic shock. The majority of these non-*albicans* species enter the bloodstream through intravascular catheters. *Candida* species, taken together, are the fourth or fifth most common cause of nosocomial bloodstream infections in the United States.

All *Candida* species pathogenic for humans are also encountered as commensals of humans, particularly in the mouth, stool, and vagina. These species grow rapidly at 25° to 37°C on simple media as oval, budding cells. In tissue, both yeasts and pseudohyphae are present. The latter are elongated branching structures with constrictions at the septae. Budding yeasts may be seen as separate structures or as projections from pseudohyphae. *C. glabrata* differs from other members of the genus in that it forms no true hyphae or pseudohyphae in vitro or in infected tissue. *C. albicans* and *C. dubliniensis* can be identified preliminarily by their ability to form germ tubes in serum—a test that requires only a few hours. These two species can be more accurately identified by the formation in special culture medium of thick-walled large spores called *chlamydospores*. Culture media now available for primary inoculation allow preliminary identification of *Candida* species by colony color. Accurate identification of *Candida* species other than *C. albicans* requires biochemical tests.

**PATHOGENESIS** Deeply invasive candidiasis is often preceded by increased colonization of the mouth, vagina, and stool with *Candida* due to broad-spectrum antibiotic therapy. Additional local and systemic factors favor infection. Oropharyngeal thrush is particularly likely to occur in neonates and in patients with diabetes mellitus, HIV infection, or dentures. Vulvovaginal candidiasis (Chap. 115) is especially common in the third trimester of pregnancy. *Candida* from the perineum can enter the urinary tract via an indwelling bladder catheter. Cuta-
neous candidiasis most often involves macerated skin, such as that in the diapered area of infants, under pendulous breasts, or on hands constantly in water or covered by occlusive gloves. *Candida* can pass from the colonized surface into deep tissue when the integrity of the mucosa or skin is violated, as, for example, by perforation of the gastrointestinal tract through trauma, surgery, or peptic ulceration or by mucosal damage due to cytotoxic agents used for cancer chemotherapy. Although *Candida* is not normally a resident of the skin, secretions from the mouth, rectum, or vagina as well as drainage from surgical wounds or tracheostomy sites can contaminate the hub or skin site of a catheter in an umbilical or central vein. Intravenous drug abuse or third-degree burns can also provide a skin portal for *Candida* that can lead to deep candidiasis. Once *Candida* has passed the integumentary barrier, very low birth weight (in neonates) and neutropenia can lead to deep candidiasis. Once *Candida* becomes increasingly common late in disease as the CD4 count falls. At CD4+ counts of <50/μL, esophageal thrush also becomes common. HIV infection appears not to be an independent risk factor for vulvovaginal thrush.

**Cutaneous candidiasis** presents as red macerated intertriginous areas, paronychia, balanitis, or pruritus ani. Candidiasis of the perineal and scrotal skin may be accompanied by discrete pustular lesions on the inner aspects of the thighs. **Chronic mucocutaneous candidiasis** (**CMC**) or *candidal granuloma* typically presents as circumscribed hyperkeratotic skin lesions, crumbling dystrophic nails, partial alopecia in areas of scalp lesions, and both oral and vaginal thrush. Other findings may include chronic ringworm, dental dysplasia, and hypoplasia of the parathyroid, adrenal, or thyroid gland. CMC is a major component of the immune polyendocrinopathy syndrome caused by a mutation in the autoimmune regulator gene (**AIR**E) on chromosome 21q22.3 (Chap. 330). CMC can begin in childhood as an autosomal dominant or recessive disorder or in association with Job’s syndrome and can occur in adults in association with thymoma. Systemic infection is very rare in CMC, but permanent alopecia and disfigurement of the face and hands can be severe. Vulvovaginal thrush (Chap. 115) causes pruritus, discharge, and sometimes pain on intercourse or urination. Speculum examination reveals an inflamed mucosa and a thin exudate, often with white curds. Excessive colonization of the gastrointestinal tract has been associated with diarrhea and with chronic fatigue syndrome, but the linkage is unconvincing.

**Esophageal candidiasis** is often asymptomatic but can cause substernal pain or a sense of obstruction on swallowing. The pain of esophageal candidiasis may be mistaken for pain of cardiac origin. Most lesions are in the distal third of the esophagus and appear on endoscopy as areas of redness and edema, focal white patches, or ulcers. Biopsy or brushing is required for diagnosis and for detection of concomitant infections, particularly herpes simplex in patients with hematologic malignancies and cytomegalovirus infection in AIDS patients. *Candida* esophagitis can cause bleeding and impaired alimentation. Hematogenous dissemination from the esophagus probably occurs in some neutropenic patients but is rarely reported in HIV-infected patients.

**Deeply Invasive Candidiasis** In the obstructed urinary tract, *Candida* can cause cystitis, pyelitis, or renal papillary necrosis. When a colonized urinary tract is grafted or instrumented, candidemia may result. However, most patients with *Candida* cultured from the urine simply have bladder colonization from a Foley catheter or a sizable volume of residual urine. Contamination of a voided midstream specimen by vaginal *Candida* is also common.

*Candidemia* originating from an intravascular catheter may clear in the immunocompetent patient when the catheter is removed. Focal seeding of the retina can take place even if candidemia clears and the patient becomes afibrile. Unilateral or bilateral small white retinal exudates appear within 2 weeks of the onset of candidemia. Lesions may regress spontaneously or enlarge slowly. The vitreous humor becomes cloudy, and the patient notices blurring, ocular pain, or a sco- toma. Retinal detachment, vitreous abscess, and extension to the anterior chamber can occur over the ensuing weeks. These retinal lesions, present in ∼10% of nonneutropenic patients with candidemia, are the principal reason that systemic antifungal therapy is recommended for all patients with candidemia. Funduscopy should be performed to ensure that retinal lesions, if present, resolve completely. Most cases with ocular involvement have occurred in nonneutropenic patients. In contrast, so-called *hepatosplenic candidiasis* is usually recognized in patients with acute leukemia who are recovering from profound neutropenia. This entity, better called *chronic disseminated candidiasis*, originates from intestinal seeding of the portal and venous circulation. Fever, modestly elevated serum concentrations of alkaline phosphatase, and multiple small abscesses evident on ultrasonography, magnetic resonance imaging, or computed tomography (CT) of the liver, spleen, or kidney suggest the diagnosis. During acute candidemia in neutropenic patients, small erythematous papules may appear anywhere on the skin (Fig. 187-1). If the patient does not expire promptly from disseminated candidiasis, the lesions will develop a necrotic center. Painful muscle lesions may also be found. Punch biopsy of a skin lesion helps distinguish this extremely grave condition from *Malassezia* folliculitis, a similar-appearing but benign condition that can involve the cape area of the chest or the extremities of a sweaty febrile patient.

Hematogenous seeding in the neutropenic patient is occasionally visible radiologically as tiny pulmonary nodules. *Candida pneumonia*, apart from hematogenous candidiasis, is very rare. *Candida endocarditis* can be caused by any *Candida* species and favors previously damaged or prothetic heart valves. The source is often an intravascular catheter or contaminated equipment used for illicit intravenous drug injection. An interval of weeks or even months between candidemia and discovery of endocarditis is common. Emboli to large arteries, such as the iliac or femoral artery, are characteristic. Intravenous injection of impure brown heroin has caused a clinical syndrome consisting of *Candida endophthalmitis* and purulent folliculitis, sometimes accompanied by vertebral osteomyelitis.

*Candida* can cause indolent arthritis, most commonly of the knee, in patients who have received glucocorticoid injections into the joint, in patients who are immunosuppressed, and in low-birth-weight neonates. Prosthetic joints may become infected during implantation. Scanty growth of *Candida* from joint fluid can cause the laboratory to
incorrectly dismiss the organism as a contaminant. *Candida* can cause subacute *peritonitis* arising either from a perforated viscus or from a peritoneal dialysis catheter.

Hematogenous dissemination can lead to *brain abscess* or chronic *meningitis*. Diagnosis of infections of ventriculoperitoneal shunts is difficult because symptoms are indolent and cultures of lumbar fluid are usually sterile.

**DIAGNOSIS** Demonstration of pseudohyphae on wet smear with confirmation by culture is the procedure of choice for diagnosing superficial candidiasis. Scrapings for the smear may be obtained from skin, nails, and oral and vaginal mucosa. A culture of urine, sputum, existing abdominal drains, endotracheal aspirates, or the vagina is not diagnostic; however, recovery of *Candida* species from multiple superficial sites has been identified as a risk factor for deeply invasive candidiasis in some patients with prolonged neutropenia or complicated abdominal surgery.

Deeper lesions due to *Candida* may be diagnosed by histologic section of biopsies or by culture of cerebrospinal fluid, blood, joint fluid, CT-guided needle aspirates, or surgical specimens. Blood cultures are useful in the diagnosis of *Candida* endocarditis and intra-abdominal sepsis but are positive less often in other forms of disseminated disease. Serologic tests for antibody or antigen are not useful.

**TREATMENT**

(See also Table 187-1.) Cutaneous candidiasis of macerated areas responds to measures that reduce moisture and chafing plus topical application of an antifungal agent in a nonocclusive base. Nystatin powder or a cream containing ciclopirox or an azole is useful. Clotrimazole, miconazole, econazole, ketoconazole, sulconazole, and oxiconazole are available as creams or lotions. *Candida* vulvovaginitis responds better to an azole than to nystatin suppositories. There is little difference in efficacy among miconazole, clotrimazole, tocosnazole, butoconazole, and terconazole vaginal formulations. Systemic treatment of *Candida* vulvovaginitis with a single 150-mg capsule of fluconazole is more convenient than topical treatment; however, this option is contraindicated in pregnancy, is less effective in patients with multiple relapses, and poses a higher risk of adverse effects. Clotrimazole troches, used five times a day, are more effective in oral candidiasis than nystatin suspension and are approximately as effective as oral fluconazole (100 mg daily). Oral fluconazole (100 to 200 mg once daily) is more convenient and more effective in esophagitis than clotrimazole troches. Esophagitis not responding to fluconazole may warrant repeat endoscopy to exclude other conditions. Itraconazole suspension (100 mg twice daily) alleviates *Candida* esophagitis in some patients in whom fluconazole treatment fails. Nearly all patients with azole-resistant oropharyngeal or esophageal candidiasis respond to a 2-week course of intravenous amphotericin B (0.3 to 0.5 mg/kg daily) or caspofungin (70 mg for one dose, then 50 mg daily). Relapse is usual.

Management of recurrent oropharyngeal candidiasis in the HIV-infected patient presents special problems. Patients with CD4 + cell counts of <100/μL who have received prolonged fluconazole therapy are at risk of developing azole resistance, requiring an increased dose to mount a response, relapsing early, and eventually failing to respond well to any dose of fluconazole. The increasing azole resistance in this population suggests that HIV-infected patients with oropharyngeal or esophageal candidiasis should be treated for each individual episode and that only when episodes become intolerably frequent or severe should prophylaxis be given.

Bladder thrush responds to bladder irrigations with amphotericin B (50 μg/mL for 5 days). If no bladder catheter is in place, oral fluconazole can be used to control candiduria. Most patients with candiduria do not have unrelieved urinary tract obstruction and do not benefit from therapy.

Intravenous amphotericin B is the drug of choice for deeply invasive candidiasis in neutropenic or seriously immunosuppressed patients. The deoxycholate formulation is usually given at a dosage of 0.5 to 0.7 mg/kg daily. Open, noncomparative studies of amphotericin B lipid complex and liposomal amphotericin B indicate that either preparation is effective in deeply invasive candidiasis. The usual dose of either formulation is 5 mg/kg daily by the intravenous route.

*Candida* endocarditis on prosthetic or native valves usually relapses unless the valve is replaced. Long-term fluconazole administration has been used to prevent recurrence after valve replacement.

In immunocompetent patients with intravenous catheter–acquired *C. albicans* fungemia, the catheter should be removed in conjunction with the administration of fluconazole (400 mg/d), amphotericin B (0.5 mg/kg daily), or caspofungin (one 70-mg dose followed by 50 mg daily by the intravenous route). Amphotericin B (0.7 to 1.0 mg/kg daily) may be appropriate as initial therapy in severely neutropenic patients. Candidemia from suppurative phlebitis of a peripheral vein may not respond until the infected portion of the vein is excised. Therapy for candidemia is continued for 2 weeks after the patient becomes afebrile. The *Candida* species involved should be considered in choosing a drug for candidemia. *C. krusei* and *C. inconspicua* are rare causes of candidemia but are resistant to fluconazole in vitro. *C. glabrata* exhibits intermediate susceptibility to fluconazole. Thus either increasing the daily fluconazole dose to 800 mg or using amphotericin B or caspofungin may be appropriate. Caspofungin displays approximately equal activity in vitro against all *Candida* species, including azole-resistant strains. Strains of *C. lusitaniae* resistant to amphotericin B but susceptible to azoles or caspofungin have been encountered. Intravenous amphotericin B, with or without fluconazole, is the preferred treatment for *Candida* endophthalmitis, although cures have been reported with fluconazole. Pars plana vitrectomy may facilitate diagnosis and cure when a *Candida* vitreous abscess is present. Injection of amphotericin B into the vitreous humor can also be helpful.

Because amphotericin B and fluconazole penetrate reasonably well into an infected joint, the pleural cavity, and the peritoneum, local injection is not indicated. Removal of prostheses (including prosthetic joints and cardiac valves), peritoneal dialysis catheters, and central venous catheters is usually essential. Debridement, along with anti-

- Removal of foreign bodies is critical, including plastic catheters for intravenous fluids, peritoneal dialysis or cerebrospinal fluid shunts, prosthetic cardiac valves, and prosthetic joints.
- The dosage of amphotericin B for deeply invasive candidiasis is 0.5 mg/kg daily, although initial doses of 0.7–1.0 mg/kg daily may be appropriate for severely immunosuppressed patients. Amphotericin B lipid complex and liposomal amphotericin B are given as 5 mg/kg daily.
fungal therapy, is beneficial in Candida osteomyelitis. All collections of pus, such as those in the postoperative abdomen, need to be drained surgically or by percutaneous, CT-guided catheterization; an exception relates to the numerous small abscesses in liver, spleen, or kidney in chronic disseminated candidiasis, which cannot be drained effectively and require prolonged antifungal therapy. In general, treatment should continue until the patient with chronic disseminated candidiasis has been afebrile and nonneutropenic for at least 2 weeks. Defects may persist on imaging studies long after cure. Relapse during another episode of neutropenia is common unless the patient is receiving amphotericin B. Repeat cytotoxic therapy or even bone marrow transplantation can be undertaken in patients with prior chronic disseminated candidiasis, but amphotericin B should be given empirically during neutropenia.

**PROPHYLAXIS** Flucnazole can decrease the incidence of deeply invasive candidiasis in recipients of allogeneic bone marrow transplants when 400 mg is given daily. Some centers continue such prophylaxis for 70 days; others discontinue it after engraftment. Studies of leukemia and other neutropenic patients have found no significant reduction in the incidence of deepy invasive candidiasis associated with prophylactic use of fluconazole or itraconazole oral suspension, although this topic remains controversial. Prophylaxis against recurrent oropharyngeal or esophageal candidiasis in HIV-infected patients is no longer recommended unless recurrences are very frequent or severe. Fluconazole (3 to 6 mg/kg) or itraconazole solution (5 mg/kg) is the recommended daily oral dose. Fluconazole prophylaxis at 400 mg daily may be useful in preventing deeply invasive candidiasis in some high-risk postoperative patients. Definition of groups at sufficient risk to benefit from fluconazole depends on the intensive care unit but likely includes patients undergoing repeat, complicated abdominal surgery and patients who are both heavily colonized with Candida and immunosuppressed at the time of complicated surgery. The presence of intravenous catheters, prolonged stays in the intensive care unit, and renal failure increase the risk of candidemia.

**FURTHER READING**

**ETIOLOGIC AGENTS** Aspergillus fumigatus is the most common cause of aspergillosis, but A. flavus, A. niger, A. nidulans, A. terreus, and several other species can also cause disease. Aspergillus is a mold with septate branching hyphae ~2 to 4 μm in diameter. The fungus is identified by its gross and microscopic appearance in culture.

**PATHOGENESIS AND PATHOLOGY** All the common species of Aspergillus that cause disease in humans are ubiquitous in the environment, growing on dead leaves, stored grain, compost piles, hay, and other decaying vegetation. The fungus can also be isolated from potable water, although the clinical significance of this observation is unknown. Inhalation of Aspergillus spores must be extremely common, but disease is rare. Invasion of lung tissue is confined almost entirely to immunosuppressed patients, in roughly 90% of whom two of the following three conditions will be operative: a granulocyte count in peripheral blood of <500/μL, treatment with suprasphyliologic doses of adrenal glucocorticoids, and a history of treatment with other immunosuppressive drugs such as cyclosporine. Invasive aspergillosis is an occasional complication of AIDS. Aspergillus infection in the neutropenic patient is characterized by hyphal invasion of blood vessels, thrombosis, necrosis, and hemorrhagic infarction. Chronic granulomatous disease of childhood also predisposes to invasive pulmonary aspergillosis, but in that situation the inflammatory response is a pyogranuloma and blood vessel invasion is rare. Massive inhalation of Aspergillus spores by healthy persons can lead to acute, diffuse, self-limited pneumonitis. Epithelioid granulomas with giant cells and central pyogenic areas containing hyphae are detected in these cases. Spontaneous recovery taking several weeks is the usual course. Such patients should be tested for underlying chronic granulomatous disease.

Aspergillus can colonize the damaged bronchial tree, pulmonary cysts, or cavities of patients with underlying lung disease. Balls of hyphae within cysts or cavities (aspergillomas), usually in the upper lobe, may reach several centimeters in diameter and may be visible on chest x-ray. Tissue invasion does not occur.

**CLINICAL MANIFESTATIONS** Allergic bronchopulmonary aspergillosis occurs in patients with preexisting asthma (particularly glucocorticoid-dependent asthma) or cystic fibrosis and causes intermittent episodes of wheezing, pulmonary infiltrates from transient bronchial plugging, sputum and blood eosinophilia, low-grade fever, and brownish or greenish flecks in the sputum. These flecks contain Aspergillus hyphae, thick mucus, eosinophils, and Charcot-Leyden crystals. Some patients with repeated exacerbations develop central bronchiectasis and progressive loss of pulmonary function.

Endobronchial saprophytic pulmonary aspergillosis presents as chronic productive cough, often with hemoptysis, in a patient with prior chronic lung disease, such as tuberculosis, sarcoidosis, bronchiectasis, or histoplasmosis. Aspergillus may be spread from its endocavitary or endobronchial site to the pleura during the course of bacterial lung abscess or surgery. Patients reported to have chronic necrotizing Aspergillus pneumonia appear in most instances to have had saprophytic endobronchial colonization and a pulmonary process attributable to another disease, with or without superimposed bacterial infections. Patients with chronic pneumonia and Aspergillus in the sputum should be assumed to have either pneumonia of a different etiology (e.g., histoplasmosis) or Aspergillus pneumonia with underlying immunosuppression (e.g., chronic granulomatous disease or infection with HIV).

Invasive aspergillosis in the immunocompromised host presents as an acute, rapidly progressive, densely consolidated pulmonary infiltrate and is most common among patients with acute leukemia and recipients of tissue transplants. Infection progresses by direct extension across tissue planes and by hematogenous dissemination to lung, brain, and other organs. Computed tomography (CT) has been particularly valuable in suggesting the diagnosis of invasive pulmonary aspergillosis in patients with neutropenia. The earliest CT finding is one or more small pulmonary nodules. As a nodule enlarges, the dense
central core of infarcted tissue becomes surrounded by edema or hemorrhage, forming a hazy rim called the halo sign. This rim disappears in a few days as the dense core enlarges. When bone marrow function recovers, the infarcted central core cavitates, creating the crescent sign. Aspergillus may invade immunosuppressed patients through the skin at a site of minor trauma or through the upper airway mucosa. Early lesions in the nose should be sought in patients with neutropenia who have fever and minimal epistaxis. Scarlet-red patches of the mucosa rapidly become necrotic and white, then black. Rapid extension into the adjacent paranasal sinus, orbit, or face is usual, with or without the appearance of lung lesions.

Aspergillus sinusitis in immunocompetent patients may take three forms. A ball of hyphae may form in a chronically obstructed paranasal sinus, without tissue invasion. Much less commonly, a chronic, fibrosing granulomatous inflammation associated with Aspergillus hyphae within tissue may begin in the sinus and spread slowly to the orbit and the brain. Aspergillus is also a cause of allergic fungal sinusitis, but dark-walled fungi (e.g., Curvularia, Alternaria) are more common in this setting. Patients usually have a history of chronic allergic rhinitis, sometimes with nasal polyps, but are otherwise healthy, presenting with painless proptosis, nasal obstruction, or dull aching pain. On CT or magnetic resonance imaging, a solid soft-tissue mass pushing out the lateral wall of the ethmoid sinus or the medial wall of the maxillary sinus may be detected. On sinus exploration, the mucosa is found to be thickened and inflamed but intact. Within the sinus cavity, sticky mucopus with strands of neutrophils, eosinophils, Charcot-Leyden crystals, and occasional hyphae can be found.

Aspergillus in HIV-infected patients most commonly involves the lung, presenting as fever, cough, and dyspnea. Typically, the CD4+ cell count is <500/µL. Roughly half of these patients have neutropenia or have recently been treated with glucocorticoids. Bilateral diffuse or focal pulmonary infiltrates with a tendency to cavitate constitute the most common radiologic manifestation. Well-localized, white, necrotic pseudomembranes full of hyphae or ulcers may develop in the trachea or the major bronchi. Progression of bronchitis to pneumonia is usual, but hematogenous dissemination is uncommon. Either allergic or invasive Aspergillus sinusitis can occur in HIV-infected patients; the allergic form can develop even at CD4+ cell counts of $>500/µL$.

The growth of Aspergillus on cerumen and detritus within the external auditory canal is termed otomycosis. Trauma to the cornea may cause Aspergillus keratitis. Endophthalmitis follows the introduction of Aspergillus into the globe by trauma or surgery. Aspergillus may infect intracardiac or intravascular prostheses.

**DIAGNOSIS** The repeated isolation of Aspergillus from sputum or the demonstration of hyphae in sputum or bronchoalveolar lavage fluid suggests endobronchial colonization or infection. Even a single isolation of Aspergillus from the sputum of a neutropenic patient or a hematopoietic stem-cell transplant recipient with pneumonia, particularly a child or a nonsmoker, suggests the diagnosis of invasive aspergillosis. In patients with advanced AIDS, fever, and cough, the isolation of Aspergillus from respiratory secretions raises the possibility of aspergillosis and thus should prompt bronchoscopy. Fungus ball of the lung is usually detectable by chest x-ray. IgG antibody to Aspergillus antigens is demonstrable in the serum of many colonized patients and of virtually all patients with fungus ball. Patients with allergic bronchopulmonary aspergillosis have specific serum IgE antibody to Aspergillus antigens and often have IgG antibody as well. No standardized test for these antibodies exists. Serum IgE concentrations are often $>1000$ ng/mL.

Biopsy is usually required for the diagnosis of invasive aspergillosis of the lung, nose, paranasal sinus, bronchi, or sites of dissemination. Blood cultures are rarely positive, even in patients with infected cardiac valves (native or prosthetic). Detection of galactomannan antigen in serum suggests the diagnosis, but sensitivity is low early in the disease and false-positive results occur, particularly in children. Aspergillus hyphae can be identified presumptively by histology, but culture is required for confirmation and for identification of the species. Only culture can reliably distinguish aspergillosis from pseudallescheriasis; drug therapy for these two diseases differs.

---

**TREATMENT**

(See also Table 188-1.) Patients with severe hemoptysis due to fungus ball of the lung may benefit from lobectomy. Poor pulmonary function in residual lung and dense pleural adhesions around the lesion can complicate the resection. Bead embolization directed to the bronchial arterial supply has been used as a temporizing measure. Systemic chemotherapy is of no value in endobronchial or endocavitary aspergillosis. Short courses of oral adrenal glucocorticoids have been used to treat acute bronchial plugging in patients with allergic bronchopulmonary aspergillosis. Two small studies have indicated that patients with allergic bronchopulmonary aspergillosis require less glucocorticoid therapy and have fewer exacerbations when given prophylaxis with oral itraconazole (200 mg twice daily). Itraconazole has also been used with glucocorticoids to treat exacerbations.

Treatment with intravenous amphotericin B (1.0 to 1.5 mg/kg daily) has elicited a response in 30 to 40% of patients with invasive aspergillosis. Intravenous voriconazole (6 mg/kg every 12 h for two doses, then 4 mg/kg every 12 h) is better tolerated and more efficacious than a regimen starting with conventional amphotericin B. Once the patient has begun to respond, voriconazole can be given orally as 200 mg twice daily. Liposomal amphotericin B at daily doses of 5 mg/kg is probably comparable to voriconazole, but no comparative study is available. Compared with conventional amphotericin B, amphotericin B colloidal dispersion shows equivalent efficacy in aspergillosis, is less nephrotoxic, and more often causes infusion-related chills and fever. Itraconazole (200 mg twice daily) is useful in some less immunosuppressed patients with indolent or slowly progressive invasive aspergillosis. Over the first 2 weeks, itraconazole can be given intravenously as 200 mg twice daily for four doses and then 200 mg daily to patients who are unable to take or unlikely to absorb oral itraconazole. The intravenous formulation is contraindicated in patients with a creatinine clearance rate of $<30$ mL/min. Itraconazole capsules are given as 200 mg twice daily. Intravenous caspofungin (70 mg once, then 50 mg daily) can be considered for patients in whom therapy with other drugs fails. Surgery is the only treatment needed for fungus ball of the sinus and for allergic fungal sinusitis. Antifungal therapy has little effect on either entity if used alone, but chronic suppressive therapy has been begun postoperatively for relapse of allergic fungal si-

*Voriconazole dose: 6 mg/kg twice daily for two doses; then 4 mg/kg twice daily; for later oral administration, 200 mg twice daily. Liposomal amphotericin B dose: 5 mg/kg daily. Conventional amphotericin B dose: 1.0 to 1.5 mg/kg daily. Amphotericin B colloidal dispersion dose: 6 mg/kg daily. Amphotericin B lipid complex dose: 5 mg/kg daily. Intravenous itraconazole dose: 200 mg twice daily for four doses, then 200 mg daily. Intravenous caspofungin dose: 70 mg once, then 50 mg daily.
Mucormycosis originating in the nose and paranasal sinuses is a prominent feature. Ischemic or hemorrhagic necrosis is a key finding. The infection is acquired from nature, with no person-to-person spread. In all forms of mucormycosis, vascular invasion by the fungus can utilize. Gastrointestinal mucormycosis occurs in patients who have received deferoxamine and among those with pulmonary, gastrointestinal, or disseminated mucormycosis. Regeneration of diabetes mellitus and a decrease in the dose of immunosuppressive drugs facilitate the treatment of mucormycosis. Extensive debridement of craniofacial lesions appears to be very important. Orbital exenteration may be required. Intravenous amphotericin B is clearly of value in craniofacial mucormycosis and should be employed in the other forms of mucormycosis as well. The maximal tolerated doses are given until progression is halted. Endoscopic examination of paranasal sinuses can help assess progression. With the deoxycholate formulation, a dosage of 1 to 1.5 mg/kg daily is indicated. Amphotericin B lipid complex or liposomal amphotericin B, each at 5 mg/kg daily, appears to be as effective as and less toxic than conventional amphotericin B. Therapy is continued for a total of 10 to 12 weeks. Voriconazole and itraconazole are of no value. Results of hyperbaric oxygen therapy have been unimpressive. Appropriate management results in cure of about half of craniofacial infections. Primary cutaneous lesions benefit from debridement; extensive plastic surgical repair may be required, but the prognosis is good. Survival is rare among patients who have received deoxycholate and among those with pulmonary, gastrointestinal, or disseminated mucormycosis.

**Further Reading**

**Etiologic Agents**

Species of *Rhizopus*, *Rhizomucor*, and *Cunninghamaella* are the most common causes of mucormycosis, but species of *Apophysomyces*, *Saksenaea*, *Mucor*, and *Absidia* also are occasionally responsible for this infection. The etiologic organism in tissue is composed of broad, rarely septate hyphae of uneven diameter (6 to 15 μm). The organisms are inexplicably difficult to grow from infected tissue. When growth does take place, it is rapid and profuse on most media at room temperature. Identification is based on the gross and microscopic appearance of the mold.

*Zygomycosis* is a term that includes mucormycosis and entomophthoromycosis. The latter is a tropical infection of the subcutaneous tissue or paranasal sinuses caused by species of *Basidioholus* and *Conidobolus*, respectively.

**Epidemiology and Pathology**

*Rhizopus* and *Rhizomucor* species are ubiquitous, appearing on decaying vegetation, dung, and foods of high sugar content. Mucormycosis is uncommon and is largely confined to patients with serious preexisting diseases. Mucormycosis originating in the paranasal sinuses and nose predominantly affects patients with poorly controlled diabetes mellitus. Patients who have undergone organ transplantation, who have a hematologic malignancy, or who are receiving long-term deferoxamine therapy are predisposed to mucormycosis of either sinus or lung. Deferoxamine chelates iron in a form that the fungus can utilize. Gastrointestinal mucormycosis occurs in a variety of conditions, including uremia, severe malnutrition, and diarrheal diseases. The infection is acquired from nature, with no person-to-person spread. In all forms of mucormycosis, vascular invasion by hyphae is a prominent feature. Ischemic or hemorrhagic necrosis is the foremost histologic finding.

**Clinical Manifestations**

Mucormycosis originating in the nose and paranasal sinuses produces a characteristic clinical picture. Low-grade fever, dull sinus pain, and sometimes nasal congestion or a thin, bloody nasal discharge are followed in a few days by double vision, increasing fever, and obtundation. Examination reveals a unilateral generalized reduction of ocular motion, chemosis, and proptosis. The nasal turbinates on the involved side may be dusky red or necrotic. A sharply delineated area of necrosis, strictly respecting the midline, may appear in the hard palate. Facial skin adjacent to paranasal sinuses may be invaded by direct extension, turning progressively red, purple, and black. Fungal invasion of the globe or ophthalmic artery leads to blindness. Opacification of one or more sinuses is detected by computed tomography (CT) or magnetic resonance imaging (MRI). Magnetic resonance angiography (MRA) with gadolinium enhancement may show invasion or obstruction of the carotid siphon. Coma is due to direct invasion of the frontal lobe. Early symptoms mimic those of bacterial sinusitis. Clouding of the sensorium may be attributed to diabetic acidosis. Cavernous sinus thrombosis may be considered when orbital invasion occurs. Without treatment, the patient may die after an interval ranging from a few days to a few weeks.

Pulmonary mucormycosis manifests as progressive severe pneumonia accompanied by high fever and toxicity. The necrotic center of large infiltrates may cavitate. Fatal hemoptysis may occur from cavities formed near the hilum. Hematogenous spread to other areas of the lung, as well as to the brain and other organs, is common. Survival beyond 2 weeks is unusual. Gastrointestinal invasion presents as one or more ulcers that tend to perforate. Hematogenous dissemination can originate from the gastrointestinal tract, lung, or paranasal sinuses. Sometimes no portal of entry can be found. Primary cutaneous inoculation is uncommon but occurs in burn eschars, underneath occlusive dressings, and at sites of minor trauma in immunocompromised adults and low-birth-weight neonates. Several reported infections with *Apophysomyces elegans* have manifested as cellulitis in diabetics or previously normal patients.

**Diagnosis**

CT or MRI is very helpful in assessing the extent of sinusitis before surgery and in evaluating the patient afterward. CT is better for detecting bony erosion; MRI better visualizes extension into the frontal lobe or carotid artery in the siphon. Lesions of the lung and craniofacial structures are best diagnosed by biopsy and histologic section. Cultural confirmation should be attempted. Wet smear of crushed tissue can provide a rapid diagnosis. Cultures of blood and cerebrospinal fluid are negative. Smear and culture of sputum may be positive during cavitation of a lung lesion.

**Treatment**

Regulation of diabetes mellitus and a decrease in the dose of immunosuppressive drugs facilitate the treatment of mucormycosis. Extensive debridement of craniofacial lesions appears to be very important. Orbital exenteration may be required. Intravenous amphotericin B is clearly of value in craniofacial mucormycosis and should be employed in the other forms of mucormycosis as well. The maximal tolerated doses are given until progression is halted. Endoscopic examination of paranasal sinuses can help assess progression. With the deoxycholate formulation, a dosage of 1 to 1.5 mg/kg daily is indicated. Amphotericin B lipid complex or liposomal amphotericin B, each at 5 mg/kg daily, appears to be as effective as and less toxic than conventional amphotericin B. Therapy is continued for a total of 10 to 12 weeks. Voriconazole and itraconazole are of no value. Results of hyperbaric oxygen therapy have been unimpressive. Appropriate management results in cure of about half of craniofacial infections. Primary cutaneous lesions benefit from debridement; extensive plastic surgical repair may be required, but the prognosis is good. Survival is rare among patients who have received deoxycholate and among those with pulmonary, gastrointestinal, or disseminated mucormycosis.

190 MISCELLANEOUS MYCOSES AND ALGAL INFECTIONS

John E. Bennett

CHROMOBLASTOMYCOSIS (CHROMOMYCOSIS) This chronic subcutaneous mycosis, rarely seen in the United States, presents as nodular or verrucoid, ulcerated, or crusted skin lesions on exposed areas of skin, particularly on the lower extremities. Over months and years, lesions extend to contiguous skin; they may be tender or itchy. Pain is not a prominent symptom. The disease, which in fact causes few symptoms, follows the introduction of any of several fungi into subcutaneous tissue by thorns or bits of vegetation. The appearance of thick-walled, dark-colored, rounded forms (“copper pennies”) in a histopathologic section of the dermis is diagnostic. Dark-walled hyphae may be seen in the stratum corneum. Surgical excision is the treatment of choice for small lesions. Cryotherapy and itraconazole with or without fluconazole have ameliorated larger lesions. Repeated treatments may be necessary.

DERMATOPHYSISIS Definition Dermatophyosis, also known as ringworm or tinea, is a chronic fungal infection of the skin, hair, or nails.

Etiology Species of *Trichophyton, Microsporum*, and *Epidermophyton* are called dermatophytes. These organisms grow in and remain confined to the keratinous structures of the body. Other mycoses, such as candidiasis, pityriasis versicolor, and tinea nigra, may include fungal invasion of keratinous structures but traditionally are not called dermatophytes.

Pathology and Pathogenesis Dermatophyte species are referred to as *anthropophilic*, *zoophilic*, or *geophilic*, depending on whether their usual reservoir in nature appears to be humans, animals, or soil, respectively. The infectivity of organisms from all these sources is low, and outbreaks are largely confined to occasional clusters of cases of scalp infection in children. Acquisition of a dermatophyosis appears to be favored by minor trauma (including that incurred during wrestling), maceration, and poor hygiene of the skin. Infection does not seem to confer solid immunity; repeated infection with the same species is common, particularly with anthropophilic species. The infrequency of scalp infection among adults has been attributed to local factors rather than immunity.

Invasion of the stratum corneum by dermatophytes may cause inflammation that is either mild or (particularly with zoophilic fungi) intense. Shedding of the stratum corneum is increased by inflammation. To the extent that fungal growth cannot keep up with shedding, inflammation may help terminate infection. Conversely, infection is probably favored when shedding is reduced by treatment with glucocorticoids and cytotoxic drugs. Antifungal drugs interfere with the ability of fungal growth to keep up with shedding.

Clinical Manifestations The disease varies with the site of infection and the fungal species involved. Foot infection (athlete’s foot, tinea pedis) may present as fissuring of the toe webs, scaling of the plantar surfaces, or vesicles around the toe webs and soles. Interdigital lesions may be pruritic or, when bacterial superinfection occurs, may be painful. Hand infection is less common but resembles foot infection.

Scalp dermatophyosis (tinea capitis) is characterized by areas of alopecia and scaling. In so-called endanthrix infection, the hair shaft separates off at the skin surface, leaving the hairs visible as black dots in the scalp. Some forms of scalp infection include an area of intense boggy suppuration called a kerion.

Dermatophyosis of the glabrous skin (Fig. 190-1) presents as circumscribed lesions with a wide variety of appearances, including scales, vesicles, and pustules. Inflammation may be minimal or intense. Central healing of less inflamed lesions may take place. The serpiginous border of inflammation is the source of the name ringworm.

Dermatophyosis of the bearded area (tinea barbae) appears as a pustular folliculitis. Onychomyosis (tinea unguium) presents as a white discoloration of the nails or as thickening, chalkiness, and crumbling of the nails. Peeling and fissuring of paronychial nail folds or keratoic debris under the nail edge also may be evident.

Diagnosis Discolored hairs, scales, and keratotic debris under infected nails should be collected for KOH or calcifluor smear and culture. In the scraping of skin lesions, a drop of water on the skin site may keep the removed scales from flying off and thus may aid in their collection. Culture is important in distinguishing dermatophytes from *Candida* and fungal saprophytes growing in keratinaceous debris.

TREATMENT

Noninflammatory lesions of the trunk, groin, hands, and feet usually respond to twice-daily applications of clotrimazole, miconazole, ketoconazole, econazole, naftifine, terbinafine, or ciclopirox olamine cream. Hyperkeratotic lesions of the palms and soles respond slowly to these agents and may benefit from the initial application of Whitfield’s ointment to thin the keratin. Ointment should not be used between the toes, in the groin, or in the gluteal crease because maceration promotes bacterial infection.

Ringworm that is moderately severe, that is unresponsive to topical
therapy, or that involves the scalp, nails, or beard area should be treated systemically. Once-daily therapy with itraconazole (200 mg), terbinafine (250 mg), microcrystalline griseofulvin (500 mg), or ultramicrocrystalline griseofulvin (375 mg) is effective. Treatment must be continued until all infected keratin is gone. Cutting off infected hair and cleansing interdigital webs can expedite cure. Secondary bacterial infection of the foot may require soaks or antibiotic agents. The likelihood of relapse of dermatophyte foot infections may be decreased by keeping the feet clean and dry. For nail infections, itraconazole or terbinafine is preferred. In distal subungual onychomycosis, a single course of either drug results in initial improvement in half of patients, of whom half relapse. Results are better with fingernails than with toenails and for more distal rather than proximal nail involvement. To save money, itraconazole can be given as a double dose (400 mg) for 1 week each month with only marginal loss of efficacy. The rare but life-threatening complications of itraconazole must be weighed against the patient’s desire to have normal-appearing nails. The duration of therapy with itraconazole or terbinafine is 2 to 3 months for fingernails and 4 to 6 months for toenails.

**Protothecosis**  Prototheca species are ubiquitous achlorophyllic algae that enter exposed areas of skin through contaminated wounds and cause localized infections in the skin, olecranon bursa, and, rarely, tendon sheaths or deeper tissue. Diagnosis is based on culture or histopathologic demonstration of morula-like sporangia containing endospores in tissue. Prototheca wickerhamii, the usual agent, grows readily on fungal culture medium. Surgical debridement and treatment with itraconazole or intravenous amphotericin B are useful.

**Fusariosis**  Fusarium species can cause localized or hematogenously disseminated infection. Indolent cellulitis or soft-tissue necrosis can occur in immunocompetent patients at the site of trauma (including burns) or adjacent to onychomycosis. Immunocompromised patients may develop skin lesions at the site of minor trauma or, more often, as a result of hematogenous dissemination. Two-thirds of patients with disseminated infection who are severely immunosuppressed, particularly those who are profoundly neutropenic, develop skin lesions. One or more tender erythematous papules enlarge rapidly, may develop a surrounding rim of erythema, and may become necrotic or ulcerated in the center. A portal of infection is not usually apparent. Blood cultures have been positive in 59% of cases. The presence of a mold growing in a culture of blood from a neutropenic patient suggests fusariosis. Blood cultures are rarely positive in aspergillosis or mucormycosis. Voriconazole or amphoteracin B is the drug of choice for fusariosis, but survival from disseminated infection depends on the diminution of neutropenia. Debridement of localized lesions in immunocompetent patients is useful.

**Malassezia infection (Pityriasis)**  Malassezia furfur is part of the normal flora of the human skin but can cause tinea (pityriasis) versicolor or catheter-acquired sepsis. Tinea versicolor appears as asymptomatic, well-delineated, hyperpigmented or hypopigmented macules centered on the upper trunk and upper arms. Confluent lesions may cover large areas, making the border difficult to find. A fine “branny” scale or folliculitis is sometimes visible. When examined microscopically by KOH mount, skin sections are seen to contain characteristic round and elongated cells. On inspection with Wood’s light, lesions either do not fluoresce or appear yellow-green. Erythrasma resembles tinea versicolor but is characterized by gram-positive bacilli on smear and coral-red fluorescence. Azole creams are effective for the treatment of small areas of tinea versicolor; however, the application of selenium sulfide shampoo (Selsun) for 10 min daily, followed by showering to remove the shampoo, is more practical for large areas. Itraconazole is also effective. Catheter-acquired sepsis due to M. furfur develops in patients (particularly neutropenic) receiving intravenous lipid. The organism requires special culture conditions for growth, and the infection is cured by catheter removal.

**TREATMENT**

Actinomycetoma may respond to prolonged combination chemotherapy—e.g., with streptomycin and either dapsone or trimethoprin-sulfamethoxazole. Eumycetoma rarely responds to chemotherapy; some cases caused by Madurella mycetomatis have appeared to respond to ketoconazole or itraconazole.

**PARACOCCIDIOIDOMYCOSIS**  Etiology  Formerly called South American blastomycosis, this mycosis is caused by Paracoccidioides brasiliensis. A dimorphic fungus, P. brasiliensis grows as a budding yeast in tissue and as either a yeast or a mold on culture medium. The organism is identified by its gross and microscopic appearance.

**Pathogenesis and Pathology**  Infection is thought to be acquired by inhalation of spores from environmental sources, possibly soil. Pulmonary infection produces few symptoms initially. Hematogenous spread to the mucous membranes of the mouth and nose, the lymph nodes, and other sites causes patients to seek medical attention. In fatal cases, the infection spreads to the adrenals, the gastrointestinal tract, and many other viscera.

**Clinical Manifestations**  Common signs include indurated ulcers of the mouth, oropharynx, larynx, and nose; enlarged and draining lymph nodes; lesions of the skin and genitalia; and productive cough, weight loss, dyspnea, and sometimes fever. Paracoccidioidomycosis is acquired only in South America, Central America, and Mexico, but its extreme indolence may delay its recognition until many years after the patient has left the endemic area. Chest radiography most often shows bilateral patchy pneumonia.

**Diagnosis**  Cultures of sputum, pus, and mucosal lesions are often diagnostic. The diagnosis can be made by smear or histologic section, although confirmation by culture is preferable. Serologic tests are useful in suggesting the diagnosis and monitoring the response to therapy.

**PENICILLIOSIS MARNEFFEI**  Penicillium marneffei has emerged as a leading cause of opportunistic infection in patients in the late stages of HIV infection in Southeast Asia—notably, northern Thailand and southern China. Infection is probably acquired by the inhalation of spores from an unknown site in nature. At the time of diagnosis, in-
Infection has usually disseminated to bone marrow, liver, spleen, skin, or bone. Clinical manifestations and histopathologic findings resemble those of histoplasmosis. Both *P. marneffei* and *Histoplasma* are dimorphic fungi, appearing as small yeast cells in tissue and as a mold in culture. Unlike *Histoplasma*, the yeastlike cells of *P. marneffei* do not bud but divide by longitudinal fission. During growth as a mold, a red pigment forming in the agar underneath *P. marneffei* colonies can aid in the organism’s identification. Treatment consists of amphotericin B administration for 2 weeks or until improvement is documented, with subsequent administration of itraconazole (400 mg daily for 8 weeks, then 200 mg daily as maintenance therapy). A few patients with a sustained response to highly active antiretroviral therapy and prolonged maintenance therapy have had itraconazole discontinued, with no subsequent relapse.

**PHAEOHYPHOMYCOSIS** This is the name given to infections caused by fungi with dark-walled hyphae, excluding those given conventional names like chromoblastomycosis. Although an extraordinary variety of fungi and clinical syndromes are encompassed by this definition, most patients have brain abscess, subcutaneous abscesses, or allergic fungal sinusitis. Most of the brain abscesses are due to *Cladophialophora bantiana*, *Ochrroconis gallopavum*, *Exophiala dermatitidis*, *Bipolaris* species, and *Ramichloridium mackenzi* (both of which are useful in culture confirmation). Patients are previously healthy. Subcutaneous abscesses are usually single, arise at the site of minor trauma, and occur in both immunosuppressed and immunocompetent individuals. A large number of dematiaceous (dark-walled) mold species cause subcutaneous phaeohyphomycosis as well as allergic fungal sinusitis. The latter entity develops in patients with allergic rhinitis and presents as an expanding mucoid mass in one or more paranasal sinuses. The tenacious mucus contains eosinophils, Charcot-Leyden crystals, and occasional hyphae. Surgical excision of phaeohyphomycotic lesions is important. Antifungal therapy may retard recurrences but is of little value without surgical excision.

**PSEUDallescheriasis**

**Etiology** Also called *Pettelidium boydii*, *Pseudallescheria boydii* is a mold frequently found in soil. When isolated in the imperfect state, the anamorph is called *Scedosporium apiospermum*. *Scedosporium prolificans* is a closely related species.

**Pathogenesis and Pathology** Wind-borne spores of *P. boydii*, arising from the soil, are the presumed source of infection. The fungus grows as a mold within tissue, causing necrosis and abscess formation.

**Clinical Manifestations** *P. boydii* resembles *Aspergillus* in its ability to colonize the endobronchial tree, to form fungus balls in the lungs or paranasal sinuses, and to invade the cornea or globe of the eye, the soft tissues, the joints, or the bones after trauma or surgery and in its propensity to invade the lungs and paranasal sinuses of immunosuppressed hosts, including patients with AIDS. Hematogenous dissemination to the eye, brain, soft tissues, and other sites is common. Severe pneumonia, often with hematogenous dissemination and brain abscesses, has followed near-drowning in stagnant water. Hyphae of *P. boydii* in tissue may be difficult to distinguish from those of *Aspergillus*. Intravascular hyphae, a hallmark of invasive aspergillosis, are also found in pseudallescheriasis in neutropenic patients.

*S. prolificans* has caused infections in bones, joints, and soft tissue, usually after trauma.

**Diagnosis** Demonstration of hyphae in tissue and culture confirmation are required for diagnosis.

**TREATMENT**

Soft-tissue infections in previously normal patients respond well to surgical debridement and treatment with itraconazole or voriconazole. Immunosuppressed patients respond poorly, and those with disseminated infection usually die. Surgical drainage is useful in brain abscesses. Voriconazole is the drug of choice for immunosuppressed individuals, and itraconazole is a suitable alternative. *P. boydii* appears to be unresponsive to systemic amphotericin B therapy, although injection of amphotericin B into an infected joint has been helpful in a few cases. In previously normal patients with *S. prolificans* soft-tissue infection, surgical debridement has been useful. The response to all antifungal agents has been poor in immunosuppressed patients, but voriconazole treatment has resulted in cure in a few cases.

**Sporotrichosis**

**Etiology** *Sporothrix schenckii* lives as a saprophyte on plants in many areas of the world. In nature and on culture at room temperature, the fungus grows as a mold: within host tissue or at 37°C on enriched media, it grows as a budding yeast. It is identified by its appearance in mold and yeast forms.

**Pathogenesis and Pathology** Infection results from the inoculation of *S. schenckii* into subcutaneous tissue through minor trauma. Nursery workers, florists, and gardeners acquire the illness from roses, sphagnum moss, and other plants. Infection may be limited to the site of inoculation (plaque sporotrichosis) or extend along proximal lymphatic channels (lymphangitic sporotrichosis). Spread beyond an extremity—the usual site of infection—is rare, and hematogenous dissemination from the skin remains unproven. The portal for osteoarticular, pulmonary, and other extracutaneous forms of sporotrichosis is unknown but is probably the lung. Untreated sporotrichosis persists for months. The inflammatory response includes neutrophil clustering and a marked granulomatous response with epithelioid and giant cells.

**Clinical Manifestations** In lymphangitic sporotrichosis, which is by far the most common manifestation, a nearly painless red papule forms at the site of inoculation. Over the next several weeks, similar nodules form along proximal lymphatic channels. The nodules intermittently discharge small amounts of pus. Ulceration may occur. The proximal extension of these lesions, often with skip areas, is quite distinctive but may be mimicked by lesions of *Nocardia brasiliensis*, *Mycobacterium marinum*, or (in rare cases) *Leishmania brasiliensis* or *Mycobacterium kansasi*.

Plaque sporotrichosis manifests as a nontender red maculopapular granuloma confined to the site of inoculation. Osteoarticular sporotrichosis presents as mono- or polycarticular arthritis of indolent onset and progression over months or years, involving the elbows, knees, wrists, ankles, and (rarely) smaller joints of the extremities. Periarticular bone develops areas of demineralization detectable on x-ray, and draining sinuses may appear over joints and bursae. Hematogenous spread to the skin may take place during polyarticular disease, but none of the skin lesions shows lymphangitic spread. Immunosuppression, including that due to advanced infection with HIV, predisposes to hematogenous spread. Pulmonary sporotrichosis usually presents as a single chronic cavitary upper-lobe lung lesion. Chronic meningitis can develop in the absence of skin or lung lesions. *S. schenckii* is difficult to recover from cerebrospinal fluid.

**Diagnosis** Culture of pus, joint fluid, sputum, or a skin biopsy specimen is preferred. The appearance of *S. schenckii* in tissue is variable. In skin lesions, the organisms are hard to find.

**TREATMENT**

Itraconazole (100 to 200 mg daily) is the drug of choice for the treatment of cutaneous sporotrichosis. A saturated solution of potassium iodide given orally is also effective, but side effects often prevent the effective use of this regimen. Therapy should be continued for 1 month after the resolution of all lesions. Fluconazole is less effective. Extra-cutaneous sporotrichosis may be cured by itraconazole (200 mg twice daily), but the response is slow and may be incomplete. Prolonged courses of intravenous amphotericin B are more effective. Cavitary pulmonary sporotrichosis may require resection for cure.

**Trichosporonosis** A change in the taxonomy of the genus *Trichosporon* moved most of the agents causing deep infections from *T. beigelii* into the species *T. asahii*, with a few categorized as *T. mucoides*. White piedra of the scalp is caused by *T. ovoides* and that of the pubic hair by *T. inkin*. *T. cutaneum* and *T. asteroides* cause su-
peripheral infections. Most of what is currently known about Tricho-
sporon infections is not species specific, so the following description refers to T. beigeli. T. capitatum, which causes disseminated infection in patients with neutropenia, was previously reclassified as Blastos-
chizomyces capitatus and will not be covered here.

T. beigeli can be isolated from soil, the human gastrointestinal
tract, and skin. The organism can enter the bloodstream of patients
with severe neutropenia through an apparent source. Hematogen-
ously disseminated infection is manifested by fever and often by the
development of several erythematous or purpuric tender papules any-
where on the body. Lesions can form large, tense hemorrhagic bullae.
In some patients, native or prosthetic cardiac valves become infected.
In tissue, hypae and yeastlike cells are seen. Amphotericin B is prob-
able the drug of choice for treatment, but recovery depends on the
return of bone marrow function.

PFISTERIA INFECTION See Chap. 378.

PNEUMOCYSTIS INFECTION Peter D. Walzer

DEFINITION AND DESCRIPTION Pneumocystis is an opportunistic fungal
pulmonary pathogen that is an important cause of pneumonia (pneu-
moocystis) in the immunocompromised host. The taxonomic classifi-
cation of Pneumocystis as a fungus is based on factors such as analysis of
gene sequences for ribosomal RNA, mitochondrial proteins, and major
enzymes; the presence of β-1,3 glucan in the cell wall; and the efficacy
of antifungal drugs that inhibit β-glucan synthesis in animal models.
However, in contrast to most fungi, Pneumocystis lacks ergosterol and
is not susceptible to antifungal drugs that inhibit ergosterol synthesis.

Although Pneumocystis organisms obtained from different sources
are morphologically very similar, they are genetically diverse and host
specific. New nomenclature, which is still evolving, has established
that organisms derived from rats and humans are separate species
termed P. carinii and termed P. jiroveci, respectively. For the purpose
of clarity, only the genus designation, Pneumocystis, will be used in
this chapter.

Research on Pneumocystis has been limited by the lack of a reliable
in vitro culture system. Developmental stages of the organism include
the small (1- to 4-μm) pleomorphic trophic form; the 5- to 8-μm cyst,
which has a thick cell wall and contains up to eight intracytoplasmic bodies;
and the precyst, an intermediate stage. The life cycle of Pneumocystis prob-
able involves sexual and asexual reproduction. Pneumocystis contains
several different antigen groups, the most prominent of which is the
95- to 140-kDa major surface glycoprotein (MSG). MSG represents a mul-
tigene family of proteins, and the ability of MSG to undergo antigenic
variation may represent a mechanism by which Pneumocystis evades
host defenses. MSG is highly immunogenic, contains protective epi-
topes, and facilitates adherence of the organism to host cells via extra-
cellular matrix proteins, surfactant proteins, and the mannose receptor.

EPIDEMIOLOGY Serologic surveys have demonstrated that Pneumocys-
tis has a worldwide distribution and that most healthy children have
been exposed to the organism by 3 to 4 years of age. Airborne trans-
mition of Pneumocystis has been documented in animal studies; per-
son-to-person transmission has been suggested by hospital outbreaks
of pneumocystosis and by molecular analysis of isolates from patients
and their close contacts. Geography has also emerged as a contributory
factor in the epidemiology of Pneumocystis infection.

PATHOGENESIS AND PATHOLOGY The host factors that predispose to the
development of pneumocystosis include defects in cellular and hu-
meral immunity. The risk of developing Pneumocystis pneumonia
among HIV patients rises markedly when circulating CD4+ cell
counts fall below 200/μL. The frequency of serum antibodies to a
specific segment of MSG is significantly higher in HIV patients who
