Editor, Edition 15
Note: Dr. Fauci’s and Dr. Longo’s works as editors and authors were performed outside the scope of their employment as U.S. government employees. These works represent their personal and professional views and not necessarily those of the U.S. government.
The 16th Edition of Harrison’s Principles of Internal Medicine is dedicated to Tinsley R. Harrison, the founding editor and Editor-in-Chief for the first five editions.

From time to time a personality scintillates across the medical firmament who dazzles all beholders. Tinsley Harrison was such a person. A delightful, vivacious, passionate physician, he stimulated everyone with whom he came into contact, and he placed an indelible stamp on the medical events of his day.

Tinsley Randolph Harrison was born in Talladega, Alabama, on March 18, 1900. His father, Groce Harrison, was a sixth-generation physician, a student of William Osler who inculcated Osler’s values into his son from an early age. Tinsley earned his undergraduate degree from the University of Michigan and his M.D. from Johns Hopkins School of Medicine. After a medical residency at the Peter Bent Brigham Hospital in Boston, where he developed his life-long interest in cardiovascular science and medicine, and additional training at Hopkins, Dr. Harrison served as chief medical resident and then joined the faculty of Vanderbilt University School of Medicine. His Chief of Medicine there, Canby Robinson, described him as “a human dynamo with unbounded energy.” After a brief period of private practice, which Harrison later described as “perhaps the greatest educational experience of my entire life,” he served successively as chair of medicine at Bowman-Gray School of Medicine, Winston-Salem, North Carolina; the Southwestern Medical School in Dallas, Texas; and the University of Alabama, Birmingham. He also served as Dean of Southwestern and the University of Alabama and as Chief of Cardiology at the latter. Dr. Harrison died in Birmingham, on August 4, 1978.

For decades he was an active experimentalist, and his important contributions to the understanding of the pathophysiology of heart failure were all the more remarkable because they were obtained before the availability of measurements of intracardiac pressures, cardiac output, and regional blood flow. Harrison’s research involved both basic studies in cardiovascular physiology as well as clinical research and were summarized in a classic text Failure of the Circulation. He was a founding member of the Council of the National Heart Institute and served as president of the American Society for Clinical Investigation and of the American Heart Association. Tinsley Harrison received the Gold Heart Award from the latter, the Kober Medal of the Association of American Physicians, and the Distinguished Teacher Award of the American College of Physicians. Few people of his generation surpassed him as a bedside teacher.

In 1945, stimulated by the publisher Blakiston, Harrison conceived of a new type of textbook of internal medicine, in which both of his interests—clinical medicine and the pathophysiologic mechanisms of disease—would be as closely interwoven as they were in his mind. He immediately recruited an editorial team; Harrison authored or co-authored almost the entire cardiovascular section. By 1950, the first edition of Principles of Internal Medicine was published.

Although Harrison was a distinguished investigator, teacher, academic leader, and editor, he was first and foremost a masterful physician who excelled in the care of the sick. The individual patient was always in the center of the stage. To put the disease first, to refer to the patient as “a case,” would arouse Harrison’s wrath. The words that he penned for the first edition of this book reflect the importance he attached to his role as a physician.

No greater opportunity or obligation can fall the lot of a human being than to be a physician. In the care of the suffering he needs technical skill, scientific knowledge, and human understanding. He who uses these with courage, humility, and wisdom will provide a unique service for his fellow man and will build an enduring edifice of character within himself. The physician should ask of his destiny no more than this, and he should be content with no less.

These words express the philosophy of the original editors and of all those who have followed.

It is to the memory of this great physician, teacher, investigator, and editor, whose life and works have so inspired us, that this sixteenth edition of Harrison’s Principles of Internal Medicine is dedicated.

THE EDITORS
NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The editors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editor nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or the results obtained from the use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is particularly important in connection with new or infrequently used drugs.
## CONTENTS

Contributionxv
Prefacexxv

### Part One

**INTRODUCTION TO CLINICAL MEDICINE**

1 The Practice of Medicine  
*The Editors*  
1

2 Decision-Making in Clinical Medicine  
*Daniel B. Mark*  
6

3 Principles of Clinical Pharmacology  
*Dan M. Roden*  
13

4 Screening and Prevention of Disease  
*Gary J. Martin*  
26

5 Women’s Health  
*Andrea Dunaif*  
28

6 Medical Disorders During Pregnancy  
*Robert L. Barbieri / John T. Repke*  
32

7 Medical Evaluation of the Surgical Patient  
*Gerald W. Smetana*  
38

8 Geriatric Medicine  
*Neil M. Resnick / David Dosa*  
43

9 Palliative and End-of-Life Care  
*Ezekiel J. Emanuel / Linda L. Emanuel*  
53

10 Complementary and Alternative Medicine  
*Stephen E. Straus*  
66

### Part Two

**CARDINAL MANIFESTATIONS AND PRESENTATION OF DISEASES**

#### Section 1  
**PAIN**

11 Pain: Pathophysiology and Management  
*Howard L. Fields / Joseph B. Martin*  
71

12 Chest Discomfort and Palpitations  
*Thomas H. Lee*  
76

13 Abdominal Pain  
*William Silen*  
82

14 Headache  
*Neil H. Raskin*  
85

15 Back and Neck Pain  
*John W. Enstrom*  
94

#### Section 2  
**ALTERATIONS IN BODY TEMPERATURE**

16 Fever and Hyperthermia  
*Charles A. Dinarello / Jeffrey A. Gelfand*  
104

17 Fever and Rash  
*Elaine T. Kaye / Kenneth M. Kaye*  
108

18 Fever of Unknown Origin  
*Jeffrey A. Gelfand / Michael V. Callahan*  
116

19 Hypothermia and Frostbite  
*Daniel F. Danzl*  
121

#### Section 3  
**NERVOUS SYSTEM DYSFUNCTION**

20 Syncope, Faintness, Dizziness, and Vertigo  
*Robert B. Daroff / Mark D. Carlson*  
126

21 Weakness, Disorders of Movement, and Imbalance  
*Richard K. Olney*  
134

22 Numbness, Tingling, and Sensory Loss  
*Arthur K. Asbury*  
141

23 Aphasia, Memory Loss, and Other Focal Cerebral Disorders  
*Marsel Mesulam*  
145

24 Sleep Disorders  
*Charles A. Czeisler / John W. Winkelman / Gary S. Richardson*  
153

#### Section 4  
**DISORDERS OF EYES, EARS, NOSE, AND THROAT**

25 Disorders of the Eye  
*Jonathan C. Horton*  
162

26 Disorders of Smell, Taste, and Hearing  
*Anil K. Lalwani / James B. Snow, Jr.*  
176

27 Infections of the Upper Respiratory Tract  
*Michael A. Ruhn / Ralph Gonzales / Merle A. Sande*  
185

28 Oral Manifestations of Disease  
*Samuel C. Durso*  
194

#### Section 5  
**ALTERATIONS IN CIRCULATORY AND RESPIRATORY FUNCTIONS**

29 Dyspnea and Pulmonary Edema  
*Roland H. Ingram, Jr. / Eugene Braunwald*  
201

30 Cough and Hemoptysis  
*Steven E. Weinberger*  
205

31 Hypoxia and Cyanosis  
*Eugene Braunwald*  
209

32 Edema  
*Eugene Braunwald*  
212

#### Section 6  
**ALTERATIONS IN GASTROINTESTINAL FUNCTION**

33 Dysphagia  
*Raj K. Goyal*  
217

34 Nausea, Vomiting, and Indigestion  
*William L. Hasler*  
219

35 Diarrhea and Constipation  
*David A. Ahlquist / Michael Camilleri*  
224

36 Weight Loss  
*Carol M. Reife*  
233

37 Gastrointestinal Bleeding  
*Loren Laine*  
235

38 Jaundice  
*Daniel S. Pratt / Marshall M. Kaplan*  
238

39 Abdominal Swelling and Ascites  
*Robert M. Glickman*  
243

#### Section 7  
**ALTERATIONS IN RENAL AND URINARY TRACT FUNCTION**

40 Azotemia and Urinary Abnormalities  
*Bradley M. Denker / Barry M. Brenner*  
246

41 Fluid and Electrolyte Disturbances  
*Gary G. Singer / Barry M. Brenner*  
252

42 Acidosis and Alkalosis  
*Thomas D. DuRose, Jr.*  
263

#### Section 8  
**ALTERATIONS IN SEXUAL FUNCTION AND REPRODUCTION**

43 Sexual Dysfunction  
*Kevin T. McVary*  
271

### Section 9

#### ALTERATIONS IN THE SKIN

- **46** Approach to the Patient with a Skin Disorder
  - Thomas J. Lawley / Kim B. Yancey
- **47** Eczema, Psoriasis, Cutaneous Infections, Acne, and Other Common Skin Disorders
  - Calvin O. McCall / Thomas J. Lawley
- **48** Skin Manifestations of Internal Disease
  - Jean L. Bolognia / Irwin M. Braverman
- **49** Immunologically Mediated Skin Diseases
  - Kim B. Yancey / Thomas J. Lawley
- **50** Cutaneous Drug Reactions
  - Olivier M. Chosidow / Robert S. Stern / Bruce U. Wintroub

### Section 10

#### HEMATOLOGIC ALTERATIONS

- **52** Anemia and Polycythemia
  - John W. Adamson / Dan L. Longo
- **53** Bleeding and Thrombosis
  - Robert I. Handin
- **54** Enlargement of Lymph Nodes and Spleen
  - Patrick H. Henry / Dan L. Longo
- **55** Disorders of Granulocytes and Monocytes
  - Steven M. Holland / John J. Gallin

### Part Three

#### GENETICS AND DISEASE

- **56** Principles of Human Genetics
  - J. Larry Jameson / Peter Kopp
- **57** Chromosome Disorders
  - Terry Hassold / Stuart Schwartz
- **58** The Practice of Genetics in Clinical Medicine
  - Susan Miesfeldt / J. Larry Jameson
- **59** Stem Cell and Gene Transfer in Clinical Medicine
  - David Bodine / J. Larry Jameson / Ron McKay

### Part Four

#### NUTRITION

- **60** Nutritional Requirements and Dietary Assessment
  - Johanna Dwyer
- **61** Vitamin and Trace Mineral Deficiency and Excess
  - Robert M. Russell
- **62** Malnutrition and Nutritional Assessment
  - Charles H. Halsted
- **63** Enteral and Parenteral Nutrition Therapy
  - Lyn Howard
- **64** Obesity
  - Jeffrey S. Flier / Eleftheria Maratos-Flier
- **65** Eating Disorders
  - B. Timothy Walsh

### Part Five

#### ONCOLOGY AND HEMATOLOGY

### Section 1

#### NEOPLASTIC DISORDERS

- **66** Approach to the Patient with Cancer
  - Dan L. Longo
Acute and Chronic Myeloid Leukemia
Mehr Wetzler / John C. Byrd / Clara D. Bloomfield

Malignancies of Lymphoid Cells
James O. Armitage / Dan L. Longo

Plasma Cell Disorders
Dan L. Longo / Kenneth C. Anderson

Transfusion Biology and Therapy
Jeffery S. Dzieczkowski / Kenneth C. Anderson

Hematopoietic Cell Transplantation
Frederick R. Appelbaum

SECTION 3
DISORDERS OF HEMOSTASIS

Disorders of the Platelet and Vessel Wall
Robert I. Handin

Disorders of Coagulation and Thrombosis
Robert I. Handin

Antiplatelet, Anticoagulant, and Fibrinolytic Therapy
Steven R. Deitcher

Part Six
INFECTIOUS DISEASES

SECTION 1
BASIC CONSIDERATIONS IN INFECTIOUS DISEASES

Introduction to Infectious Diseases: Host–Pathogen Interactions
Lawrence C. Madoff / Dennis L. Kasper

Molecular Mechanisms of Microbial Pathogenesis
Gerald B. Pier

Approach to the Acutely Ill Infected Febrile Patient
Tamar F. Barlam / Dennis L. Kasper

Immunization Principles and Vaccine Use
Gerald T. Keusch / Kenneth J. Bart / Mark Miller

Health Advice for International Travel
J.S. Keystone / P.E. Kozarsky

SECTION 2
CLINICAL SYNDROMES: COMMUNITY-ACQUIRED INFECTIONS

Infective Endocarditis
Adolf W. Karchmer

Infections of the Skin, Muscle, and Soft Tissues
Dennis L. Stevens

Osteomyelitis
Jeffrey Parsonnet / James H. Maguire

Intraabdominal Infections and Abscesses
Dennis L. Kasper / Dori F. Zaleznik

Acute Infectious Diarrheal Diseases and Bacterial Food Poisoning
Dennis L. Kasper / Dori F. Zaleznik

Clostridium difficile-Associated Disease, Including Pseudomembranous Colitis
Dale N. Gerding / Stuart Johnson

Sexually Transmitted Diseases: Overview and Clinical Approach
King K. Holmes

SECTION 3
CLINICAL SYNDROMES: NOSOCOMIAL INFECTIONS

Hospital-Acquired Infections
Robert A. Weinstein

Infections in Transplant Recipients
Robert Finberg / Joyce Fingeroth

SECTION 4
APPROACH TO THERAPY FOR BACTERIAL DISEASES

Treatment and Prophylaxis of Bacterial Infections
Gordon L. Archer / Ronald E. Polk

SECTION 5
DISEASES CAUSED BY GRAM-POSITIVE BACTERIA

Pneumococcal Infections
Daniel M. Musher

Staphylococcal Infections
Franklin D. Lowy

Streptococcal and Enterococcal Infections
Michael R. Wessels

Diphtheria and Other Corynebacterial Infections
Randall K. Holmes

Infections Caused by Listeria monocytogenes
Anne Schuchat / Claire V. Broome

Tetanus
Elias Abruyn

Botulism
Elias Abruyn

Gas Gangrene and Other Clostridial Infections
Dennis L. Kasper / Lawrence C. Madoff

SECTION 6
DISEASES CAUSED BY GRAM-NEGATIVE BACTERIA

Meningococcal Infections
David S. Stephens / Robert S. Manford / Lee M. Wetzler

Gonococcal Infections
Sanjay Ram / Peter A. Rice

Moraxella catarrhalis and Other Moraxella Species
Daniel M. Musher

Haemophilus Infections
Timothy F. Murphy

Infections Due to HACEK Group and Miscellaneous Gram-Negative Bacteria
Dennis L. Kasper / Tamar F. Barlam

Legionella Infection
Feng-Yee Chang / Victor L. Yu

Pertussis and Other Bordetella Infections
Scott A. Halperin

Diseases Caused by Gram-Negative Enteric Bacilli
Thomas A. Russo

Helicobacter pylori Infections
John C. Atherton / Martin J. Blaser

Infections Due to Pseudomonas Species and Related Organisms
Christopher A. Ohl / Matthew Pollock

Salmonellosis
Cammie F. Lesser / Samuel I. Miller

Shigellosis
Gerald T. Keusch / Dennis J. Kopecko

Infections Due to Campylobacter and Related Species
Martin J. Blaser

Cholera and Other Vibrios
Matthew K. Waldor / Gerald T. Keusch

Brucellosis
Michael J. Corbel / Nicholas J. Beeching

Tularemia
Richard F. Jacobs

Plague and Other Yersinia Infections
David T. Dennis / Grant L. Campbell

Bartonella Infections, Including Cat-Scratch Disease
Lucy Stuart Tompkins

Donovanosis
Gavin Hart

SECTION 7
MISCELLANEOUS BACTERIAL INFECTIONS

Nocardiosis
Gregory A. Filice

Actinomycosis
Thomas A. Russo
148 Infections Due to Mixed Anaerobic Organisms  
Dennis L. Kasper

### SECTION 8  
MYCOBACTERIAL DISEASES

149 Antimycobacterial Agents  
Richard J. Wallace, Jr. / David E. Griffith

150 Tuberculosis  
Mario C. Raviglione / Richard J. O’Brien

151 Leprosy (Hansen’s Disease)  
Robert H. Gelber

152 Nontuberculous Mycobacteria  
C. Fordham von Reyn

### SECTION 9  
SPIROCHETAL DISEASES

153 Syphilis  
Sheila A. Lakehart

154 Endemic Treponematoses  
Sheila A. Lakehart

155 Leptospirosis  
Peter Speelman

156 Relapsing Fever  
David T. Dennis / Edward B. Hayes

157 Lyme Borreliosis  
Allen C. Steere

### SECTION 10  
DISEASES CAUSED BY RICKETTSIA, MYCOPLASMA, AND CHLAMYDIA

158 Rickettsial Diseases  
David H. Walker / Didier Raoult / J. Stephen Dumler / Thomas J. Marrie

159 Infections Due to Mycoplasmas  
William M. McCormack

160 Chlamydial Infections  
Walter E. Stamm

### SECTION 11  
VIRAL DISEASES: GENERAL CONSIDERATIONS

161 Medical Virology  
Fred Wang / Elliott Kieff

162 Antiviral Chemotherapy, Excluding Antiretroviral Drugs  
Lindsey R. Baden / Raphael Dolin

### SECTION 12  
INFECOTIONS DUE TO DNA VIRUSES

163 Herpes Simplex Viruses  
Lawrence Corey

164 Varicella-Zoster Virus Infections  
Richard J. Whitley

165 Epstein-Barr Virus Infections, Including Infectious Mononucleosis  
Jeffrey I. Cohen

166 Cytomegalovirus and Human Herpesvirus Types 6, 7, and 8  
Martin S. Hirsch

167 Molluscum Contagiosum and Other Poxviruses, Excluding Smallpox Virus  
Fred Wang

168 Parvovirus  
Neil R. Blacklow

169 Human Papillomavirus Infections  
Richard C. Reichman

### SECTION 13  
INFECTIONS DUE TO DNA AND RNA RESPIRATORY VIRUSES

170 Common Viral Respiratory Infections and Severe Acute Respiratory Syndrome (SARS)  
Raphael Dolin

### SECTION 14  
INFECOTIONS DUE TO HUMAN IMMUNODEFICIENCY VIRUS AND OTHER HUMAN RETROVIRUSES

172 The Human Retroviruses  
Dan L. Longo / Anthony S. Fauci

173 Human Immunodeficiency Virus Disease: AIDS and Related Disorders  
Anthony S. Fauci / H. Clifford Lane

### SECTION 15  
INFECTIONS DUE TO RNA VIRUSES

174 Viral Gastroenteritis  
Umesh D. Parashar / Roger I. Glass

175 Enteroviruses and Reoviruses  
Jeffrey I. Cohen

176 Measles (Rubella)  
Anne Gershon

177 Rubella (German Measles)  
Anne Gershon

178 Mumps  
Anne Gershon

179 Rabies Virus and Other Rhabdoviruses  
Cathleen A. Hanlon / Lawrence Corey

180 Infections Caused by Arthropod- and Rodent-Borne Viruses  
Clarence J. Peters

181 Ebola and Marburg Viruses  
Clarence J. Peters

### SECTION 16  
FUNGIAL AND ALGAL INFECTIONS

182 Diagnosis and Treatment of Fungal Infections  
John E. Bennett

183 Histoplasmosis  
John E. Bennett

184 Coccidioidomycosis  
John E. Bennett

185 Blastomycosis  
John E. Bennett

186 Cryptococcosis  
John E. Bennett

187 Candidiasis  
John E. Bennett

188 Aspergillosis  
John E. Bennett

189 Mucormycosis  
John E. Bennett

190 Miscellaneous Mycoses and Algal Infections  
John E. Bennett

191 Pneumocystis Infection  
Peter D. Walzer

### SECTION 17  
PROTOZOAL AND HELMINTHIC INFECTIONS: GENERAL CONSIDERATIONS

192 Laboratory Diagnosis of Parasitic Infections  
Charles E. Davis

193 Agents Used to Treat Infections Due to Parasites and Pneumocystis  
Thomas A. Moore

### SECTION 18  
PROTOZOAL INFECTIONS

194 Amebiasis and Infection with Free-Living Amebas  
Sharon L. Reed

195 Malaria and Babesiosis: Diseases Caused by Red Blood Cell Parasites  
Nicholas J. White / Joel G. Breman
196 Leishmaniasis
Barbara L. Herwaldt

197 Trypanosomiasis
Louis V. Kirchhoff

198 Toxoplasma Infection
Lloyd H. Kasper

199 Protozoal Intestinal Infections and Trichomoniasis
Peter F. Weller

SECTION 19
HELMINTHIC INFECTIONS

200 Trichinella and Other Tissue Nematodes
Peter F. Weller

201 Intestinal Nematodes
Peter F. Weller / Thomas B. Nutman

202 Filarial and Related Infections
Thomas B. Nutman / Peter F. Weller

203 Schistosomiasis and Other Trematode Infections
Adel A.F. Mahmoud

204 Cestodes
A. Clinton White, Jr. / Peter F. Weller

Part Seven
BIOTERRORISM AND CLINICAL MEDICINE

205 Microbial Bioterrorism
H. Clifford Lane / Anthony S. Fauci

206 Chemical Bioterrorism
Charles G. Harst / Jonathan Newmark / James A. Romano

207 Radiation Bioterrorism
Zelig A. Tochner / Ofer Lehavi / Eli Glatstein

Part Eight
DISORDERS OF THE CARDIOVASCULAR SYSTEM

SECTION 1
DIAGNOSIS OF CARDIOVASCULAR DISORDERS

208 Approach to the Patient with Cardiovascular Disease
Eugene Braunwald

209 Physical Examination of the Cardiovascular System
Robert A. O'Rourke / Eugene Braunwald

210 Electrocardiography
Ary L. Goldberger

211 Noninvasive Cardiac Imaging: Echocardiography, Nuclear Cardiology, and MRI / CT Imaging
Rick A. Nishimura / Raymond J. Gibbons / James F. Glockner / A. Jamil Tajik

212 Diagnostic Cardiac Catheterization and Angiography
Donald S. Baim / William Grossman

SECTION 2
DISORDERS OF RHYTHM

213 The Bradyarrhythmias: Disorders of Sinus Node Function and AV Conduction Disturbances
Mark E. Josephson / Peter Zimethbaum

214 The Tachyarrhythmias
Mark E. Josephson / Peter Zimethbaum

SECTION 3
DISORDERS OF THE HEART

215 Normal and Abnormal Myocardial Function
Eugene Braunwald

216 Heart Failure and Cor Pulmonale
Eugene Braunwald

217 Cardiac Transplantation and Prolonged Assisted Circulation
Sharon A. Hunt

SECTION 4
VASCULAR DISEASE

224 The Pathogenesis of Atherosclerosis
Peter Libby

225 Prevention and Treatment of Atherosclerosis
Peter Libby

226 Ischemic Heart Disease
Andrew P. Selwyn / Eugene Braunwald

227 Unstable Angina and Non-ST-Elevation Myocardial Infarction
Christopher P. Cannon / Eugene Braunwald

228 ST-Segment Elevation Myocardial Infarction
Elliott M. Antman / Eugene Braunwald

229 Percutaneous Coronary Revascularization
Donald S. Baim

230 Hypertensive Vascular Disease
Naomi D.L. Fisher / Gordon H. Williams

231 Diseases of the Aorta
Victor J. Dzau / Mark A. Creager

232 Vascular Diseases of the Extremities
Mark A. Creager / Victor J. Dzau

Part Nine
DISORDERS OF THE RESPIRATORY SYSTEM

SECTION 1
DIAGNOSIS OF RESPIRATORY DISORDERS

233 Approach to the Patient with Disease of the Respiratory System
Jeffrey M. Drazen / Steven E. Weinberger

234 Disturbances of Respiratory Function
Steven E. Weinberger / Jeffrey M. Drazen

235 Diagnostic Procedures in Respiratory Disease
Steven E. Weinberger / Jeffrey M. Drazen
Part Ten
CRITICAL CARE MEDICINE

SECTION 1
RESPIRATORY CRITICAL CARE

249 Principles of Critical Care Medicine
John P. Kress / Jesse B. Hall

250 Respiratory Failure
Craig Lilly / Edward P. Ingenito / Steven D. Shapiro

251 Acute Respiratory Distress Syndrome
Bruce D. Levy / Steven D. Shapiro

252 Mechanical Ventilatory Support
Edward P. Ingenito / Jeffrey M. Drazen

SECTION 2
SHOCK AND CARDIAC ARREST

253 Approach to the Patient with Shock
Ronald V. Maier

254 Severe Sepsis and Septic Shock
Robert S. Manford

255 Cardiogenic Shock and Pulmonary Edema
Judith S. Hochman / David Ingbar

256 Cardiovascular Collapse, Cardiac Arrest, and Sudden Cardiac Death
Robert J. Myerburg / Agustin Castellanos

SECTION 3
NEUROLOGIC CRITICAL CARE

257 Acute Confusional States and Coma
Allan H. Ropper

258 Critical Care Neurology
J. Claude Hemphill

Part Eleven
DISORDERS OF THE KIDNEY AND URINARY TRACT

259 Adaptation to Renal Injury
Robert M. Brenner / Barry M. Brenner

260 Acute Renal Failure
Hugh R. Brady / Barry M. Brenner

261 Chronic Renal Failure
Karl Skorecki / Jacob Green / Barry M. Brenner

262 Dialysis in the Treatment of Renal Failure
Ajay K. Singh / Barry M. Brenner

263 Transplantation in the Treatment of Renal Failure
Charles B. Carpenter / Edgar L. Milford / Mohamed H. Sayegh

264 Glomerular Diseases
Hugh R. Brady / Yvonne M. O’Meara / Barry M. Brenner

265 Tubular Disorders
John R. Asplin / Fredric L. Coe

266 Tubulointerstitial Diseases of the Kidney
Alan S. L. Yu / Barry M. Brenner

267 Vascular Injury to the Kidney
Kamal F. Badd / Barry M. Brenner

268 Nephrolithiasis
John R. Asplin / Fredric L. Coe / Murray J. Favus

269 Urinary Tract Infections and Pyelonephritis
Walter E. Stamm

270 Urinary Tract Obstruction
Julian L. Seifter / Barry M. Brenner

271 Approach to the Patient with Gastrointestinal Disease
William L. Hasler / Chung Owyang

272 Gastrointestinal Endoscopy
Mark Topazian

273 Diseases of the Esophagus
Raj K. Goyal

274 Peptic Ulcer Disease and Related Disorders
John Del Valle

275 Disorders of Absorption
Henry J. Binder

276 Inflammatory Bowel Disease
Sonia Friedman / Richard S. Blumberg

277 Irritable Bowel Syndrome
Chung Owyang

278 Familial Mediterranean Fever and Other Hereditary Recurrent Fevers
Daniel L. Kastner

279 Common Diseases of the Colon and Anorectum and Mesenteric Vascular Insufficiency
Susan L. Gearhart / Gregory Bulkley

280 Acute Intestinal Obstruction
William Silen

281 Acute Appendicitis and Peritonitis
William Silen

282 Approach to the Patient with Liver Disease
Marc Ghany / J. H. Hoofnagle

283 Evaluation of Liver Function
Daniel S. Pratt / Marshall M. Kaplan

284 The Hyperbilirubinemas
Allan W. Wolkoff

285 Acute Viral Hepatitis
Jules L. Dienstag / Kurt J. Isselbacher

286 Toxic and Drug-Induced Hepatitis
Jules L. Dienstag / Kurt J. Isselbacher

287 Chronic Hepatitis
Jules L. Dienstag / Kurt J. Isselbacher

288 Alcoholic Liver Disease
Mark E. Mailliard / Michael F. Sorrell

289 Cirrhosis and Its Complications
Raymond T. Chung / Daniel K. Podolsky

290 Infiltrative, Genetic, and Metabolic Diseases Affecting the Liver
Daniel K. Podolsky

CONTRIBUTORS

Numbers in brackets refer to chapters written or co-written by the contributor.

ELIAS ABRUTYN, MD
Professor of Medicine and Public Health, Associate Provost and Associate Dean for Faculty Affairs; Interim Chief, Infectious Diseases, Drexel University College of Medicine, Philadelphia [124, 125]

JOHN C. ACHERMAN, MRCP, MRCPCH, MD
Wellcome Trust Clinician Scientist, Department of Medicine and Institute of Child Health, University College London, London, UK [328]

JOHN W. ADAMSON, MD
Executive Vice President for Research, Director, Blood Research Institute, Blood Center of Southeastern Wisconsin, Milwaukee [52, 90]

DAVID A. AHLQUIST, MD
Professor of Medicine, Mayo Clinic College of Medicine; Consultant in Gastroenterology, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester [35]

LEENA ALÁ-KOKKO, MD, PhD
Professor of Medicine, Center for Gene Therapy, Tulane University Health Sciences Center, New Orleans [342]

KENNETH C. ANDERSON, MD
Chief, Division of Hematologic Neoplasia; Director, Jerome Lipper Multiple Myeloma Center, Dana-Farber Cancer Institute; Kraft Family Professor of Medicine, Harvard Medical School, Boston [98, 99]

E Liott M. ANTMAN, MD
Professor of Medicine, Harvard Medical School; Director, Samuel A. Levine Cardiac Unit, Brigham and Women’s Hospital, Boston [229]

FREDERICK R. APPELLBAUM, MD
Member and Director, Clinical Research Division, Fred Hutchinson Cancer Research Center; Professor and Head, Division of Medical Oncology, University of Washington School of Medicine, Seattle [100]

GORDON L. ARCHER, MD
Professor of Medicine and Microbiology/Immunology; Chair, Division of Infectious Diseases, Department of Medicine, Virginia Commonwealth University Medical Center, Richmond [118]

JAMES O. ARmitAGE, MD
Joe Shapiro Professor of Medicine, University of Nebraska, Omaha [97]

ARTHUR K. ASbury, MD
Van Meter Professor of Neurology Emeritus, University of Pennsylvania School of Medicine, Philadelphia [22, 363, 365]

JOHN R. ASPlIN, MD
Assistant Professor of Medicine, Section of Nephrology, University of Chicago Pritzker School of Medicine, Chicago [265, 268]

JOHN C. AThERTON, MD
Professor of Gastroenterology, Wolffson Digestive Diseases Centre and Institute of Infectious, Immunity and Inflammation, University of Nottingham, Nottingham, England [135]

PAUL S. AUERBACH, MD, MS
Clinical Professor of Surgery, Department of Surgery, Division of Emergency Medicine, Stanford University School of Medicine, Los Altos [378]

K. FRANK AUSTEN, MD
AstraZeneca Professor of Respiratory and Inflammatory Diseases, Harvard Medical School; Director, Inflammation and Allergic Diseases Research Section, Division of Rheumatology, Immunology, and Allergy, Department of Medicine, Brigham and Women’s Hospital, Boston [298]

BERNARD M. BABIOR, MD, PhD
Professor and Head, Division of Biochemistry, Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla [92]

LINDSEY R. BADEN, MD
Assistant Professor of Medicine, Harvard Medical School; Division of Infectious Diseases, Brigham and Women’s Hospital, Boston [162]

KAMAL F. BADR, MD
Professor and Chair, Department of Internal Medicine, American University of Beirut (Lebanon); Attending Physician, American University of Beirut Medical Center, Beirut, Lebanon [267]

DONALD S. BAiM, MD
Professor of Medicine, Harvard Medical School; Director, Center for Integration of Medicine and Innovative Technology, Brigham and Women’s Hospital, Boston [212, 229]

ROBERT L. BARBERI, MD
Kate Macy Ladd Professor of Obstetrics, Gynecology, and Reproductive Biology, Harvard Medical School; Chairman, Obstetrics and Gynecology, Brigham and Women’s Hospital, Boston [6]

TAMAR F. BARLAM, MD
Associate Professor of Medicine, Boston University School of Medicine, Boston [106, 131]

KENNETH J. BART, MD
Director, Graduate School of Public Health, Professor of Epidemiology and Biostatistics, San Diego State University, San Diego [107]

SHARI S. BASSUK, ScD
Epidemiologist, Division of Preventive Medicine, Brigham and Women’s Hospital, Boston [327]

M. FLINT BEAL, MD
Anne Parrish Titzel Professor and Chair, Department of Neurology and Neurosciences, Weill Medical College of Cornell University; Neurologist-in-Chief, New York Presbyterian Hospital, New York [345, 355]

NICHOLAS J. BEECHING, FRCP, FRACP, DCH, DTM&H
Senior Lecturer in Infectious Diseases, Liverpool School of Tropical Medicine; Clinical Lead, Tropical and Infectious Disease Unit, Royal Liverpool University Hospital, Liverpool, United Kingdom [141]

ROBERT S. BENJAMIN, MD
Professor of Medicine, Chairman, Department of Sarcoma Medical Oncology, The University of Texas MD Anderson, Houston [84]

JOHN E. BENNETT, MD
Head, Clinical Mycology Section, Laboratory of Clinical Investigation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Potomac [182–190]

EDWARD J. BENZ, JR., MD
Richard and Susan Smith Professor of Medicine, Professor of Pediatrics, Professor of Pathology, Harvard Medical School; President and CEO, Dana-Farber Cancer Institute; Director, Dana-Farber/Harvard Cancer Center, Boston [91]

SHALENDAR BHASIN, MD
Professor of Medicine, University of California Los Angeles School of Medicine; Chief, Division of Endocrinology, Charles R. Drew University, Los Angeles [325]

DAVID R. BICKERS, MD
Carl Truman Nelson Professor and Chair, Department of Dermatology, College of Physicians and Surgeons, Columbia University Medical Center, New York [51]

HENRY J. BINDER, MD
Professor of Medicine, Professor of Cellular and Molecular Physiology, Yale University, New Haven [275]

THOMAS D. BIRD, MD
Professor of Neurology and Medicine, University of Washington; Veterans Affairs Puget Sound Medical Center, Seattle [350, 364]

NEIL R. BLACKLOW, MD
Chairman Emeritus, Department of Medicine, Professor of Medicine, University of Massachusetts Medical School, Worcester; Visiting Professor of Medicine, Harvard Medical School, Boston [168]

MARTIN J. BLASER, MD
Chairman, Department of Medicine, Frederick H. King Professor of Internal Medicine; Professor of Microbiology, New York University School of Medicine, New York [135, 139]

CLARA D. BLOOMFIELD, MD
William G. Pace III Professor of Cancer Research, Cancer Scholar and Senior Advisor, The Ohio State University Comprehensive Cancer and The Arthur G. James Cancer Hospital and Richard J. Solove Research Institute, Columbus [96]

RICHARD S. BLUMBERG, MD
Chief, Division of Gastroenterology, Hepatology, and Endoscopy, Brigham and Women’s Hospital, Boston [276]

DAVID M. BODINE, PhD
Chief, Hematopoiesis Section, Genetics and Molecular Biology Branch, National Human Genome Research Institute, Bethesda [59]

JEAN L. BOLOGNIA, MD
Professor of Dermatology, Yale University School of Medicine, New Haven [48]

GEORGE J. BOSL, MD
Chairman, Department of Medicine, Memorial Sloan-Kettering Cancer Center; Professor of Medicine, Weill Medical College of Cornell University, New York [82]
MICHAEL J. CORBEL, PhD, DSc(Med), FiBiol, FRCPath
Head, Division of Bacteriology, National Institute for Biological Standards and Control, Potters Bar, United Kingdom [141]

LAWRENCE COREY, MD
Professor, Medicine and Laboratory Medicine; Head, Virology Division, University of Washington; Head, Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, Seattle [163, 179]

FELICIA COSMAN, MD
Associate Professor of Clinical Medicine, Columbia University College of Physicians and Surgeons; Medical Director, Clinical Research Center, Helen Hayes Hospital, West Haverstraw, New York [333]

MARK A. CREAGER, MD
Professor of Medicine, Harvard Medical School; Physician, Brigham and Women’s Hospital, Boston [231, 232]

PHILIP E. CRYER, MD
Irene E. and Michael M. Karl Professor of Endocrinology and Metabolism in Medicine, Washington University School of Medicine, St. Louis [324]

RONALD G. CRYSTAL, MD
Professor and Chair, Department of Genomic Medicine, Weill Medical College of Cornell University; Chief, Division of Pulmonary and Critical Care Medicine, New York Presbyterian Hospital-Weill Cornell Medical Center, New York [309]

JOHN J. CUSH, MD
Medical Director, Arthritis Center, Presbyterian Hospital of Dallas, Dallas [311]

CHARLES A. CZESLIER, MD, PhD
Professor of Medicine, Harvard Medical School; Chief, Division of Sleep Medicine; Director, Sleep Disorders and Circadian Medicine, Brigham and Women’s Hospital, Boston [24]

MARINOS C. DALAKAS, MD
Professor of Neurology; Chief, Neuromuscular Diseases Section, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda [369]

JOSEPH DALMAU, MD, PhD
Associate Professor of Neurology, Department of Neurology, University of Pennsylvania, Philadelphia [87]

DANIEL F. DANZL, MD
Professor and Chair, Department of Emergency Medicine, University of Louisville School of Medicine, Louisville [19]

ROBERT B. DAROFF, MD
Professor of Neurology and Associate Dean, Case Western Reserve University School of Medicine, Cleveland [20]

CHARLES E. DAVIS, MD
Professor of Pathology and Medicine Emeritus, University of California San Diego School of Medicine; Director Emeritus, Microbiology Laboratory, University of California San Diego Medical Center, San Diego [192]

STEVEN R. DEITCHER, MD
Head, Section of Hematology and Coagulation Medicine, Department of Hematology-Transfusion Medicine, The Cleveland Clinic Foundation, Cleveland [103]

JOHN DEL VALLE, MD
Professor and Senior Associate Chair of Medicine, Graduate Medical Education, Department of Internal Medicine, University of Michigan Health System, Ann Arbor [274]

MAHLON R. DELONG, MD
Timmie Professor of Neurology; Director of Neuroscience, Emory University School of Medicine, Atlanta [351]

MARIE B. DEMAY, MD
Associate Professor of Medicine, Harvard Medical School, Boston [331]

BRADLEY M. DENKER, MD
Assistant Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women’s Hospital, Boston [40]

DAVID T. DENNIS, MD, MPH
Faculty Affiliate, Department of Microbiology, Colorado State University; Medical Epidemiologist, Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins [143, 156]

ROBERT J. DESNICK, MD, PhD
Professor and Chair, Department of Human Genetics, Mount Sinai School of Medicine of New York University, New York [337]

BETTY DIAMOND, MD
Chief, Division of Rheumatology, Department of Microbiology and Immunology, Albert Einstein College of Medicine, New York [299]

JULES L. DIENSTAG, MD
Professor of Medicine, Harvard Medical School; Physician, Massachusetts General Hospital, Boston [78, 285–287, 291]

WILLIAM P. DILLON, MD
Professor of Radiology, Section Chief, Neuroradiology, Vice-Chair for Research Radiology, University of California San Francisco, San Francisco [347]

CHARLES A. DINARELLO, MD
Professor of Medicine, University of Colorado Health Sciences Center, Denver [16]

ROBERT G. DLUHY, MD
Professor of Medicine, Harvard Medical School, Brigham and Women’s Hospital, Boston [321]

RAFAEL DOLIN, MD
Maxwell Finland Professor of Medicine (Microbiology and Molecular Genetics); Dean for Academic and Clinical Programs, Harvard Medical School, Boston [162, 170, 171]

DAVID M. DOZA, MD, MPH
Assistant Professor of Medicine, Brown Medical School; Division of Geriatrics, Rhode Island Hospital, Providence [8]

DANIEL B. DRACHMAN, MD
Professor of Neurology and Neuroscience; WW Smith Charitable Foundation Professor of Neuroimmunology; Director, Neuromuscular Unit, The Johns Hopkins University School of Medicine, Baltimore [366]

JEFFREY M. DRAZEN, MD
Professor of Medicine, Harvard Medical School, Boston [233–235, 252]

THOMAS D. DUBOSE, JR., MD
Professor and Chair, Department of Internal Medicine, Professor, Department of Physiology and Pharmacology, Wake Forest University School of Medicine, Winston-Salem [42]

J. STEPHEN DUMLER, MD
Professor, Division of Medical Microbiology, Department of Pathology and the Program in Cellular and Molecular Medicine, The Johns Hopkins University School of Medicine; Department of Molecular Microbiology and Immunology, The Johns Hopkins University Bloomberg School of Public Health, Baltimore [158]

ANDREA E. DUNAI, MD
Charles F. Kettering Professor of Medicine, Northwestern University Feinberg School of Medicine; Chief, Division of Endocrinology, Metabolism and Molecular Medicine, Northwestern University, Chicago [5]

SAMUEL C. DURSO, MD
Associate Professor of Medicine, Division of Geriatric Medicine and Gerontology, The Johns Hopkins University School of Medicine; Deputy Director of Education, Co-Director Fellowship Training Program, Director of Ambulatory Clinical Services, Baltimore [28]

JANICE P. DUTCHER, MD
Professor of Medicine, New York Medical College; Associate Director, Clinical Affairs, Our Lady of Mercy Cancer Center, Bronx [88]

JOHANNA T. DWYER, DSc
Professor of Medicine and Community Health, Tufts University School of Medicine and Friedman School of Nutrition; Director, Frances Stern Nutrition Center; Tufts-New England Medical Center Sensor Scientist; Nutritional Epidemiology Program, Jean Mayer USDA Human Nutrition Center on Aging at Tufts, Boston [60]

VICTOR J. DZAU, MD
Hershey Professor of Medicine, Harvard Medical School; Chairman, Department of Medicine and Director of Research, Brigham and Women’s Hospital, Boston [231, 232]

JEFFREY S. DZIEZCKOWSKI, MD
Physician, New Britain General Hospital, New Britain [99]

J. DONALD EASTON, MD
Professor and Chair, Department of Clinical Neurosciences, Brown Medical School and Rhode Island Hospital, Providence [349]

DAVID A. EHRRMANN, MD
Associate Professor, Section of Endocrinology, Department of Medicine, University of Chicago Pritzker School of Medicine, Chicago [44]

EZKIEL J. EMAUHU, MD, PhD
Chief, Department of Clinical Bioethics, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda [9]

LINDA L. EMAUHU, MD
Buehler Professor of Geriatric Medicine, Director, Buehler Center on Aging, Northwestern University School of Medicine, Chicago [9]

JOHN W. ENGSTROM, MD
Professor of Neurology; Vice Chairman, Residency Program Director, University of California San Francisco, San Francisco [15, 354]

ANTHONY S. FAUCI, MD
Chief, Laboratory of Immune Regulation; Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda [172, 173, 205, 295, 306]

MURRAY J. FAVUS, MD
Professor of Medicine, University of Chicago Pritzker School of Medicine, Division of Biological Sciences, Chicago [268, 334]

ROBERT G. FENTON, MD, PhD
Associate Professor of Medicine, University of Maryland Greenebaum Cancer Center, Baltimore [69]
Eliot A. Phillipsorn, MD
Sir John and Lady Eaton Professor and Chair, Department of Medicine, University of Toronto, Toronto, Ontario, Canada [246, 247]

Gerald B. Pier, PhD
Professor of Medicine (Microbiology and Molecular Genetics), Harvard School of Medicine, Boston [105]

Daniel K. Podolsky, MD
Mallinckrodt Professor of Medicine, Harvard Medical School; Chief, Gastroenterology, Massachusetts General Hospital, Boston [289, 290]

Ronald E. Polk, Pharm, D.
Professor of Pharmacy and Medicine, Chair, Department of Pharmacy, School of Pharmacy, Virginia Commonwealth University, Richmond [118]

Matthew Pollack, MD
Professor of Medicine, Uniformed Services University; F. Edward Hébert School of Medicine; Attending Staff Physician, Internal Medicine and Infectious Diseases, National Naval Medical Center, Bethesda [136]

Richard J. Pollack, PhD
Instructor of Tropical Public Health, Department of Immunology and Infectious Diseases, Harvard School of Public Health, Boston [379]

John T. Potts, Jr., MD
Jackson Distinguished Professor of Clinical Medicine, Harvard Medical School, Boston [332]

Lawrie W. Powell, MD, PhD
Professor of Medicine, The University of Queensland and The Royal Brisbane and Women’s Hospital, Brisbane, Queensland, Australia [336]

Alvin C. Powers, MD
Ruth K. Scoville Professor of Medicine, Division of Diabetes, Endocrinology, and Metabolism, Vanderbilt University Medical Center; Chief, Diabetes and Endocrinology Section, VA Tennessee Valley Healthcare System, Nashville [323]

Daniel S. Pratt, MD
Assistant Professor of Medicine, Tufts University School of Medicine; Medical Director of Liver Transplantation, New England Medical Center, Boston [38, 283]

Daniel T. Price, MD
Assistant Professor of Medicine, Boston University School of Medicine; Staff Physician, Boston Veterans Affairs Medical Center, West Roxbury [223]

Darwin J. Prockop, MD, PhD
Director of Center for Gene Therapy and Professor of Biochemistry, Tulane Health Sciences Center, New Orleans [342]

Stanley B. Prusiner, PhD
Director, Institute for Neurodegenerative Diseases; Professor, Departments of Neurology, Biochemistry and Biophysics, University of California San Francisco, San Francisco [362]

Daniel J. Rader, MD
Associate Professor, Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia [335]

Sanjay Ram, MD
Assistant Professor of Medicine, Section of Infectious Diseases, Boston University School of Medicine and Boston Medical Center, Boston [128]

Didier Raoult, MD
Professor of Medicine, Unité des Rickettsies, School of Medicine, University of Aix-Marseille, Marseille, France [158]

Neil H. Raskin, MD
Professor of Neurology, University of California San Francisco, San Francisco [14]

Mario C. Raviglione, MD
Director, Stop TB Department, World Health Organization, Geneva, Switzerland [150]

Sharon L. Reed, MD
Professor of Pathology and Medicine, Director, Microbiology and Virology Laboratories, University of California Medical Center, San Diego [194]

Antonio J. Reginato, MD
Professor of Medicine; Head, Division of Rheumatology, Cooper University Medical Center, Robert Wood Johnson Medical School at Camden, Camden [313]

Richard C. Reichman, MD
Professor of Medicine, Microbiology and Immunology; Head, Infectious Diseases Unit, Senior Associate Dean for Clinical Research, University of Rochester School of Medicine and Dentistry, Rochester [169]

Carol M. Reife, MD
Assistant Professor of Medicine, Jefferson Medical College of Thomas Jefferson University, Philadelphia [36]

John J. Reilly, MD
Associate Professor of Medicine, Harvard Medical School; Clinical Director, Pulmonary and Critical Care Medicine, Brigham and Women’s Hospital, Boston [242]

John T. Repke, MD, FACOG
Professor and Chair, Department of Obstetrics and Gynecology, Pennsylvania State University College of Medicine; Obstetrician-Gynecologist In-Chief, The Milton S. Hershey Medical Center, Hershey [6]

Neil M. Resnick, MD
Professor of Medicine, University of Pittsburgh School of Medicine; Chief, Division of Geriatric Medicine, University of Pittsburgh Institute on Aging, Pittsburgh [8]

Victor I. Reus, MD
Professor of Psychiatry, University of California San Francisco; Medical Director, Langley Porter Hospital, San Francisco [371]

C. Fordham von Reyn, MD
Professor of Medicine, Chief, Infectious Diseases and International Health, Dartmouth Medical School, Lebanon [152]

Peter A. Rice, MD
Professor of Medicine and Chief, Section of Infectious Diseases, Boston University Medical Center, Boston [128]

Stuart Rich, MD
Professor of Medicine, Rush University Medical, Chicago [220]

Gary S. Richardson, MD
Assistant Professor of Psychiatry, Case Western Reserve University, Cleveland; Senior Research Scientist, Sleep Disorders and Research Center, Henry Ford Hospital, Detroit [24]

Gary L. Robertson, MD
Professor of Medicine and Neurology, Northwestern University Feinberg School of Medicine, Chicago [319]

Dan M. Roden, MD
Professor of Medicine and Pharmacology; Chief, Division of Clinical Pharmacology, Vanderbilt University School of Medicine, Nashville [3]

James A. Romano, Jr., PhD
Commander, US Army Medical Research Institute of Chemical Defense, Maryland [206]

Karen L. Roos, MD
John and Nancy Nelson Professor of Neurology, Indiana University School of Medicine, Indianapolis [360]

Allan H. Ropper, MD
Professor and Chairman of Neurology, Tufts University School of Medicine; Chief, Department of Neurology, St. Elizabeth’s Medical Center, Boston [257, 356, 357]

Roger N. Rosenberg, MD
Zale Distinguished Chair and Professor of Neurology, University of Texas Southwestern Medical Center at Dallas; Attending Neurologist, Parkland Memorial Hospital and Zale-Lipsky University Hospital, Dallas [352]

Myrna R. Rosenfeld, MD, PhD
Associate Professor of Neurology, Department of Neurology, University of Pennsylvania, Philadelphia [87]

Wendell Rossos, MD
Florence Reynaud McAlister Professor of Medicine and Medical Research, Department of Medicine, Duke University Medical School, Durham [93]

Michael A. Rubin, MD, PhD
Assistant Professor, Internal Medicine, Division of Infectious Diseases, Division of Clinical Epidemiology, Salt Lake City [27]

Robert M. Russell, MD
Professor, Friedman School of Nutrition Science and Policy; Director and Scientist, Jean Mayer USDA Human Nutrition Center on Aging at Tufts, Boston [61]

Thomas A. Russo, MD, CM
Assistant Professor of Medicine, Division of Infectious Diseases, Department of Medicine, State University of New York at Buffalo; Veterans Affairs Medical Center, Buffalo [134, 147]

Stephen M. Sagar, MD
Professor of Neurology, Case Western Reserve School of Medicine; Director of Neuro-Oncology, Ireland Cancer Center, University Hospitals of Cleveland, Cleveland [358]

Merle A. Sande, MD
Professor of Medicine, University of Utah School of Medicine; President, Academic Alliance for AIDS Care and Prevention in Africa Foundation, Salt Lake City [27]

Edward A. Sausville, MD, PhD
Associate Director for Clinical Research, Greenebaum Cancer Center, University of Maryland, Baltimore [70]

Mohamed H. Sayegh, MD
Associate Professor of Medicine, Harvard Medical School; Director, Transplantation Research Center, Brigham and Women’s Hospital and Children’s Hospital, Boston [263]

Howard L. Scher, MD
D. Wayne Calloway Chair in Urologic Oncology, Attending Physician and Chief, Genitourinary Oncology Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center; Professor of Medicine, Weill Medical College of Cornell University, New York [80, 81]
Contributors xxiii

FRANK E. SPEIZER, MD
Edward H. Kass Professor of Medicine, Harvard Medical School; Co-Director, Channing Laboratory, Brigham and Women’s Hospital; Professor of Environmental Science, Harvard School of Public Health, Boston [238]

ANDREW SPIELMAN, ScD
Professor of Tropical Public Health, Harvard School of Public Health, Boston [379]

JERRY L. SPIVAK, MD
Professor of Medicine and Oncology, Johns Hopkins University School of Medicine, Baltimore [95]

WALTER E. STAMMI, MD
Professor of Medicine and Head, Division of Allergy and Infectious Diseases, University of Washington School of Medicine, Seattle [160, 269]

ALLEN C. STEERE, MD
Professor of Medicine, Harvard Medical School; Director of Rheumatology, Massachusetts General Hospital, Boston [157]

DAVID S. STEPHENS, MD
Director, Division of Infectious Diseases, Emory University Hospital; Stephen W. Schwarzmann Professor and Executive Vice Chair, Department of Medicine, Emory University School of Medicine, Atlanta [127]

ROBERT S. STERN, MD
Carl I. Herzog Professor of Dermatology, Harvard Medical, Boston [50]

DENNIS L. STEVENS, MD, PhD
Professor of Medicine, University of Washington School of Medicine, Seattle; Chief, Infectious Diseases, VA Medical Center, Boise [110]

RICHARD M. STONE, MD
Clinical Director, Adult Leukemia Program, Dana-Farber Cancer Institute/Brigham and Women’s Hospital; Associate Professor of Medicine, Harvard Medical School, Boston [85]

STEPHEN E. STRAUS, MD
Senior Investigator, Laboratory of Clinical Investigation, National Institute of Allergy and Infectious Diseases; Director, National Center for Complementary and Alternative Medicine, National Institutes of Health, Bethesda [10, 370]

MORTON N. SWARTZ, MD
Professor, Department of Medicine, Harvard Medical School; Chief Emeritus, Infectious Disease, Chief, James Jackson Firm Medical Services, Massachusetts General Hospital, Boston [361]

A. JAMIL TAJIK, MD
Thomas J. Watson, Jr., Professor; Professor of Medicine and Pediatrics, Mayo Clinic College of Medicine Chair (Emeritus); Division of Cardiovascular Diseases and Internal Medicine; Consultant, Section of Pediatric Cardiology, Mayo Clinic, Minnesota [211]

JOEL D. TAURG, MD
Professor of Internal Medicine, and William M. and Gatha Burnett Professor for Arthritis Research, University of Texas Southwestern Medical Center, Dallas [296, 305]

SCOTT J. THALER, MD
Chief Medical Officer, AERAS Global TB Vaccine Foundation, Bethesda [314]

ZELIG A. TOCHNER, MD
Associate Professor, Department of Radiation Oncology, University of Pennsylvania Medical Center, Philadelphia [207]

LUCY STUART TOMPKINS, MD
Professor of Medicine (Infectious Diseases and Geographic Medicine), Professor of Microbiology, Immunology and Pathology, Stanford University School of Medicine, Stanford [144]

MARK TOPAZIAN, MD
Associate Professor of Medicine, Yale University School of Medicine; Assistant Director, Gastrointestinal Procedure Center, Yale New Haven Hospital, New Haven [227]

PHILLIP P. TOSKES, MD
Professor of Medicine and Director, Division of Gastroenterology, Hepatology and Nutrition; Associate Chairman for Clinical Affairs, Department of Medicine, University of Florida, Gainesville [293, 294]

JEFFREY M. TRENT, PhD
President and Scientific Director; Senior Investigator, Molecular Diagnostics and Target Validation Division, T-Gen, Phoenix [68]

ÉLBERT P. TRUOLOCK, MD
Rosemary and J. Jerome Flance Professor of Pulmonary Medicine, Washington University School of Medicine; Medical Director, Lung Transplantation Program, Barnes-Jewish Hospital, St. Louis [248]

KENNETH L. TYLER, MD
Reuler-Lewin Family Professor of Neurology; Professor of Medicine, Microbiology and Immunology, University of Colorado Health Sciences Center; Chief, Neurology Service, Denver VA Medical Center, Denver [360]
MICHAEL R. WESSELS, MD  
Professor of Pediatrics and Medicine (Microbiology and Molecular Genetics), Harvard Medical School; Chief, Division of Infectious Diseases, Children’s Hospital, Boston [121]

PETER J. ZIMETBAUM, MD  
Assistant Clinical Professor of Medicine, Harvard Medical School; Senior Physician, Beth Israel Deaconess Medical Center, Boston [112]

LEE M. WETZLER, MD  
Associate Professor of Medicine and Microbiology, Boston University School of Medicine, Boston [127]

MEIR WETZLER, MD  
Associate Professor of Medicine, Roswell Park Cancer Institute, Buffalo [96]

A. CLINTON WHITE, JR., MD  
Professor, Infectious Diseases Section, Department of Medicine, Baylor College of Medicine, Houston [204]

NICHOLAS J. WHITE, MD, DSc  
Professor of Tropical Medicine, Mahidol University, Bangkok, Thailand; and Oxford University, Oxford, UK [195]

RICHARD J. WHITLEY, MD  
Loeb Eminent Scholar in Pediatrics; Professor of Pediatrics, Microbiology, Medicine, and Neurosurgery, University of Alabama at Birmingham, Birmingham [164]

GORDON H. WILLIAMS, MD  
Professor of Medicine, Harvard Medical School; Chief, Cardiovascular Endocrinology Section, Brigham and Women’s Hospital, Boston [230, 321]

JOHN W. WINKELMAN, MD, PhD  
Assistant Professor of Psychiatry, Harvard Medical School; Medical Director, Sleep Health Center, Brigham and Women’s Hospital, Boston [24]

BRUCE U. WINTROUB, MD  
Professor and Chair of Dermatology, Associate Dean, School of Medicine, University of California San Francisco, San Francisco [50]

BERT VOGELSTEIN, MD  
Professor of Oncology and Pathology, Howard Hughes Investigator, The Sidney Kimmel Comprehensive Cancer Center, The Johns Hopkins University School of Medicine, Baltimore [68]

EVERETT E. VOKES, MD  
Director, Section of Hematology/Oncology; John E. Ultmann Professor of Medicine and Radiation Oncology, University of Chicago, Chicago [74]

TAMARA J. VOKES, MD  
Assistant Professor of Clinical Medicine, University of Chicago Pritzker School of Medicine, Chicago [334]

MATTHEW K. WALDOR, MD, PhD  
Associate Professor of Medicine and Microbiology, Tufts University School of Medicine, Boston [140]

DAVID H. WALKER, MD  
Professor and Chairman, Department of Pathology; Director, WHO Collaborating Center for Tropical Diseases, University of Texas Medical Branch, Galveston [158, 239]

RICHARD J. WALLACE, JR., MD  
Chairman, Department of Microbiology, John Chapman Professorship in Microbiology, Professor of Medicine, University of Texas Health Center, Tyler [149]

B. TIMOTHY WALSH, MD  
Ruane Professor of Psychiatry, College of Physicians and Surgeons, Columbia University; Director, Eating Disorders Research Unit, New York State Psychiatric Institute, New York [65]

PETER D. WALZER, MD  
Associate Chief of Staff for Research, Cincinnati VA Medical Center; Professor of Medicine, University of Cincinnati, Cincinnati [191]

FREDERICK C.S. WANG, MD  
Associate Professor of Dermatology, Emory University School of Medicine; Director, Mohs Surgery Unit, The Emory Clinic, Atlanta [73]

CARL V. WASHINGTON, JR., MD  
Assistant Professor of Dermatology, Emory University School of Medicine; Director, Mohs Surgery Unit, The Emory Clinic, Atlanta [73]

ANTHONY P. WEETMAN, MD, DSc  
Professor of Medicine and Dean, University of Sheffield Medical School; Consultant Physician, Northern General Hospital, Sheffield, UK [320]

STEVEN E. WEINBERGER, MD  
Professor of Medicine, Harvard Medical School; Senior Vice President, Medical Knowledge and Education Division, American College of Physicians, Philadelphia [30, 233–235, 240]

ROBERT A. WEINSTEIN, MD  
Professor of Medicine, Rush Medical College; Chair, Infectious Diseases, Cook County Hospital; Chief Operating Officer, The CORE Center, Chicago [116]

PETER F. WELLER, MD, FACP  
Professor of Medicine, Harvard Medical School; Co-Chief, Infectious Diseases Division; Chief, Allergy and Inflammation Division; Senior Vice Chair of Research, Department of Medicine, Beth Israel Deaconess Medical Center, Boston [199–202, 204]

MICHAEL R. WESSELS, MD  
Professor of Pediatrics and Medicine (Microbiology and Molecular Genetics), Harvard Medical School; Chief, Division of Infectious Diseases, Children’s Hospital, Boston [121]
The first edition of *Harrison’s Principles of Internal Medicine* was published more than half a century ago. Over the decades, this textbook has evolved to reflect the continuing advances in the field of internal medicine and to meet the growing information base required of medical students and clinical practitioners. The users of this sixteenth edition of *Harrison’s* will not even have to open the volume to see that it marks a transition point in the book’s history. The new cover is only the most obvious indication of a new direction for *Harrison’s*.

In shaping and revising this new version, the Editors have committed themselves to making the textbook as useful as possible to students and practitioners coping with the demands of modern medicine. The growth of evidence-based medicine, the prominence of managed care, and the explosion of information in fundamental areas such as the genetics of disease are only three of the many factors that make these demands different from those faced by physicians only a decade ago. Just as the cover retains key elements of the classic book, the content of the sixteenth edition retains the essential facts that remain clinically useful and important. However, through modifications in both its format and its content, the new *Harrison’s* addresses the changing needs of its readers.

The sixteenth edition of *Harrison’s* has a full-color format that facilitates quick reference and allows the inclusion of hundreds more high-quality illustrations than in previous editions. We expect that the reader’s convenience will be well served by the placement of color illustrations within the chapters rather than in the separate color atlas used in earlier editions. While providing the basic-science information that is critical to an understanding of biology and pathophysiology, this edition focuses more directly and extensively than ever on crucial aspects of clinical practice. Areas of emphasis include the approach to the patient, differential diagnosis, state-of-the-art treatment options, and disease prevention. Key topics, such as the immune system and HIV infection/AIDS, are covered in chapters amounting to “mini-textbooks.” New sections offer information on the formidable challenges posed by critical care medicine and by the threat of bioterrorism. New chapters provide coverage of highly relevant clinical topics such as disease screening, perimenopausal management and hormone replacement therapy, and end-of-life care. Virtually every chapter in this edition has been substantially rewritten, and 46 chapters either are entirely new or have new authors.

These are only highlights of the changes that the Editors hope will make the new *Harrison’s* a helpful tool—not only for the student who needs an expert source of basic knowledge in internal medicine, but also for the pressured practitioner who needs a clear, concise, and balanced distillation of the best information on which to base daily clinical decisions.

Part One, “Introduction to Clinical Medicine,” contains a new chapter that provides practical information about the screening approaches that every internist should consider for routine health maintenance. This chapter discusses the principles and guidelines used in screening for common conditions such as cancer, hypertension, lipid disorders, and osteoporosis. Another new chapter offers a pragmatic approach to the medical evaluation of patients who are about to undergo surgical procedures. In light of the growth of the hospice movement and the increased awareness of the sensitive issues—physical, mental, social, and existential—that surround end-of-life care, a new chapter on this complex topic provides insights, information, and guidance to practitioners dealing with dying patients and their families. The chapter on women’s health has been entirely revised and offers a broad overview of the approach to disorders that affect women disproportionately.

Part Two, “Cardinal Manifestations and Presentation of Diseases,” serves as a comprehensive introduction to clinical medicine as well as a practical guide to the care of patients with these manifestations. Each section focuses on a particular group of disorders, examining the concepts of pathophysiology and differential diagnosis that must be considered in caring for patients with these common clinical presentations. Major symptoms are reviewed and correlated with specific disease states, and clinical approaches to patients presenting with these symptoms are summarized. Every chapter has been updated, and three chapters have new authors. The chapter on sexual dysfunction now addresses disorders in both men and women.

Given the rapid advances in human genetics over the past several years, Part Three, “Genetics and Disease,” has once again been completely updated. The material included in this edition is strongly geared toward clinical practice, in which genetic information increasingly comes into play. The new chapter on stem cell and gene transfer in clinical medicine addresses a timely and controversial topic, defining different types of stem cells and discussing their potential clinical applications.

Part Four, “Nutrition,” covers nutritional considerations related to clinical medicine. Areas of focus include nutritional and dietary assessment, nutritional requirements, protein-energy malnutrition, eating disorders, obesity, and enteral and parenteral nutrition therapy.

The core of *Harrison’s* continues to encompass the disorders of the organ systems and is contained in Parts Five through Sixteen. These sections include succinct accounts of the pathophysiology of diseases involving the major organ systems as well as infectious diseases, with an emphasis on clinical manifestations, diagnostic procedures, differential diagnosis, and treatment strategies and guidelines.

Part Five, “Oncology and Hematology,” includes four chapters by new authors. An increasing proportion of patients who develop cancer are being cured. It is important to detect late consequences as early as possible in their natural history to optimize outcome. The chapter on the late consequences of cancer and its treatment helps physicians following such patients to know what to look for in addition to a recurrence of the cancer. Advances in the management of many cancers are highlighted—for example, the dramatic impact of imatinib mesylate (Gleevec) on chronic myeloid leukemia and gastrointestinal stromal cell tumors and the role of rituximab in the management of lymphoma and autoimmune diseases. The chapter delineating the principles of radiation therapy has been entirely rewritten by Eli Glatstein and is a companion piece to this author’s chapter on radiation bioterrorism in Part Seven (see below). The hematology section features the World Health Organization’s new classification of lymphoid and myeloid neoplasms. One of the most rapidly expanding areas of medicine is the development of novel agents to interfere with blood coagulation. With a new author who is an expert in this field, the chapter on anticoagulant, fibrinolytic, and antiplatelet therapy reviews all these new products and their indications.

Part Six, “Infectious Diseases,” summarizes the latest information on pathology, genetics, and epidemiology while focusing sharply on the needs of clinicians who must accurately diagnose and treat infections under time pressure and cost constraints. In particular, the inclusion of dozens more illustrations in full color provides easily accessible information to assist clinicians with these challenges. Specific recommendations are provided for therapeutic regimens, including the drug of choice, dose, duration, and alternatives. Current trends in antimicrobial resistance are presented and considered in light of their impact on therapeutic choices. A new chapter offers key information on the management of the complex clinical issues raised by *Clostridium difficile*–associated disease, including pseudomembranous colitis. New authors cover the latest advances in the management of diseases...
caused by staphylococci and nontuberculous mycobacteria, viral gastroenteritis, and brucellosis. The superb chapter by Raphael Dolin on common viral respiratory infections has been expanded to include thorough coverage of severe acute respiratory syndrome (SARS). Now placed in a separate section with the overview of the human retroviruses, the chapter on HIV infection and AIDS by Anthony S. Fauci and H. Clifford Lane has been completely revised and updated, with an emphasis on therapeutic strategies. This chapter is widely considered to be a classic in the field; its clinically pragmatic focus in combination with its comprehensive and analytical approach to the pathogenesis of HIV disease has allowed its use as the sole complete reference on HIV/AIDS in medical schools.

In recent years, physicians have found themselves on the front line of response to bioterrorist attacks around the world. Since the attacks on the United States on September 11, 2001, and the subsequent anthrax attacks, the nation has been preparing for the further attacks that will inevitably come. Part Seven, “Bioterrorism and Clinical Medicine,” consists of entirely new material written by authorities in three areas of bioterrorism: microbial, chemical, and radiation. Edited by Harrison’s editor Anthony S. Fauci, these chapters are written succinctly and include easily readable charts, tables, and algorithms; their goal is to confer an understanding of the pathogenesis, diagnosis, treatment, and prognosis of the diseases in question.

Part Eight, “Disorders of the Cardiovascular System,” is once again edited by the preeminent expert in the field, Eugene Braunwald. A new chapter covers the clinically important topics of unstable angina and non-ST-segment elevation myocardial infarction; three other chapters have new authors; and every chapter has been revised to reflect the latest trends and strategies for management. These include primary percutaneous coronary intervention for ST-segment elevation myocardial infarction as well as new drugs and devices for the treatment of heart failure.

Enormous strides have been made in the use of lung transplantation for selected patients with end-stage, irreversible, pulmonary parenchymal and vascular disease. Part Nine, “Disorders of the Respiratory System,” includes a chapter by a new author that focuses on the selection of patients for this intervention. New authors have also taken on the broad topic of pneumonia and lung abscess, providing focus and a clinical perspective to help the reader grasp the central issues involved in the diagnosis and management of both community-acquired and nosocomial disease.

With advances in health care delivery and pressures aimed at cost containment, critical care units account for a growing percentage of hospital beds. Part Ten, “Critical Care Medicine,” is a new section of Harrison’s that is devoted to the provision of optimal care in this medical setting of growing importance. Incorporating both new chapters and refocused chapters on topics covered in previous editions, this part deals with three main areas: respiratory critical care, shock and cardiac arrest, and neurologic critical care. The approach to the patient and the central tenets underlying critical care are at the heart of this part of the sixteenth edition.

Part Eleven, “Disorders of the Kidney and Urinary Tract,” includes contributions from several new authors and, as in previous editions, provides a thorough overview of the urinary-tract disorders encountered in internal medicine.

Part Twelve, “Disorders of the Gastrointestinal System,” includes a new chapter on familial Mediterranean fever. The chapter on the approach to the patient with gastrointestinal disease has been completely reworked by a new author, as has the chapter on diverticular and vascular disease of the bowel. The chapters on the various categories of viral hepatitis have been extensively revised and updated to reflect breakthrough advances in treatment.

The first chapter in Part Thirteen, “Disorders of the Immune System, Connective Tissue, and Joints,” provides an introduction to the immune system that has become a classic in its field and is often used as the textbook of immunology in postgraduate and medical school courses. This chapter combines an in-depth description and analysis of the principles of basic immunology with an easy flow into the application of these principles to clinical disease states. Its description of the relationship of innate to adaptive immunity is a model for understanding the intricacies of the human immune system. Once again, the authors have extensively revised this chapter to bring it up to date with regard to recent rapid advances in both basic and clinical immunology. In the section on disorders of immune-mediated injury, the spondyloarthropathies have been grouped together in one chapter that clearly and comprehensively discusses the similarities and dissimilarities among the various diseases in this category. The breakthrough advances in immunomodulatory therapy that have been realized in rheumatology over the past few years are captured in the spondyloarthropathy chapters and the extensively revised chapters on rheumatoid arthritis and systemic lupus erythematosus. A new chapter covers fibromyalgia, arthritis associated with systemic disease, and other arthritides.

Part Fourteen, “Endocrinology and Metabolism,” includes six chapters with new authors as well as a timely new chapter on the perimenopause transition and hormone replacement therapy. The writing of the latter chapter coincided with publication of results from the Women’s Health Initiative that unexpectedly showed an increased risk of cardiovascular disease among women who received estrogen treatment. The author reviews the literature in this area and provides practical algorithms for the management of patients during this transition. The new authors of the chapter on disorders of sexual differentiation highlight novel insights derived from elucidation of the genetic basis of sex determination. The outstanding new review of bone and mineral metabolism lays a superb foundation for an understanding of the pathophysiology and treatment of various metabolic bone diseases. The newly authored version of the chapter on disorders of lipoprotein metabolism offers a much sharper focus on the classification, diagnosis, and treatment of disorders of cholesterol and triglyceride metabolism, emphasizing the use of statins for the reduction of cardiovascular risk.

The new chapter on Wilson disease reports on the substantially modified treatment recommendations for this entity.

Part Fifteen, “Neurologic Disorders,” has been extensively updated. A comprehensive new chapter on Alzheimer’s disease and related dementias summarizes the recent explosion of knowledge on this topic, highlighting the new understanding of the genetics of these dementias and the molecules that trigger them as well as providing a clinical guide to diagnosis, differential diagnosis, and the latest treatments. The new chapter on Parkinson’s disease reviews the recent genetic findings and provides an authoritative approach to therapy, including surgical options. The chapter on cerebrovascular diseases has been extensively rewritten, offering an evidence-based approach to the treatment and prevention of stroke, the third leading killer in the Western world. The updated chapter on multiple sclerosis presents the most recent advances in therapy and a practical approach to management of different stages of the disease. Finally, the recognition of bovine spongiform encephalopathy in many regions of the world has focused the global health care community on the biology and clinical manifestations of prion diseases; the sixteenth edition of Harrison’s includes a comprehensive review of this subject by Nobel Laureate Stanley Prusiner.

Part Sixteen, “Poisoning, Drug Overdose, and Envenomation,” has been thoroughly revised and streamlined to focus on the topics most relevant to internal medicine. In view of the requirements for continuing education for licensure and relicensure as well as the emphasis on certification and recertification, a revision of the PreTest Self-Assessment and Review will again be published with this edition. This volume is in the capable hands of a new author, Dr. Charles Wiener from Johns Hopkins. It consists of several hundred questions based on the sixteenth edition of Harrison’s, along with answers and explanations for the answers. The Companion Handbook, which was pioneered as a supplement to the eleventh edition of Harrison’s, has been reworked as a concise quick-reference clinical manual; the Manual of Medicine will appear
shortly after the publication of this edition, along with a PDA version, Harrison’s OnHand. In 1998, Harrison’s went online to provide a “living” textbook of internal medicine. In addition to permitting full search capabilities of the text, Harrison’s Online offers frequent updates, reports of clinical trials, practice guidelines, online lectures, and concise reviews of timely topics as well as additional and updated references (with links to MEDLINE abstracts) and illustrations.

We wish to express our appreciation to our many associates and colleagues, who, as experts in their fields, have offered us constructive criticism and helpful suggestions. We acknowledge especially the contributions of the following individuals: Joseph Alpert, Michael Bray, Mark D. Carlson, Daniel H. Lowenstein, Lawrence C. Madoff, Thomas R. Martin, Chung Owyang, Alice Pau, and Mary Wright.

We thank in particular Kenneth and Elaine Kaye and Lindsey Baden, who gathered many high-quality illustrations of infectious disease manifestations. We also express our gratitude to Eileen J. Scott, who has applied her editorial expertise to the past six editions of Harrison’s, and Marsha Cohen, who has been the text and cover designer for the past five editions.

This book could not have been edited without the dedicated help of our co-workers in the editorial offices of the individual editors. We are especially indebted to Patricia L. Duffey, Gregory K. Folksers, Sarah Matero, Julie B. McCoy, Jaylyn Olivo, Elizabeth Robbins, Leslie Runnels, Kathryn Saxon, Marie Scurti, and Sue Anne Tae.

Finally, we continue to be highly indebted to three outstanding members of the McGraw-Hill organization: Mariapaz Ramos Englis, Senior Managing Editor; Robert Laffler, Production Director; and Martin J. Wonsiewicz, Publisher. They are an effective team who have given the Editors constant encouragement and sage advice. They have been instrumental in guiding the many changes instituted with this edition of Harrison’s and in bringing this volume to fruition in a timely manner.

THE EDITORS
This page intentionally left blank.
WHAT IS EXPECTED OF THE PHYSICIAN  The accelerating pace of change in medicine stems from an explosion of scientific information and the need to blend this information into the art and practice of medicine. The role of science in medicine is clear. Science-based technology and deductive reasoning form the foundation for the solution to many clinical problems. Spectacular advances in genetics, biochemistry, and imaging techniques allow access to the innermost parts of the cell and the most remote recesses of the body. Revelations about the nature of genes and single cells have opened the portal for formulating a new molecular basis for the physiology of systems. These physiologic insights will undoubtedly result in a better understanding of complex disease processes and new approaches to disease treatment and prevention. Highly advanced therapeutic maneuvers are increasingly a major part of medical practice. Yet skill in the most sophisticated application of laboratory technology and in the use of the latest therapeutic modality alone does not make a good physician.

When a patient poses challenging clinical problems, an effective physician must be able to identify the crucial elements in a complex history and physical examination and to extract the key laboratory results from the crowded computer printouts of data in order to determine a rational therapeutic course of action. Where this effort often falls short is in the patient-physician relationship, which has traditionally characterized the practice of medicine, is increasingly in jeopardy because of the growing complexity of medicine and the changes in health care delivery systems. The physician must be aware that the hospital is an intimidating environment for most individuals. Hospitals are filled with unfamiliar personnel; they may be obliged to share a room with other patients who have their own health problems. It is little wonder that patients who have their own health problems. It is little wonder that hospital patients are apprehensive and fearful. Physicians should instill confidence and should be reassuring (as depicted humorously in Fig. 1-1) but should never be arrogant. A professional attitude, coupled with warmth and openness, can do much to alleviate anxiety and to encourage patients to share all aspects of their medical history. Whatever the patient’s attitude, the physician needs to consider the setting in which an illness occurs—in terms not only of the patients themselves but also of their familial, social, and cultural backgrounds. The ideal patient-physician relationship is based on thorough knowledge of the patient, on mutual trust, and on the ability to communicate.

THE PATIENT-PHYSICIAN RELATIONSHIP: A HUMANE APPROACH IN THE FACE OF CHANGE  In this era of “techno-medicine,” physicians need to approach patients not as “cases” or “diseases” but as individuals whose problems all too often transcend their physical complaints. Most patients are anxious and fearful. Physicians should instill confidence and should be reassuring (as depicted humorously in Fig. 1-1) but should never be arrogant. A professional attitude, coupled with warmth and openness, can do much to alleviate anxiety and to encourage patients to share all aspects of their medical history. Whatever the patient’s attitude, the physician needs to consider the setting in which an illness occurs—in terms not only of the patients themselves but also of their familial, social, and cultural backgrounds. The ideal patient-physician relationship is based on thorough knowledge of the patient, on mutual trust, and on the ability to communicate.

Technological Complexity and Managed Care  The one-to-one patient-physician relationship, which has traditionally characterized the practice of medicine, is increasingly in jeopardy because of the growing complexity of medicine and the changes in health care delivery systems. Often the management of an individual patient is a team effort involving a number of physicians and other professional personnel. Increasingly, hospitalists assume the responsibility for patient management in the inpatient setting. The patient can benefit greatly from effective collaboration among health care professionals, but it is the duty of the patient’s principal physician to provide guidance through an illness. To carry out this difficult task, this physician must be familiar with the techniques, skills, and objectives of specialist physicians and of colleagues in the fields allied to medicine. In giving the patient an opportunity to benefit from scientific advances, the primary physician must retain responsibility for the major decisions concerning diagnosis and treatment.

The practice of medicine in a managed-care setting puts additional stress on the patient-physician relationship. Whatever the potential advantages of organized medical groups such as health maintenance organizations (HMOs), there are also drawbacks, including the loss of the clear identification of the physician who is primarily and continuously responsible for the patient. Even under these circumstances, it is essential for each patient to have a physician who has an overview of the problems and who is familiar with the patient’s reaction to the illness, the drugs the patient is given, and the challenges the patient faces. Moreover, in managed-care settings, many physicians must treat patients within a restricted time frame, with limited access to specialists, and under organizational guidelines that may compromise their ability to exercise their individual clinical judgment. As difficult as these restrictions may be, it is the ultimate responsibility of the physician, in close consultation with the patient, to determine what is best for the patient. This responsibility cannot be relinquished in the name of compliance with organizational guidelines.

The Modern Hospital Environment  The physician must be aware that the hospital is an intimidating environment for most individuals. Hospitalized patients find themselves surrounded by air jets, buttons, and lights; invaded by tubes and wires; and beset by the numerous members of the health care team—nurses, nurses’ aides, physicians’ assistants, social workers, technologists, physical therapists, medical students, house officers, attending and consulting physicians, and many others. They may be transported to special laboratories and imaging facilities replete with blinking lights, strange sounds, and unfamiliar personnel; they may be obliged to share a room with other patients who have their own health problems. It is little wonder that
patients may lose their sense of reality. A strong personal relationship with the physician helps to sustain the patient in such a stressful situation.

Societal Trends Many trends in contemporary society tend to make medical care impersonal. These trends, some of which have been mentioned already, include (1) vigorous efforts to reduce the escalating costs of health care; (2) the growing number of managed-care programs, which are intended to reduce costs but in which the patient may have little choice in selecting a physician or in seeing that physician consistently; (3) increasing reliance on technological advances and computerization for many aspects of diagnosis and treatment; (4) increased geographic mobility of both patients and physicians; (5) the need for numerous physicians to be involved in the care of most patients who are seriously ill; and (6) an increasing tendency on the part of patients to express their frustrations with the health care system through malpractice suits.

Given these changes in the medical care system, it is a major challenge for physicians to maintain the humane aspects of medical care. The American Board of Internal Medicine, working together with the American College of Physicians—American Society of Internal Medicine and the European Federation of Internal Medicine, has published a Charter on Medical Professionalism that underscores three main principles in physicians’ contract with society: (1) the primacy of patient welfare, (2) patient autonomy, and (3) social justice. The humanistic qualities of a physician must encompass integrity, respect, and compassion. Availability, the expression of sincere concern, the willingness to take the time to explain all aspects of the illness, and a nonjudgmental attitude when dealing with patients whose cultures, lifestyles, attitudes, and values differ from those of the physician are just a few of the characteristics of the humane physician. Every physician will, at times, be challenged by patients who evoke strongly negative or positive emotional responses. Physicians should be alert to their own reactions to such patients and situations and should consciously monitor and control their behavior so that the patient’s best interest remains the principal motivation for their actions at all times.

An important aspect of patient care involves an appreciation of the “quality of life,” a subjective assessment of what each patient values most. Such an assessment requires detailed, sometimes intimate knowledge of the patient, which can usually be obtained only through deliberate, unhurried, and often repeated conversations. It is in these situations that the time constraints of a managed-care setting may prove particularly problematic. Time pressures will always threaten these interactions but do not diminish the importance of understanding patients’ priorities from their point of view.

The famous statement of Dr. Francis Peabody is even more relevant today than when delivered more than three-quarters of a century ago:

The significance of the intimate personal relationship between physician and patient cannot be too strongly emphasized, for in an extraordinarily large number of cases both the diagnosis and treatment are directly dependent on it. One of the essential qualities of the clinician is interest in humanity, for the secret of the care of the patient is in caring for the patient.

CLINICAL SKILLS ▪ History-Taking The written history of an illness should embody all the facts of medical significance in the life of the patient. Recent events should be given the most attention. The patient should, at some early point, have the opportunity to tell his or her own story of the illness without frequent interruption and, when appropriate, receive expressions of interest, encouragement, and empathy from the physician. Any event related by the patient, however trivial or apparently remote, may be the key to the solution of the medical problem. In general, only patients who feel comfortable will provide the physician with complete information.

An informative history is more than an orderly listing of symptoms; something is always gained by listening to patients and noting the way in which they describe their symptoms. Inflections of voice, facial expression, gestures, and attitude may reveal important clues to the meaning of the symptoms to the patient. Because patients vary in their medical sophistication and ability to recall facts, the reported medical history should be corroborated whenever possible. The family and social history can also provide important insights into the types of diseases that should be considered. In listening to the history, the physician discovers not only something about the disease but also something about the patient. The process of history-taking provides an opportunity to observe the patient’s behavior and to watch for features to be pursued more thoroughly during the physical examination.

The very act of eliciting the history provides the physician with the opportunity to establish or enhance the unique bond that is the basis for the ideal patient-physician relationship. It is helpful to develop an appreciation of the patient’s perception of the illness, the patient’s expectations of the physician and the medical care system, and the financial and social implications of the illness to the patient. The confidentiality of the patient-physician relationship should be emphasized, and the patient should be given the opportunity to identify any aspects of the history that should not be disclosed to others.

Physical Examination Physical signs are objective indications of disease whose significance is enhanced when they confirm a functional or structural change already suggested by the patient’s history. At times, however, the physical signs may be the only evidence of disease.

The physical examination should be performed methodically and thoroughly, with consideration for the patient’s comfort and modesty. Although attention is often directed by the history to the diseased organ or part of the body, the examination of a new patient must extend from head to toe in an objective search for abnormalities. Unless the physical examination is systematic, important segments may be omitted. The results of the examination, like the details of the history, should be recorded at the time they are elicited, not hours later when they are subject to the distortions of memory. Skill in physical diagnosis is acquired with experience, but it is not merely technique that determines success in eliciting signs. The detection of a few scattered palpable hepatic nodules or a small mass in the abdomen is not a question of keener eyes and ears or more sensitive fingers but of a mind alert to these findings. Since physical findings are subject to change, the physical examination should be repeated as frequently as the clinical situation warrants.

Laboratory Tests and Imaging Studies The availability of a wide array of laboratory tests has increased our reliance on these studies for the solution of clinical problems. The accumulation of laboratory data does not relieve the physician from the responsibility of careful observation, examination, and study of the patient. It is also essential to bear in mind the limitations of such tests. By virtue of their impersonal quality, complexity, and apparent precision, they often gain an aura of authority regardless of the fallibility of the tests themselves, the instruments used in the tests, and the individuals performing or interpreting them. Physicians must weigh the expense involved in the laboratory procedures they order relative to the value of the information they are likely to provide.

Single laboratory tests are rarely ordered. Rather, physicians generally request “batteries” of multiple tests, which are often useful. For example, abnormalities of hepatic function may provide the clue to such nonspecific symptoms as generalized weakness and increased fatigability, suggesting the diagnosis of chronic liver disease. Sometimes a single abnormality, such as an elevated serum calcium level, points to particular diseases, such as hyperparathyroidism or underlying malignancy.

The thoughtful use of screening tests should not be confused with indiscriminate laboratory testing. The use of screening tests is based on the fact that a group of laboratory determinations can be carried out conveniently on a single specimen at relatively low cost. Screening tests are most useful when they are directed toward common diseases or disorders and when their results indicate other useful tests or interventions that may be costly to perform. Biochemical measurements, together with simple laboratory examinations such as blood count,
urinalysis, and sedimentation rate, often provide the major clue to the presence of a pathologic process. At the same time, the physician must learn to evaluate occasional abnormalities among the screening tests that may not necessarily connote significant disease. An in-depth workup following a report of an isolated laboratory abnormality in a person who is otherwise well is almost invariably wasteful and unproductive. Among the more than 40 tests that are routinely performed, one or two are often slightly abnormal. If there is no suspicion of an underlying illness, these tests are ordinarily repeated to ensure that the abnormality does not represent a laboratory error. If an abnormality is confirmed, it is important to consider its potential significance in the context of the patient’s condition and other test results.

The technical capability of imaging studies is one of the most rapidly advancing areas of medicine. These tests provide remarkably detailed anatomical information that can be a pivotal factor in medical decision-making. Ultrasonography, a variety of isotopic scans, computed tomography, magnetic resonance imaging, and positron emission tomography have benefited patients by opening new diagnostic vistas and by largely supplanting older, more invasive approaches. In our effort to make diagnoses quickly, it is tempting to order a battery of imaging studies. All physicians have had cases in which imaging studies turned up findings leading to an unexpected diagnosis. Nonetheless, patients must endure each of these tests, and the added cost of unnecessary testing is substantial. A skilled physician must learn to use these powerful diagnostic tools judiciously, always asking whether the results will alter management and benefit the patient.

PRINCIPLES OF PATIENT CARE □ Evidence-Based Medicine Sackett has defined evidence-based medicine as “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.” Rigorously obtained evidence is contrasted with anecdotal experience, which is often biased. Even the most experienced physicians can be influenced by recent experiences with selected patients, unless they are attuned to the importance of using larger, more objective studies for making decisions. The prospectively designed, double-blind, randomized clinical trial represents the “gold standard” for providing evidence regarding therapeutic decisions.

For a more complete discussion of evidence-based medicine, see Chap. 2.

Practice Guidelines The intelligent and cost-effective practice of medicine consists of making diagnostic and therapeutic choices that are most appropriate to a particular patient and clinical situation. Professional organizations and government agencies are developing formal clinical-practice guidelines in an effort to aid physicians and other caregivers in this endeavor. As the evidence base of medicine increases, guidelines can provide a useful framework for managing patients with particular diagnoses or symptoms. They can protect patients—particularly those with inadequate health care benefits—from receiving substandard care. Guidelines can also protect conscientious caregivers from inappropriate charges of malpractice and society from the excessive costs associated with the overuse of medical resources. On the other hand, clinical guidelines tend to oversimplify the complexities of medicine. Groups with differing perspectives may develop divergent recommendations regarding issues as basic as the need for periodic sigmoidoscopy in middle-aged persons. Furthermore, guidelines do not—and cannot be expected to—take into account the uniqueness of each individual and of his or her illness. The challenge for the physician is to integrate into clinical practice the useful recommendations offered by the experts who prepare clinical practice guidelines without accepting them blindly or being inappropriately constrained by them.

Medical Decision-Making Medical decision-making occurs throughout the diagnostic and treatment process. It involves the ordering of additional tests, requests for consults, and decisions regarding prognosis and treatment. This process requires an in-depth understanding of the pathophysiology and natural history of disease. It is for this reason that these topics are strongly emphasized in this textbook. As described above, medical decision-making should be evidence-based so that patients derive the full benefit of the scientific knowledge available to physicians. Formulating a differential diagnosis requires not only a broad knowledge base but also the ability to assess the relative probabilities of various diseases and to understand the significance of missing diagnoses that may be less likely. Arriving at a diagnosis requires the application of the scientific method. Hypotheses are formed, data are collected, and objective conclusions are reached concerning whether to accept or reject a particular diagnosis. Analysis of the differential diagnosis is an iterative process. As new information or test results are acquired, the group of disease processes being considered can be contracted or expanded appropriately.

Despite the importance of evidence-based medicine, much of medical decision-making relies on judgment—a process that is difficult to quantify or even to assess qualitatively. Especially when a relevant evidence base is unavailable, physicians must use their knowledge and experience as a basis for weighing known factors along with the inevitable uncertainties and then making a sound judgment. Several quantitative tools may be invaluable in synthesizing the available information, including diagnostic tests, Bayes’ theorem, and multivariate statistical models. Diagnostic tests serve to reduce uncertainty about a diagnosis or prognosis in a particular individual and to help the physician decide how best to manage that individual’s condition. Not only laboratory tests and procedures but also the history and the physical examination can be considered part of the battery of diagnostic tests. The accuracy of a given test is ascertained by determining its sensitivity (true positive rate) and specificity (true negative rate) as well as the predictive value of a positive and negative result. Bayes’ theorem uses information on a test’s sensitivity and specificity, in conjunction with the pretest probability of a diagnosis, to determine mathematically the posttest probability of the diagnosis. More complex clinical problems can be approached with multivariate statistical models, which generate highly accurate information even when multiple factors are acting individually or together to affect disease risk, progression, or response to treatment. Studies comparing the performance of statistical models with that of expert clinicians have documented equivalent accuracy, although the models tend to be more consistent. Thus multivariate statistical models may be particularly helpful to less experienced clinicians.

Information technology is playing an ever-increasing role in medicine. Laboratory data are accessed almost universally through computers. Many medical centers now have electronic medical records, computerized order entry, and bar-coded tracking of medications. Some of these systems are interactive and provide reminders or warn of potential medical errors. Nonetheless, at this point, clinical decisions are still best made by the physician. Many decisions are not easily compacted into practice guidelines or computerized approaches. Clinical knowledge and an understanding of the patient’s needs, supplemented by quantitative tools, still seem to represent the best approach to practicing medicine.

Assessing the Outcome of Treatment Clinicians generally use objective and readily measurable parameters to judge the outcome of a therapeutic intervention. For example, findings on physical or laboratory examination—such as the level of blood pressure, the patency of a coronary artery on an angiogram, or the size of a mass on a radiologic examination—can provide information of critical importance. However, patients usually seek medical attention for subjective reasons; they wish to obtain relief from pain, to preserve or regain function, and to enjoy life. The components of a patient’s health status or quality of life can include bodily comfort, capacity for physical activity, personal and professional function, sexual function, cognitive function, and overall perception of health. Each of these important areas can be assessed by means of structured interviews or specially designed questionnaires. Such assessments also provide useful parameters by which the physician can judge the patient’s subjective view of his or her disability and the response to treatment, particularly in chronic illness.
The practice of medicine requires consideration and integration of both objective and subjective outcomes.

**Care of the Elderly**  
Over the next several decades, the practice of medicine will be greatly influenced by the health care needs of the growing elderly population. In the United States the population over age 65 will almost triple over the next 30 years. The physician must understand and appreciate the decline in physiologic reserve associated with aging; the different responses of the elderly to common diseases; and disorders that occur commonly with aging, such as depression, dementia, frailty, urinary incontinence, and fractures.  

**Incurable Disorders and Death**  
Hospitalization can be mitigated by such explanations.

The dread of the unknown that is inherent in the fundamental principles of medical ethics are to act in the patient's best interest and to respect the patient's autonomy. Most patients possess only limited medical knowledge and must rely on their physicians for advice. Confusion or even disagreement about approaches to disease management may arise (see also “Medicine on the Internet,” below), and—in the end—the patient’s informed choices must prevail. Physicians must respect their patients’ autonomy, fully discussing the alternatives for care and the risks, benefits, and likely consequences of each alternative.

When patients require diagnostic and therapeutic procedures that are painful and that pose some risk, they are generally required to sign a consent form. In such cases, it is particularly important for the patient to understand clearly the risks entailed in these procedures; this is the definition of informed consent. It is incumbent on the physician to explain the procedures in a clear and understandable manner and to ascertain that the patient comprehends both the nature of the procedure and the attendant risks. The dread of the unknown that is inherent in hospitalization can be mitigated by such explanations.

**Incurable Disorders and Death**  
No problem is more distressing than that presented by the patient with an incurable disease, particularly when premature death is inevitable. What should the patient and family be told? What measures should be taken to maintain life? What can be done to maintain the quality of life? How is death to be defined?

Although some would argue otherwise, there is no ironclad rule that the patient must immediately be told “everything,” even if the patient is an adult with substantial family responsibilities. How much is told should depend on the individual’s ability to deal with the possibility of imminent death; often this capacity grows with time, and, whenever possible, gradual rather than abrupt disclosure is the best strategy. A wise and insightful physician is often guided by an understanding of what a patient wants to know and when he or she wants to know it. The patient’s religious beliefs may also be taken into consideration. The patient must be given an opportunity to talk with the physician and ask questions. Patients may find it easier to share their feelings about death with their physician, who is likely to be more objective and less emotional, than with family members. As William Osler wrote: “One thing is certain; it is not for you to don the black cap and, assuming the judicial function, take hope away from any patient.” Even when the patient directly inquires, “Am I dying?” the physician must attempt to determine whether this is a request for information or a demand for reassurance. Only open communication between the patient and the physician can resolve this question and guide the physician in what to say and how to say it.

The physician should provide or arrange for emotional, physical, and spiritual support and must be compassionate, unhurried, and open. There is much to be gained by the laying on of hands. Pain should be adequately controlled, human dignity maintained, and isolation from the family avoided. These aspects of care tend to be overlooked in hospitals, where the intrusion of life-sustaining apparatus can so easily detract from attention to the whole person and encourage concentration instead on the life-threatening disease, against which the battle will ultimately be lost in any case. In the face of terminal illness, the goal of medicine must shift from care to care, in the broadest sense of the term. In offering care to the dying patient, the physician must be prepared to provide information to family members and to deal with their guilt and grief. It is important for the doctor to assure the family that everything possible has been done.  

**For a more complete discussion of women’s health, see Chap. 5.**  

**Medical Errors**  
A report from the Institute of Medicine concluded that “to err is human” but called for an ambitious agenda to reduce medical-error rates and improve patient safety by designing and implementing fundamental changes in health care systems. Adverse drug reactions occur in at least 5% of hospitalized patients, and the incidence increases with use of a large number of drugs. No matter what the clinical situation, it is the responsibility of the physician to use powerful therapeutic measures wisely, with due regard for their beneficial action, potential dangers, and cost. It is also the responsibility of hospitals and health care organizations to develop systems to reduce risk and ensure patient safety. Medication errors can be reduced through the use of ordering systems that eliminate misreading of handwriting and through vigilance regarding dilution errors. Implementation of infection-control systems, enforcement of hand-washing protocols, and careful oversight of antibiotic use can minimize complications of nosocomial infections. The harm that a physician can do is not limited to the imprudent use of medication or procedures. Equally important are ill-considered or unjustified remarks. Many a patient has developed a cardiac neurosis because the physician ventured a grave prognosis on the basis of a misinterpreted finding of a heart murmur.

**Informed Consent and Respect for the Patient’s Autonomy**  
The fundamental principles of medical ethics are to act in the patient’s best interest and to respect the patient’s autonomy. Most patients possess only limited medical knowledge and must rely on their physicians for advice. Confusion or even disagreement about approaches to disease management may arise (see also “Medicine on the Internet,” below), and—in the end—the patient’s informed choices must prevail. Physicians must respect their patients’ autonomy, fully discussing the alternatives for care and the risks, benefits, and likely consequences of each alternative.

When patients require diagnostic and therapeutic procedures that are painful and that pose some risk, they are generally required to sign a consent form. In such cases, it is particularly important for the patient to understand clearly the risks entailed in these procedures; this is the definition of informed consent. It is incumbent on the physician to explain the procedures in a clear and understandable manner and to ascertain that the patient comprehends both the nature of the procedure and the attendant risks. The dread of the unknown that is inherent in hospitalization can be mitigated by such explanations.

**Incurable Disorders and Death**  
No problem is more distressing than that presented by the patient with an incurable disease, particularly when premature death is inevitable. What should the patient and family be told? What measures should be taken to maintain life? What can be done to maintain the quality of life? How is death to be defined?

Although some would argue otherwise, there is no ironclad rule that the patient must immediately be told “everything,” even if the patient is an adult with substantial family responsibilities. How much is told should depend on the individual’s ability to deal with the possibility of imminent death; often this capacity grows with time, and, whenever possible, gradual rather than abrupt disclosure is the best strategy. A wise and insightful physician is often guided by an understanding of what a patient wants to know and when he or she wants to know it. The patient’s religious beliefs may also be taken into consideration. The patient must be given an opportunity to talk with the physician and ask questions. Patients may find it easier to share their feelings about death with their physician, who is likely to be more objective and less emotional, than with family members. As William Osler wrote: “One thing is certain; it is not for you to don the black cap and, assuming the judicial function, take hope away from any patient.” Even when the patient directly inquires, “Am I dying?” the physician must attempt to determine whether this is a request for information or a demand for reassurance. Only open communication between the patient and the physician can resolve this question and guide the physician in what to say and how to say it.

The physician should provide or arrange for emotional, physical, and spiritual support and must be compassionate, unhurried, and open. There is much to be gained by the laying on of hands. Pain should be adequately controlled, human dignity maintained, and isolation from the family avoided. These aspects of care tend to be overlooked in hospitals, where the intrusion of life-sustaining apparatus can so easily detract from attention to the whole person and encourage concentration instead on the life-threatening disease, against which the battle will ultimately be lost in any case. In the face of terminal illness, the goal of medicine must shift from care to care, in the broadest sense of the term. In offering care to the dying patient, the physician must be prepared to provide information to family members and to deal with their guilt and grief. It is important for the doctor to assure the family that everything possible has been done.  

**For a more complete discussion of women’s health, see Chap. 5.**  

**THE EXPANDING ROLE OF THE PHYSICIAN**  
**Genetics and Medicine**  
The genomic era is leading to a revolution in the practice of medicine. The sequencing of the entire human genome has set researchers on the path to elucidating the genetic components of common chronic diseases—hypertension, diabetes, atherosclerosis, many cancers, autoimmune disorders, dementias, and behavioral disorders. Forthcoming information should make it possible to determine individual susceptibility to these conditions early in life and to implement individualized prevention programs. Subclassification of many diseases on a genetic basis may allow the selection of appropriate therapy for each patient. As the response to drugs becomes more predictable, pharmacotherapy should become more rational.

Patients will be best served if physicians play an active role in applying this powerful, sensitive new information rather than being passive bystanders who are intimidated by the new technology. This is a rapidly evolving field, and physicians and other health care professionals must continue to educate themselves so that they can apply this new knowledge to the benefit of their patients’ health and well-being. Genetic testing requires wise counsel based on an understanding of the value and limitations of the tests as well as the implications of their results for specific individuals.  

**For a more complete discussion of the use of genetic testing, see Chap. 58.**  

**Medicine on the Internet**  
The explosion in use of the Internet through personal computers is having an important influence on health care. The Internet makes a wide range of information available to physicians and patients almost instantaneously at any time of the day or night and from anywhere in the world. This medium holds enormous potential for delivering up-to-date information, practice guidelines, state-of-the-art conferences, journal contents, textbooks (including this text), and direct communications with other physicians and specialists, thereby expanding the depth and breadth of information available to the physician about the diagnosis and care of patients. Most medical journals
Delivering Cost-Effective Medical Care  As the cost of medical care has risen, it has become necessary to establish priorities in the expenditure of resources. In some instances, preventive measures offer the greatest return for the expenditure; outstanding examples include vaccination, improved sanitation, reduction in accidents and occupational hazards, and biochemical- and DNA-based screening of newborns. As one more specific example, the detection of phenylketonuria by newborn screening may result in a net saving of many thousands of dollars.

As resources become increasingly constrained, society must weigh the benefits of performing costly procedures that provide only a limited increase in life expectancy against the pressing need for more primary care for those persons who do not have adequate access to medical services. For the individual patient, it is important to reduce costly hospital admissions as much as possible if total health care is to be affordable. This policy, of course, depends on close cooperation among patients, their physicians, employers, payers, and government. It is equally important for physicians to know the cost of the diagnostic procedures they order and the drugs and other therapies they prescribe and to monitor both costs and effectiveness. The medical profession should provide leadership and guidance to the public in matters of cost control, and physicians must take this responsibility seriously without being or seeming to be self-serving. However, the economic aspects of health care delivery must not interfere with the welfare of patients. The patient must be able to rely on the individual physician as his or her principal advocate in matters of health care.

Accountability  As the public has become more educated and more sophisticated regarding health-related issues, expectations of the health care system in general and of physicians in particular have risen. Physicians are expected to maintain mastery of rapidly advancing fields (the science of medicine) while considering their patients’ unique needs (the art of medicine). Thus, physicians are held accountable not only for the technical aspects of the care that they provide but also for their patients’ satisfaction with the delivery and costs of care.

In the United States, there are increasing demands for physicians to account for the way in which they practice medicine by meeting certain standards prescribed by federal and state governments. The hospitalization of patients whose health care costs are reimbursed by the government and other third parties is subjected to utilization review. Thus the physician must defend the cause for and duration of a patient’s hospitalization if it falls outside certain “average” standards. Authorization for reimbursement is increasingly based on documentation of the nature and complexity of an illness, as reflected by recorded elements of the history and physical examination. The purpose of these regulations is both to improve standards of health care and to contain spiraling health care costs. This type of review is being extended to all phases of medical practice and is profoundly altering the practice of medicine. Physicians are also expected to give evidence of their continuing competence through mandatory continuing education, patient-record audits, recertification by examination, or relicensing.
available for the prevention and care of disease—these are our ambitions.

COUNCIL ON GRADUATE MEDICAL EDUCATION: Thirteenth Report: Phys-

2 \hspace{1cm} \textbf{DECISION-MAKING IN CLINICAL MEDICINE}
Daniel B. Mark

To the medical student who requires 2 h to collect a patient’s history and perform a physical examination, and several additional hours to organize them into a coherent presentation, the experienced clinician’s ability to reach a diagnosis and decide on a management plan in a fraction of the time seems extraordinary. While medical knowledge and experience play a significant role in the senior clinician’s ability to arrive at a differential diagnosis and plan quickly, much of the process involves skill in clinical decision-making. The first goal of this chapter is to provide an introduction to the study of clinical reasoning.

Equally bewildering to the student are the proper use of diagnostic tests and the integration of the results into the clinical assessment. The novice medical practitioner typically uses a “shotgun” approach to testing, hoping to hit a target without knowing exactly what that target is. The expert, on the other hand, usually has a specific target in mind and efficiently adjusts the testing strategy to it. The second goal of this chapter is to review briefly some of the crucial basic statistical concepts that govern the proper interpretation and use of diagnostic tests; quantitative tools available to assist in clinical decision-making will also be discussed.

Evidence-based medicine is the term used to describe the integration of the best available research evidence with clinical judgment and experience in the care of patients. The third goal of this chapter is to provide a brief overview of some of the tools of evidence-based medicine.

CLINICAL DECISION-MAKING

CLINICAL REASONING The most important clinical actions are not procedures or prescriptions but the judgments from which all other aspects of clinical medicine flow. In the modern era of large randomized trials and evidence-based medicine, it is easy to overlook the importance of this elusive mental activity and focus instead on the algorithmic practice guidelines constructed to improve care. One reason for this apparent neglect is that much more research has been done on how doctors should make decisions (e.g., using a Bayesian model discussed below) than on how they actually do. Thus, much of what we know about clinical reasoning comes from empirical studies of nonmedical problem-solving behavior.

Despite the great technological advances of the twentieth century, uncertainty still plays a pivotal role in all aspects of medical decision-making. We may know that a patient does not have long to live, but we cannot be certain how long. We may prescribe a potent new receptor blocker to reverse the course of a patient’s illness, but we cannot be certain that the therapy will achieve the desired result and that result alone. Uncertainty in medical outcomes creates the need for probabilities and other mathematical/statistical tools to help guide decision-making. (These tools are reviewed later in the chapter.)

Uncertainty is compounded by the information overload that characterizes modern medicine. Today’s experienced clinician needs close to 2 million pieces of information to practice medicine. Doctors subscribe to an average of 7 journals, representing over 2500 new articles each year. Computers offer the obvious solution both for management of information and for better quantitation and management of the daily uncertainties of medical care. While the technology to computerize medical practice is available, many practical problems remain to be solved before patient information can be standardized and integrated with medical evidence on a single electronic platform.

The following three examples introduce the subject of clinical reasoning:

• A 46-year-old man presents to his internist with a chief complaint of hemoptysis. The physician knows that the differential diagnosis of hemoptysis includes over 100 different conditions, including cancer and tuberculosis (Chap. 30). The examination begins with some general background questions, and the patient is asked to describe his symptoms and their chronology. By the time the examination is completed, and even before any tests are run, the physician has formulated a working diagnostic hypothesis and planned a series of steps to test it. In an otherwise healthy and nonsmoking patient recovering from a viral bronchitis, the doctor’s hypothesis would be that the acute bronchitis is responsible for the small amount of blood-streaked sputum the patient observed. In this case, a chest x-ray may provide sufficient reassurance that a more serious disorder is not present.

• A second 46-year-old patient with the same chief complaint who has a 100-pack-year smoking history, a productive morning cough, and episodes of blood-streaked sputum may generate the principal diagnostic hypothesis of carcinoma of the lung. Consequently, along with the chest x-ray, the physician obtains a sputum cytology examination and refers this patient for fiberoptic bronchoscopy.

• A third 46-year-old patient with hemoptysis who is from a developing country is evaluated with an echocardiogram as well, because the physician thinks she hears a soft diastolic rumble at the apex on cardiac auscultation, suggesting rheumatic mitral stenosis.

These three simple vignettes illustrate two aspects of expert clinical reasoning: (1) the use of cognitive shortcuts as a way to organize the complex unstructured material that is collected in the clinical evaluation, and (2) the use of diagnostic hypotheses to consolidate the information and indicate appropriate management steps.

THE USE OF COGNITIVE SHORTCUTS Cognitive shortcuts or rules of thumb, sometimes referred to as heuristics, can help solve complex problems, of the sort encountered daily in clinical medicine, with great efficiency. Clinicians rely on three basic types of heuristics. When assessing a patient, clinicians often weigh the probability that this patient’s clinical features match those of the class of patients with the leading diagnostic hypotheses being considered. In other words, the clinician is searching for the diagnosis for which the patient appears to be a representative example; this cognitive shortcut is called the representativeness heuristic.

It may take only a few characteristics from the history for an expert clinician using the representativeness heuristic to arrive at a sound diagnostic hypothesis. For example, an elderly patient with new-onset fever, cough productive of copious sputum, unilateral pleuritic chest...
pain, and dyspnea is readily identified as fitting the pattern for acute pneumonia, probably of bacterial origin. Evidence of focal pulmonary consolidation on the physical examination will increase the clinician’s confidence in the diagnosis because it fits the expected pattern of acute bacterial pneumonia. Knowing this allows the experienced clinician to conduct an efficient, directed, and therapeutically productive patient evaluation although there may be little else in the history or physical examination of direct relevance. The inexperienced medical student or resident, who has not yet learned the patterns most prevalent in clinical medicine, must work much harder to achieve the same result and is often at risk of missing the important clinical problem in a sea of compulsively collected but unhelpful data.

However, physicians using the representativeness heuristic can reach erroneous conclusions if they fail to consider the underlying prevalence of two competing diagnoses (i.e., the prior, or pretest, probabilities). Consider a patient with pleuritic chest pain, dyspnea, and a low-grade fever. A clinician might consider acute pneumonia and acute pulmonary embolism to be the two leading diagnostic alternatives. Using the representativeness heuristic, the clinician might judge both diagnostic candidates to be equally likely, although to do so would be wrong if pneumonia was much more prevalent in the underlying population. Mistakes may also result from a failure to consider that a pattern based on a small number of prior observations will likely be less reliable than one based on larger samples.

A second commonly used cognitive shortcut, the availability heuristic, involves judgments made on the basis of how easily prior similar cases or outcomes can be brought to mind. For example, the experienced clinician may recall 20 elderly patients seen over the past few years who presented with painless dyspnea of acute onset and were found to have acute myocardial infarction. The novice clinician may spend valuable time seeking a pulmonary cause for the symptoms before considering and discovering the cardiac diagnosis. In this situation, the patient’s clinical pattern does not fit the expected pattern of acute myocardial infarction, but experience with this atypical presentation, and the ability to recall it, can help direct the physician to the diagnosis.

Errors with the availability heuristic can come from several sources of recall bias. For example, rare catastrophes are likely to be remembered with a clarity and force out of proportion to their value, and recent experience is, of course, easier to recall and therefore more influential on clinical judgments.

The third commonly used cognitive shortcut, the anchoring heuristic, involves estimating a probability by starting from a familiar point (the anchor) and adjusting to the new case from there. Anchoring can be a powerful tool for diagnosis but is often used incorrectly. For example, a clinician may judge the probability of coronary artery disease (CAD) to be very high after a positive exercise thallium test, because the prediction has been anchored to the test result (“positive test = high probability of CAD”). Yet, as discussed below, this prediction would be inaccurate if the clinical (pretest) picture of the patient being tested indicates a low probability of disease (e.g., a 30-year-old woman with no risk factors). As illustrated in this example, anchors are not necessarily the same as the pretest probability (see “Measures of Disease Probability and Bayes’ Theorem,” below).

**Diagnostic Hypothesis Generation** Cognitive scientists studying the thought processes of expert clinicians have observed that clinicians group data into packets, or “chunks,” which are stored in their memories and manipulated to generate diagnostic hypotheses. Because short-term memory can typically hold only 7 to 10 items at a time, the number of packets that can be actively integrated into hypothesis-generating activities is similarly limited. The cognitive shortcuts discussed above play a key role in the generation of diagnostic hypotheses, many of which are discarded as rapidly as they are formed.

A diagnostic hypothesis sets a context for diagnostic steps to follow and provides testable predictions. For example, if the enlarged and quite tender liver felt on physical examination is due to acute hepatitis (the hypothesis), certain specific liver function tests should be mark-

One of the factors that makes teaching diagnostic reasoning so difficult is that expert clinicians do not follow a fixed pattern in patient examinations. From the outset, they are generating, refining, and discarding diagnostic hypotheses. The questions they ask in the history are driven by the hypotheses they are working with at the moment. Even the physical examination is driven by specific questions rather than a preordained checklist. While the student is palpating the abdomen of the alcoholic patient, waiting for a finding to strike him, the expert clinician is on a focused search mission. Is the spleen enlarged? How big is the liver? Is it tender? Are there any palpable masses or nodules? Each question focuses the attention of the examiner to the exclusion of all other inputs until answered, allowing the examiner to move on to the next specific question.

Negative findings are often as important as positive ones in establishing and refining diagnostic hypotheses. Chest discomfort that is not provoked or worsened by exertion in an active patient reduces the likelihood that chronic ischemic heart disease is the underlying cause. The absence of a resting tachycardia and thyroid gland enlargement reduces the likelihood of hyperthyroidism in a patient with paroxysmal atrial fibrillation.

The acuity of a patient’s illness can play an important role in overriding considerations of prevalence and other issues described above. For example, clinicians are taught to consider aortic dissection routinely as a possible cause of acute severe chest discomfort along with myocardial infarction, even though the typical history of dissection is different from myocardial infarction and dissection is far less prevalent (Chap. 231). This recommendation is based on the recognition that a relatively rare but catastrophic diagnosis like aortic dissection is very difficult to make unless it is explicitly considered. If the clinician fails to elicit any of the characteristic features of dissection by history and finds equivalent blood pressures in both arms and no pulse deficits, he or she may feel comfortable in discarding the aortic dissection hypothesis. If, however, the chest x-ray shows a widened mediastinum, the hypothesis may be reinstated and a diagnostic test ordered [e.g., thoracic computed tomography (CT) scan, transesophageal echocardiogram] to evaluate it more fully. In nonacute situations, the prevalence of potential alternative diagnoses should play a much more prominent role in diagnostic hypothesis generation.

**Generation of Diagnostic Hypotheses** Because the generation and evaluation of appropriate diagnostic hypotheses is a skill that not all clinicians possess to an equal degree, errors in this process can occur; in the patient with serious acute illness these may lead to tragic consequences. Consider the following hypothetical example. A 45-year-old male patient with a 3-week history of a “flulike” upper respiratory infection (URI) presented to his physician with symptoms of dyspnea and a productive cough. Based on the presenting complaint, the clinician pulled out a “URI Assessment Form” to improve quality and efficiency of care. The physician quickly completed the examination components outlined on this structured form, noting in particular the absence of fever and a clear chest examination. He then prescribed an antibiotic for presumed bronchitis, showed the patient how to breathe into a paper bag to relieve his “hyperventilation,” and sent him home with the reassurance that his illness was not serious. After a sleepless night with significant dyspnea unrelieved by rebreathing into a bag, the patient developed nausea and vomiting and collapsed. He was brought into the Emergency Department in cardiac arrest and could not be resuscitated. Autopsy showed a posterior wall myocardial infarction and a fresh thrombus in an atherosclerotic right coronary artery. What went wrong? The clinician decided, even before starting the history, that the patient’s complaints were not serious. He therefore felt confident that he could perform an abbreviated and focused examination using the URI assessment protocol rather than considering the full range of possibilities and performing appropriate tests to con-
firm or refute his initial hypotheses. In particular, by concentrating on
the “URL,” the clinician failed to elicit the full dyspnea history, which
would have suggested a far more serious disorder, and neglected to
search for other symptoms that could have directed him to the correct
diagnosis.

This example illustrates how patients can diverge from textbook
symptoms and the potential consequences of being unable to adapt the
diagnostic process to real-world challenges. The expert, while recog-
nizing that common things occur commonly, approaches each evalu-
ation on high alert for clues that the initial diagnosis may be wrong.
Patients often provide information that “does not fit” with any of the
leading diagnostic hypotheses being considered. Distinguishing real
clues from false trails can only be achieved by practice and experience.
A less experienced clinician who tries to be too efficient (as in the
above example) can make serious judgment errors. Furthermore, the
value of conducting a rapid systematic clinical survey of symptoms
and organ systems to avoid missing important but inapparent clues
cannot be overstated.

MAJOR INFLUENCES ON CLINICAL DECISION-MAKING

More than a decade of research on variations in clinician practice patterns has shed much light on forces that shape clinical decisions. The use of heuristic “shortcuts,” as detailed above, provides a partial explanation, but several other key factors play an important role in shaping diagnostic hypotheses and management decisions. These factors can be grouped conceptually into three overlapping categories: (1) factors related to physician personal characteristics and practice style, (2) factors related to the practice setting, and (3) economic incentive factors.

Practice Style Factors

One of the key roles of the physician in medical care is to serve as the patient’s agent to ensure that necessary care is provided at a high level of quality. Factors that influence this role include the physician’s knowledge, training, and experience. It is ob-
vious that physicians cannot practice evidence-based medicine (EBM; described later in the chapter) if they are unfamiliar with the evidence. As would be expected, specialists generally know the evidence in their field better than do generalists. Surgeons may be more enthusiastic about recommending surgery than medical doctors because their belief in the beneficial effects of surgery is stronger. For the same reason, invasive cardiologists are much more likely to refer chest pain patients for diagnostic catheterization than are noninvasive cardiologists or generalists. The physician beliefs that drive these different practice styles are based on personal experience, recollection, and interpretation of the available medical evidence. For example, heart failure specialists are much more likely than generalists to achieve target angio-
tensin-converting enzyme (ACE) inhibitor therapy in their heart failure patients because they are more familiar with what the targets are (as defined by large clinical trials), have more familiarity with the specific drugs (including dosages and side effects), and are less likely to overreact to foreseeable problems in therapy such as a rise in creatinine levels or symptomatic hypotension. Other intriguing research has shown a wide distribution of acceptance times of antibiotic therapy for peptic ulcer disease following widespread dissemination of the “evidence” in the medical literature. Some gastroenterologists ac-
cepted this new therapy before the evidence was clear (reflecting, per-
haps, an aggressive practice style), and some gastroenterologists lagged behind (a conservative practice style, associated in this case with older physicians). As a group, internists lagged several years be-
hind gastroenterologists.

The opinion of influential leaders can also have an important effect on practice patterns. Such influence can occur at both the national level (e.g., expert physicians teaching at national meetings) and the local level (e.g., local educational programs, “curbside consultants”). Opin-
ion leaders do not have to be physicians. When conducting rounds with clinical pharmacists, physicians are less likely to make medica-
tion errors and more likely to use target levels of evidence-based ther-
apies.

The patient’s welfare is not the only concern that drives clinical
decisions. The physician’s perception about the risk of a malpractice
suit resulting from either an erroneous decision or a bad outcome cre-
ates a style of practice referred to as defensive medicine. This practice
involves using tests and therapies with very small marginal returns to
preclude future criticism in the event of an adverse outcome. For ex-
ample, a 40-year-old woman who presents with a long-standing history
of intermittent headache and a new severe headache along with a nor-
mal neurologic examination has a very low likelihood of structural
intracranial pathology. Performance of a head CT or magnetic reso-
nance imaging (MRI) scan in this situation would constitute defensive
medicine. On the other hand, the results of the test could provide
reassurance to an anxious patient.

Practice Setting Factors

Factors in this category relate to the physical resources available to the physician’s practice and the practice envi-
ronment. Physician-induced demand is a term that refers to the re-
peated observation that physicians have a remarkable ability to accom-
modate to and employ the medical facilities available to them. A
classic early study in this area showed that physicians in Boston had
an almost 50% higher hospital admission rate than did physicians in
New Haven, despite there being no obvious differences in the health
of the cities’ inhabitants. The physicians in New Haven were not aware
of using fewer hospital beds for their patients, nor were the Boston
physicians aware of using less stringent criteria to admit patients. In
both cities, physicians unconsciously adopted their practice styles to
the available level of hospital beds.

Other environmental factors that can influence decision-making in-
clude the local availability of specialists for consultations and proce-
dures, “high tech” facilities such as angiography suites, a heart surgery
program, and MRI machines.

Economic Incentives

Economic incentives are closely related to the other two categories of practice-modifying factors. Financial issues can exert both stimulatory and inhibitory influences on clinical prac-
tice. In general, physicians are paid on a fee-for-service, capitation, or
salary basis. In fee-for-service, the more the physician does, the more
the physician gets paid. The incentive in this case is to do more. When
fees are reduced (discounted fee-for-service), doctors tend to increase
the number of services billed for. Capitation, in contrast, provides a
fixed payment per patient per year, encouraging physicians to take on
more patients but to provide each patient with fewer services. Expen-
sive services are more likely to be affected by this type of incentive
than inexpensive preventive services. Salary compensation plans pay
physicians the same regardless of the amount of clinical work per-
formed. The incentive here is to see fewer patients.

In summary, expert clinical decision-making can be appreciated as a
complex interplay between cognitive devices used to simplify large
amounts of complex information interacting with physician biases re-
flecting education, training, and experience, all of which are shaped
by powerful, sometimes perverse, external forces. In the next section,
a set of statistical tools and concepts that can assist in making clinical
decisions under uncertainty are reviewed.

QUANTITATIVE METHODS TO AID CLINICAL DECISION-MAKING

The process of medical decision-making can be divided into two parts:
(1) defining the available courses of action and estimating the likely
outcomes with each, and (2) assessing the desirability of the outcomes.
The former task involves integrating key information about the patient
along with relevant evidence from the medical literature to create the
structure of a decision problem. The remainder of this chapter will
review some quantitative tools available to assist the clinician in these
activities. These tools can be divided into those that assist the clinician
in making better outcome predictions, which are then used to make
decisions, and those that support the decision process directly. While
these tools are not yet used routinely in daily clinical practice, the
computerization of medicine is creating the required platform for their
future widespread dissemination.
The purpose of performing a test on a patient is to reduce uncertainty about the patient’s diagnosis or prognosis and to aid the clinician in making management decisions. Although diagnostic tests are commonly thought of as laboratory tests (e.g., measurement of serum amylase level) or procedures (e.g., colonoscopy or bronchoscopy), any technology that changes our understanding of the patient’s problem qualifies as a diagnostic test. Thus, even the history and physical examination can be considered a form of diagnostic test. In clinical medicine, it is common to reduce the results of a test to a dichotomous outcome, such as positive or negative, normal or abnormal. In many cases, this simplification results in the waste of useful information. However, such simplification makes it easier to demonstrate some of the quantitative ways in which test data can be used.

To characterize the accuracy of diagnostic tests, four terms are routinely used (Table 2-1). The true-positive rate, i.e., the sensitivity, provides a measure of how well the test correctly identifies patients with disease. The false-negative rate is calculated as \(1 - \text{sensitivity}\). The true-negative rate, i.e., the specificity, reflects how well the test correctly identifies patients without disease. The false-positive rate is \(1 - \text{specificity}\). A perfect test would have a sensitivity of 100% and a specificity of 100% and would completely separate patients with disease from those without it.

Calculating sensitivity and specificity require selection of a cutpoint value for the test, called the positivity criterion, to define the threshold value at or above which the test is considered “positive.” As the cutpoint is moved to improve sensitivity, specificity typically falls and vice versa. This dynamic tradeoff between more accurate identification of subjects with disease versus those without disease is often displayed graphically as a receiver operating characteristic (ROC) curve (Fig. 2-1). An ROC curve plots sensitivity (y-axis) versus 1 − specificity (x-axis). Each point on the curve represents a potential cutpoint with an associated sensitivity and specificity value. The area under the ROC curve is often used as a quantitative measure of the information content of a test. Values range from 0.5 (no diagnostic information at all, test is equivalent to flipping a coin) to 1.0 (perfect test).

In the testing literature, ROC areas are often used to compare alternative tests that can be used for a particular diagnostic problem. The test with the highest area (i.e., closest to 1.0) is presumed to be the most accurate. However, ROC curves are not a panacea for evaluation of diagnostic test utility. Like Bayes’ theorem (discussed below), they are typically focused on only one possible test parameter (e.g., ST-segment response in a treadmill exercise test) to the exclusion of other potentially relevant data. In addition, ROC area comparisons do not simulate the way test information is actually used in clinical practice. Finally, biases in the underlying population used to generate the ROC curves (e.g., related to an unrepresentative test sample) can bias the ROC area and the validity of a comparison among tests.

**Measures of Disease Probability and Bayes’ Theorem**

Unfortunately, there are no perfect tests; after every test is completed the true disease state of the patient remains uncertain. Quantitating this residual uncertainty can be done with Bayes’ theorem. This theorem provides a simple mathematical way to calculate the posttest probability of disease from three parameters: the pretest probability of disease, the test sensitivity, and the test specificity (Table 2-2). The pretest probability is a quantitative expression of the confidence in a diagnosis before the test is performed. In the absence of more relevant information it is usually estimated from the prevalence of the disease in the underlying population. For some common conditions, such as CAD, nomograms and statistical models have been created to generate better estimates of pretest probability from elements of the history and physical examination. The posttest probability, then, is a revised statement of the confidence in the diagnosis, taking into account what was known both before and after the test.

To understand conceptually how Bayes’ theorem creates this revised confidence statement, it is useful to examine a nomogram version of Bayes’ theorem that uses the same three parameters to predict the posttest probability of disease (Fig. 2-2). In this nomogram, the accuracy of the diagnostic test in question is summarized by the likelihood ratio for a positive test, which is the ratio of the true-positive rate to the false-positive rate (or sensitivity/\(1 - \text{specificity}\)). For example, a test with a sensitivity of 0.90 and a specificity of 0.90 has a likelihood ratio of 0.90/(1 − 0.90), or 9. Thus, for this hypothetical test, a “positive” result is 9 times more likely in a patient with the disease than in a patient without it. The more accurate the test, the higher the likelihood ratio. However, if sensitivity is excellent but specificity is less so, the likelihood ratio will be substantially reduced (e.g., with a 90% sensitivity but a 60% specificity, the likelihood ratio is 2.25). Most tests in medicine have likelihood ratios for a positive result between 1.5 and 20.

**Applications to Diagnostic Testing in CAD**

Consider two tests commonly used in the diagnosis of CAD, an exercise treadmill and an exercise thallium-201 single photon emission CT (SPECT) test (Chap. 226). Meta-analysis has shown the treadmill to have an average sensitivity of 66% and an average specificity of 84%, yielding a likelihood ratio of 4.1 \([0.66/(1 - 0.84)]\). If we use this test on a patient with a pretest probability of CAD of 10%, the posttest probability of disease following a positive test result rises only to about 30%. If a patient with a pretest probability of CAD of 80% has a positive test result, the posttest probability of disease is about 95%.

<td>True-positive (TP)</td>
<td>False-positive (FP)</td>
</tr>
<tr>
<td>Negative</td>
<td>False-negative (FN)</td>
<td>True-negative (TN)</td>
</tr>
</tbody>
</table>

**IDENTIFICATION OF PATIENTS WITH DISEASE**

- True-positive rate (sensitivity) = \(\frac{TP}{TP + FN}\)
- False-negative rate = \(\frac{FN}{TP + FN}\)
- True-positive rate = \(1 - \text{false-negative rate}\)

**IDENTIFICATION OF PATIENTS WITHOUT DISEASE**

- True-negative rate (specificity) = \(\frac{TN}{TN + FP}\)
- False-positive rate = \(\frac{FP}{TN + FP}\)
- True-negative rate = \(1 - \text{false-positive rate}\)
The exercise thallium SPECT test is a more accurate test for the diagnosis of CAD. For our purposes, assume that it has both a sensitivity and specificity of 90%, yielding a likelihood ratio of 9.0 (0.90/(1 – 0.90)). If we again test our low pretest probability patient and he has a positive test, using Fig. 2-2 we can demonstrate that the posttest probability of CAD rises from 10 to 50%. However, from a decision-making point of view, the more accurate test has not been able to improve diagnostic confidence enough to change management. In fact, the test has moved us from being fairly certain that the patient did not have CAD to being completely undecided (a 50:50 chance of disease). In a patient with a pretest probability of 80%, using the more accurate thallium SPECT test raises the posttest probability to 97% (compared with 95% for the exercise treadmill). Again, the more accurate test does not provide enough improvement in posttest confidence to alter management, and neither test has improved much upon what was known from clinical data alone.

If the pretest probability is low (e.g., 20%), even a positive result on a very accurate test will not move the posttest probability to a range high enough to rule in disease (e.g., 80%). Conversely, with a high pretest probability, a negative test will not adequately rule out disease. Thus, the largest gain in diagnostic confidence from a test occurs when the clinician is most uncertain before performing it (e.g., pretest probability between 30 and 70%). For example, if a patient has a pretest probability for CAD of 50%, a positive exercise treadmill test will move the posttest probability to 80% and a positive exercise thallium SPECT test will move it to 90% (Fig. 2-2).

Bayes’ theorem, as presented above, employs a number of important simplifications that should be considered. First, few tests have only two useful outcomes, positive or negative, and many tests provide numerous pieces of data about the patient. Even if these can be integrated into a summary result, multiple levels of useful information may be present (e.g., strongly positive, positive, indeterminate, negative, strongly negative). While Bayes’ theorem can be adapted to this more detailed test result format, it is computationally complex to do so. Second, Bayes’ theorem assumes that the information from the test is completely unique and nonoverlapping with information used to estimate the pretest probability. This independence assumption, however, is often wrong. In many cases, test results are correlated with patient characteristics. For example, the findings of cardiomegaly and pulmonary edema on chest x-ray are correlated with the historic features of heart failure and with the physical findings of a displaced left ventricular apical impulse, an S3 gallop, and rales. The unique predictive information contributed by the test in this case (the chest x-ray) is only a fraction of its total information because much had already been learned about the probability of heart failure before the test was done.

Finally, it has long been thought that sensitivity and specificity are prevalence-independent parameters of test accuracy, and many texts still make this assertion. This statistically useful assumption, however, is clinically wrong. For example, a treadmill exercise test has a sensitivity in a population of patients with one-vessel CAD of around 30%, whereas the sensitivity in severe three-vessel CAD approaches 80%. Thus, the best estimate of sensitivity to use in a particular decision will often vary depending on the distribution of disease stages present in the tested population. A hospitalized population typically has a higher prevalence of disease and in particular a higher prevalence of more advanced disease stages than an outpatient population. As a consequence, test sensitivity will tend to be higher in hospitalized patients, whereas test specificity will be higher in outpatients.

### TABLE 2-2 Measures of Disease Probability

| Pretest probability of disease = probability of disease before test is done. May use population prevalence of disease or more patient-specific data to generate this probability estimate. | Posttest probability of disease = probability of disease accounting for both pretest probability and test results. Also called predictive value of the test. | Bayes’ theorem |
| --- |
| Pretest probability × test sensitivity | Pretest probability × test sensitivity + (1 – disease prevalence) × test false-positive rate | Posttest probability = (test sensitivity/(1 – test specificity)) × pretest probability |
| Example [with a pretest probability of 0.50 and a “positive” diagnostic test result (test sensitivity = 0.90, test specificity = 0.90)]: | | Posttest probability = (0.50)(0.90) + (0.50)(0.10) = 0.90 |

### FIGURE 2-2 Nomogram version of Bayes’ Theorem used to predict the posttest probability of disease (left-hand scale) using the pretest probability of disease (right-hand scale) and the likelihood ratio for a positive test (middle scale). The likelihood ratio is calculated as the sensitivity/(1 – specificity). To use, place a straightedge connecting the pretest probability and the likelihood ratio, and read off the posttest probability. This figure illustrates the value of a positive exercise treadmill test (likelihood ratio 4) and a positive exercise thallium SPECT study (likelihood ratio 9) in the patient with a pretest probability of coronary artery disease of 50%. Treadmill results shown in solid line; thallium results in dashed line. (Adapted from Fagan TJ: N Engl J Med 293:257, 1975. Copyright 1975, Massachusetts Medical Society. All rights reserved.)
When statistical models have been compared directly with expert clinicians, they have been found to be more consistent, as would be expected, but not significantly more accurate. Their biggest promise, then, would seem to be to make less-experienced clinicians more accurate predictors of outcome.

**DECISION SUPPORT TOOLS**

**DECISION SUPPORT SYSTEMS** Over the past 30 years, many attempts have been made to develop computer systems to help clinicians make decisions and manage patients. Conceptually, computers offer a very attractive way to handle the vast information load that today's physicians face. The computer can help by making accurate predictions of outcome, simulating the whole decision process, or providing algorithmic guidance. Computer-based predictions using Bayesian or statistical regression models inform a clinical decision but do not actually reach a "conclusion" or "recommendation." Artificial intelligence systems attempt to simulate or replace human reasoning with a computer-based analogue. To date, such approaches have achieved only limited success. Reminder or protocol-directed systems do not make predictions but use existing algorithms, such as practice guidelines, to guide clinical practice. In general, however, decision support systems have shown little impact on practice. Reminder systems, although not yet in widespread use, have shown the most promise, particularly in correcting drug dosing and in promoting guideline adherence. The full potential of these approaches will only be achieved when computers are fully integrated into medical practice.

**DECISION ANALYSIS** Compared with the methods discussed above, decision analysis represents a completely different approach to decision support. Its principal application is in decision problems that are complex and involve a substantial risk, a high degree of uncertainty in some key area, or an idiosyncratic feature that does not "fit" the available evidence. Three general steps are involved. First, the decision problem must be clearly defined. Second, the elements of the decision must be made explicit. This involves specifying the alternatives being considered, their relevant outcomes, the probabilities attached to each outcome, and the relative desirability (called "utility") of each outcome. Cost can also be assigned to each branch of the decision tree, allowing calculation of cost effectiveness. Finally, the decision tree must be "analyzed" to find the strategy with the best expected outcome.

An example of a decision tree used to evaluate strategies for management of the risk of infective endocarditis after catheter-associated *Staphylococcus aureus* bacteremia is shown in Fig. 2-3. Approximately 35,000 cases of *S. aureus* bacteremia occur each year in the United States. The development of complicating endocarditis, which occurs in about 6% of cases, is associated with high morbidity (31% mortality, 21% stroke rate) and medical costs. The three choices for management of the bacteremia are (1) transesophageal echocardiography (TEE), (2) a 4-week course of intravenous antibiotics (long-course), or (3) a 2-week course of intravenous antibiotics (short-course). In the TEE strategy, a 4-week course of antibiotics is given if endocarditis is evident and a 2-week course is given if it is not. With each strategy, there is a risk that the patient will develop endocarditis with or without major complications. In this analysis, the longest quality-adjusted survival (5.47 quality-adjusted life-years) was associated with the 4-week antibiotic course strategy, which also had the highest costs ($14,136 per patient), whereas the lowest costs ($9,830 per patient) and worst outcomes (5.42 quality-adjusted life-years) were associated with the 2-week antibiotic course strategy. From a clinical point of view (ignoring costs), the 4-week antibiotic course was best. From a cost-effectiveness point of view, the TEE strategy (5.46 quality-adjusted life-years and $10,051 per patient costs) provided the best balance of added benefits and costs. Thus, decision analysis can be extremely helpful in clarifying tradeoffs in outcomes and costs in difficult management areas where it is highly unlikely that an adequate randomized trial will ever be done, such as the above.

**Filling in the Decision Tree** The data needed to fill in a decision tree (Fig. 2-3) are typically cobbled together from a variety of sources, including the literature (randomized trials, meta-analyses, observational studies) and expert opinion. Once the decision tree is finished, the decision is “analyzed” by calculating the average value of each limb of the tree. The decision arm with the highest net value (or expected utility) is the preferred choice. The value of this exercise, however, is not so much in developing a prescription for action as it is in exploring the key elements and pressure points of a complex or difficult decision. The process of building the decision tree forces the analyst to be explicit about the choices being considered and all their relevant outcomes. Areas of high uncertainty are readily identified. Sensitivity analyses are an integral part of decision analysis and involve systematically varying the value of each key parameter in the model alone (one-way sensitivity analysis), in pairs (two-way), or in higher combinations (multivariable) to assess the impact on choice of preferred management strategy. In the above example, varying the incidence of endocarditis resulting from *S. aureus* bacteremia from 3% to >50% had no impact on the choice of TEE as the preferred strategy.

User-friendly personal computer–based software packages now make the creation and analysis of decision trees much more straightforward than in the past. However, the process is still far too cumbersome and time-consuming to be used on a routine basis. When medicine is practiced from a fully computerized platform, a library of
EVIDENCE-BASED MEDICINE

The “art of medicine” is traditionally defined as a practice combining medical knowledge (including scientific evidence), intuition, and judgment in the care of patients (Chap. 1). EBM updates this construct by placing a much greater emphasis on the processes by which the clinician gains knowledge of the most up-to-date and relevant clinical research. The key processes of EBM can be summarized in four steps:

1. Formulating the management question to be answered
2. Searching the literature and on-line databases for applicable research data
3. Appraising the evidence gathered with regard to its validity and relevance
4. Integrating this appraisal with knowledge about the unique aspects of the patient (including preferences).

Steps 2 and 3 are the heart of EBM as it is currently used in practice. The process of searching the world’s research literature and appraising the quality and relevance of studies thus identified can be quite time consuming and requires skills and training that many clinicians do not possess. Thus, the best starting point for most EBM searches is the identification of recent systematic overviews of the problem in question. Selected resources to assist in this search are listed in Table 2-3.

Generally, the EBM tools listed in Table 2-3 provide access to research information in one of two forms. The first, primary research reports, is the original peer-reviewed research work that is published in medical journals. Initial access to this information in an EBM search may be gained through MEDLINE, which provides access to a huge amount of data in abstract form. The difficulty with MEDLINE is locating reports that are on point in a sea of irrelevant or unhelpful information and being reasonably certain that important reports have not been overlooked. The second form, systematic reviews, comprehensively summarizes the available evidence on a particular topic up to a certain date and provides the interpretation of the reviewer. Ex-plicit criteria are used to find all the relevant scientific research and grade its quality. The prototype for this kind of resource is the Cochrane Database of Systematic Reviews. One of the key components of a systematic review is a meta-analysis.

Meta-analysis This is research done on research data for the purpose of combining and summarizing the available evidence quantitatively. Although it can be used to combine nonrandomized studies, meta-analysis is most valuable when used to summarize all the randomized trials on a particular therapeutic problem. Ideally, unpublished trials should be identified and included to avoid publication bias (i.e., only “positive” trials tend to get published). Furthermore, some of the best meta-analyses obtain and analyze the raw patient-level data from the individual trials rather than working only with what is available in the published reports of each trial. Importantly, not all published meta-analyses are reliable sources of evidence on a particular problem. Their methodology must be carefully scrutinized to ensure proper study design and analysis. The results of a well done meta-analysis are likely to be most persuasive if it includes at least several large-scale, properly performed randomized trials. In many cases, where the available trials are small or poorly done, the best that may be concluded is that substantial additional trials are required to reach a reliable conclusion about a particular therapy.

Meta-analyses typically focus on summary measures of relative treatment benefit, such as odds ratios or relative risks. Clinicians should also examine what absolute risk reduction (ARR) can be expected from the therapy. A useful summary metric of absolute treatment benefit is the number needed to treat (NNT) to prevent one adverse outcome event (e.g., death, stroke). NNT is simply 1/ARR. For example, if a hypothetical therapy reduced mortality over a 5-year follow-up by 33% (the relative treatment benefit) from 12% (control arm) to 8% (treatment arm), the absolute risk reduction would be 12% − 8% = 4% and the NNT = ¼ or 25. Thus, we would need to treat 25 patients for 5 years to prevent 1 death. If we applied our hypothetical treatment to a lower risk population, say with a 6% 5-year mortality, the 33% relative treatment benefit would reduce absolute mortality by 2% (from 6% to 4%) and the NNT for the same therapy in this different group of patients would be 50.

Note: ACP, American College of Physicians; EBM, evidence-based medicine.
Drugs are the cornerstone of modern therapeutics. Nevertheless, it is well recognized among physicians and among the lay community that the outcome of drug therapy varies widely among individuals. While this variability has been perceived as an unpredictable, and therefore inevitable, accompaniment of drug therapy, this is not the case. The goal of this chapter is to describe the principles of clinical pharmacology that can be used for the safe and optimal use of available and new drugs.

Drugs interact with specific target molecules to produce their beneficial and adverse effects. The chain of events between administration of a drug and production of these effects in the body can be divided into two important components, both of which contribute to variability in drug actions. The first component comprises the processes that determine drug delivery to, and removal from, molecular targets. The resultant description of the relationship between drug concentration and time is termed pharmacokinetics. The second component of variability in drug action comprises the processes that determine variability in drug actions despite equivalent drug delivery to effector drug sites. This description of the relationship between drug concentration and effect is termed pharmacodynamics. As discussed further below, pharmacodynamic variability can arise as a result of variability in function of the target molecule itself or of variability in the broad biologic context in which the drug-target interaction occurs to achieve drug effects.

Two important goals of the discipline of clinical pharmacology are (1) to provide a description of conditions under which drug actions vary among human subjects; and (2) to determine mechanisms underlying this variability, with the goal of improving therapy with available drugs as well as pointing to new drug mechanisms that may be effective in the treatment of human disease. The first steps in the discipline were empirical descriptions of the influence of disease X on drug action Y or of individuals or families with unusual sensitivities to adverse drug effects. These important descriptive findings are now being replaced by an understanding of the molecular mechanisms underlying variability in drug actions. Thus, the effects of disease, drug coadministration, or familial factors in modulating drug action can now be reinterpreted as variability in expression or function of specific genes whose products determine pharmacokinetics and pharmacodynamics. Nevertheless, it is the personal interaction of the patient with the physician or other health care provider that first identifies unusual variability in drug actions; maintained alertness to unusual drug responses continues to be a key component of improving drug safety.

Unusual drug responses, segregating in families, have been recognized for decades and initially defined the field of pharmacogenetics. Now, with an increasing appreciation of common polymorphisms across the human genome, comes the opportunity to reinterpret descriptive mechanisms of variability in drug action as a consequence of specific DNA polymorphisms, or sets of DNA polymorphisms, among individuals. This approach defines the nascent field of pharmacogenomics, which may hold the opportunity of allowing practitioners to incorporate a molecular understanding of the basis of disease with an individual’s genomic makeup to prescribe personalized, highly effective, and safe therapies.

**INDICATIONS FOR DRUG THERAPY** It is self-evident that the benefits of drug therapy should outweigh the risks. Benefits fall into two broad categories: those designed to alleviate a symptom, and those designed to prolong useful life. An increasing emphasis on the principles of evidence-based medicine and techniques such as large clinical trials and meta-analyses have defined benefits of drug therapy in specific patient subgroups. Establishing the balance between risk and benefit is not always simple: for example, therapies that provide symptomatic benefits but shorten life may be entertained in patients with serious and highly symptomatic diseases such as heart failure or cancer. These decisions illustrate the continuing highly personal nature of the relationship between the prescriber and the patient.

Some adverse effects are so common, and so readily associated with drug therapy, that they are identified very early during clinical use of a drug. On the other hand, serious adverse effects may be sufficiently uncommon that they escape detection for many years after a drug begins to be widely used. The issue of how to identify rare but serious adverse effects (that can profoundly affect the benefit-risk perception in an individual patient) has not been satisfactorily resolved. Potential approaches range from an increased understanding of the molecular and genetic basis of variability in drug actions to expanded postmarketing surveillance mechanisms. None of these have been completely effective, so practitioners must be continuously vigilant to the possibility that unusual symptoms may be related to specific drugs, or combinations of drugs, that their patients receive.

Beneficial and adverse reactions to drug therapy can be described by a series of dose-response relations (Fig. 3-1). Well-tolerated drugs demonstrate a wide margin, termed the therapeutic ratio, therapeutic index, or therapeutic window, between the doses required to produce a therapeutic effect and those producing toxicity. In cases where there is a similar relationship between plasma drug concentration and effects, monitoring plasma concentrations can be a highly effective aid in managing drug therapy, by enabling concentrations to be maintained above the minimum required to produce an effect and below the concentration range likely to produce toxicity. Such monitoring has been most widely used to guide therapy with specific agents, such as certain antiarrhythmics, anticonvulsants, and antibiotics. Many of the principles in clinical pharmacology and examples outlined below—that can
be applied broadly to therapeutics—have been developed in these arenas.

**PRINCIPLES OF PHARMACOKINETICS**

The processes of absorption, distribution, metabolism, and elimination—collectively termed *drug disposition*—determine the concentration of drug delivered to target effector molecules. Mathematical analysis of these processes can define specific, and clinically useful, parameters that describe drug disposition. This approach allows prediction of how factors such as disease, concomitant drug therapy, or genetic variants affect these parameters, and how dosages therefore should be adjusted. In this way, the chances of undertreatment due to low drug concentrations or adverse effects due to high drug concentrations can be minimized.

**BIOAVAILABILITY** When a drug is administered intravenously, each drug molecule is by definition available to the systemic circulation. However, drugs are often administered by other routes, such as orally, subcutaneously, intramuscularly, rectally, sublingually, or directly into desired sites of action. With these other routes, the amount of drug actually entering the systemic circulation may be less than with the intravenous route. The fraction of drug available to the systemic circulation by other routes is termed **bioavailability**. Bioavailability may be <100% for two reasons: (1) absorption is reduced, or (2) the drug undergoes metabolism or elimination prior to entering the systemic circulation. Bioavailability (\(F\)) is defined as the area under the time-concentration curve (\(AUC\)) after a drug dose, divided by \(AUC\) after the same dose intravenously (Fig. 3-2A).

**Absorption** Drug administration by nonintravenous routes often involves an absorption process characterized by the plasma level increasing to a maximum value at some time after administration and then declining as the rate of drug elimination exceeds the rate of absorption (Fig. 3-2A). Thus, the peak concentration is lower and occurs later than after the same dose given by rapid intravenous injection. The extent of absorption may be reduced because a drug is incompletely released from its dosage form, undergoes destruction at its site of administration, or has physicochemical properties such as insolvability that prevent complete absorption from its site of administration.

The rate of absorption can be an important consideration for determining a dosage regimen, especially for drugs with a narrow therapeutic ratio. If absorption is too rapid, then the resulting high concentration may cause adverse effects not observed with a more slowly absorbed formulation. At the other extreme, slow absorption is deliberately designed into “slow-release” or “sustained-release” drug formulations in order to minimize variation in plasma concentrations during the interval between doses, because the drug’s rate of elimination is offset by an equivalent rate of absorption controlled by formulation factors (Fig. 3-3).

**Presystemic Metabolism or Elimination** When a drug is administered orally, it must transverse the intestinal epithelium, the portal venous system, and the liver prior to entering the systemic circulation (Fig. 3-4). At each of these sites, drug availability may be reduced; this mechanism of reduction of systemic availability is termed **presystemic elimination**, or first-pass elimination, and its efficiency assessed as extraction ratio. Uptake into the enterocyte is a combination of passive and active processes, the latter mediated by specific drug uptake transport molecules. Once a drug enters the enterocyte, it may undergo metabolism, be transported into the portal vein, or undergo excretion back into the intestinal lumen. Both excretion into the intestinal lumen and metabolism decrease systemic bioavailability. Once a drug passes this enterocyte barrier, it may also undergo uptake (again often by specific uptake transporters such as the organic cation transporter or organic anion transporter) into the hepatocyte, where bioavailability can be further limited by metabolism or excretion into the bile.

The drug transport molecule that has been most widely studied is...
Other drugs undergo very extensive presystemic metabolism but can still be administered by the oral route, using much higher doses than those required intravenously. Thus, a typical intravenous dose of verapamil would be 1 to 5 mg, compared to the usual single oral dose of 40 to 120 mg. Even small variations in the presystemic elimination of very highly extracted drugs such as propranolol or verapamil can cause large interindividual variations in systemic availability and effect. Oral amiodarone is 35 to 50% bioavailable because of poor solubility. Therefore, prolonged administration of usual oral doses by the intravenous route would be inappropriate. Administration of low-dose aspirin can result in exposure of cyclooxygenase in platelets in the portal vein to the drug, but systemic sparing by first-pass deacetylation in the liver. This is an example of presystemic metabolism being exploited to therapeutic advantage.

**FIRST-ORDER DISTRIBUTION AND ELIMINATION** Most pharmacokinetic processes are first order; i.e., the rate of the process depends on the amount of drug present. In the simplest pharmacokinetic model (Fig. 3-2A), a drug bolus is administered instantaneously to a central compartment, from which drug elimination occurs as a first-order process. The first-order (concentration-dependent) nature of drug elimination leads directly to the relationship describing drug concentration (C) at any time (t) following the bolus:

\[ C = \left(\frac{dose}{V_s}\right) \cdot e^{-0.693t/t_s} \]

where \( V_s \) is the volume of the compartment into which drug is delivered and \( t_s \) is elimination half-life. As a consequence of this relationship, a plot of the logarithm of concentration vs time is a straight line (Fig. 3-2A, inset). **Half-life** is the time required for 50% of a first-order process to be complete. Thus, 50% of drug elimination is accomplished after one drug elimination half-life; 75% after two; 87.5% after three, etc. In practice, first-order processes such as elimination are near-complete after four to five half-lives.

In some cases, drug is removed from the central compartment not only by elimination but also by distribution into peripheral compartments. In this case, the plot of plasma concentration vs time after a bolus demonstrates two (or more) exponential components (Fig. 3-2B). In general, the initial rapid drop in drug concentration represents not elimination but drug distribution into and out of peripheral tissues (also first-order processes), while the slower component represents drug elimination; the initial precipitous decline is usually evident with administration by intravenous but not other routes. Drug concentrations at peripheral sites are determined by a balance between drug distribution to and redistribution from peripheral sites, as well as by elimination. Once the distribution process is near-complete (four to five distribution half-lives), plasma and tissue concentrations decline in parallel.

**Clinical Implications of Half-Life Measurements** The elimination half-life not only determines the time required for drug concentrations to fall to near-immeasurable levels after a single bolus, but it is the key determinant of the time required for steady-state plasma concentrations to be achieved after any change in drug dosing (Fig. 3-5). This applies to the initiation of chronic drug therapy (whether by multiple oral doses or by continuous intravenous infusion), a change in chronic drug dose or dosing interval, or discontinuation of drug. When drug effect parallels drug concentrations, the time required for a change in drug dosing to achieve a new level of effect is therefore determined by the elimination half-life.

During chronic drug administration, a point is reached at which the amount of drug administered per unit time equals drug eliminated per unit time, defining the steady state. With a continuous intravenous infusion, plasma concentrations at steady state are stable, while with chronic oral drug administration, plasma concentrations vary during the dosing interval but the time-concentration profile between dosing intervals is stable (Fig. 3-5).

**DRUG DISTRIBUTION** Distribution from central to peripheral sites, or from extracellular to intracellular sites, can be accomplished by passive mechanisms such as diffusion or by specific drug transport mech-

---

**FIGURE 3-4** Mechanism of presystemic clearance. After drug enters the enterocyte, it can undergo metabolism, excretion into the intestinal lumen, or transport into the portal vein. Similarly, the hepatocyte may accomplish metabolism and biliary excretion prior to the entry of drug and metabolites to the systemic circulation. (Adapted by permission from DM Roden, in DP Zipes, J Jalife (eds): Cardiac Electrophysiology: From Cell to Bedside, 4th ed. Philadelphia, Saunders, 2003. Copyright 2003 with permission from Elsevier.)

P-glycoprotein, the product of the normal expression of the MDR1 gene. P-glycoprotein is expressed on the apical aspect of the enterocyte and on the canalicular aspect of the hepatocyte (Fig. 3-4); in both locations, it serves as an efflux pump, thus limiting availability of drug to the systemic circulation.

Most drug metabolism takes place in the liver, although the enzymes accomplishing drug metabolism may be expressed, and hence drug metabolism may take place, in multiple other sites, including kidney, intestinal epithelium, lung, and plasma. Drug metabolism is generally conceptualized as “phase I,” which generally results in more polar metabolites that are more readily excreted, and “phase II,” during which specific endogenous compounds are conjugated to the drugs or their metabolites, again to enhance polarity and thus excretion. The major process during phase I is drug oxidation, generally accomplished by members of the cytochrome P450 (CYP) monooxygenase superfamily. CYPs that are especially important for drug metabolism (Table 3-1) include CYP3A4, CYP3A5, CYP2D6, CYP2C9, CYP2C19, CYP1A2, and CYP2E1, and each drug may be a substrate for one or more of these enzymes. The enzymes that accomplish phase II reactions include glucuronyl-, acetyl-, sulfo- and methyltransferases. Drug metabolites may exert important pharmacologic activity, as discussed further below.

**Clinical Implications of Altered Bioavailability** Some drugs undergo near-complete presystemic metabolism and thus cannot be administered orally. Lidocaine is an example; the drug is well absorbed but undergoes near-complete extraction in the liver, so only lidocaine metabolites (which may be toxic) appear in the systemic circulation following administration of the parent drug. Similarly, nitroglycerin cannot be used orally because it is completely extracted prior to reaching the systemic circulation. The drug is therefore used by the sublingual or transdermal routes, which bypass presystemic metabolism.

Other drugs undergo very extensive presystemic metabolism but can still be administered by the oral route, using much higher doses...
anisms that are only now being defined at the molecular level. Models such as those shown in Fig. 3-2 allow derivation of a volume term for each compartment. These volumes rarely have any correspondence to actual physiologic volumes, such as plasma volume or total-body water volume. For many drugs rarely have any correspondence to actual physiologic volumes, such as plasma volume or total-body water volume. For many drugs, the indication may be so urgent that a loading dose of lidocaine (3 to 4 mg/kg) as a single bolus often results transiently in very high concentrations, with a risk of adverse effects such as seizures. Since the distribution half-life of the drug is 8 min, a more appropriate loading regimen is the same dose, administered as two to four divided boluses every 8 min, or a rapid infusion (e.g., 10 mg/min for 20 min).

Some drugs are so predictably lethal when infused too rapidly that special precautions should be taken to prevent accidental boluses. For example, solutions of potassium for intravenous administration >20

**LOADING DOSES** For some drugs, the indication may be so urgent that the time required to achieve steady-state concentrations may be too long. Under these conditions, administration of “loading” dosages may result in more rapid elevations of drug concentration to achieve therapeutic effects earlier than with chronic maintenance therapy (Fig. 3-5). Nevertheless, the time required for true steady state to be achieved is still determined only by elimination half-life. This strategy is only appropriate for drugs exhibiting a defined relationship between drug dose and effect. A loading dose can be estimated from the desired plasma level (C) and the apparent volume of distribution (V):

\[
\text{Loading dose} = C \times V
\]

Alternatively, the loading amount required to achieve steady-state plasma levels can also be determined if the fraction of drug eliminated during the dosing interval and the maintenance dose are known. For example, if the fraction of digoxin eliminated daily is 35% and the planned maintenance dose is 0.25 mg daily, then the loading dose required to achieve steady-state levels would be (0.25/0.35) = 0.75 mg.

In congestive heart failure, the central volume of distribution of lidocaine is reduced. Therefore, lower-than-normal loading regimens are required to achieve equivalent plasma drug concentrations and to avoid toxicity.

**Clinical Implications of Drug Distribution** Digoxin accesses its cardiac site of action slowly, over a distribution phase of several hours. Thus after an intravenous dose, plasma levels fall but those at the site of action increase over hours. Only when distribution is near-complete does the concentration of digoxin in plasma reflect pharmacologic effect. For this reason, there should be a 6- to 8-h wait after administration before plasma levels of digoxin are measured as a guide to therapy.

Animal models have suggested, and clinical studies are confirming, that limited drug penetration into the brain, the “blood-brain barrier,” often represents a robust P-glycoprotein-mediated efflux process from capillary endothelial cells in the cerebral circulation. Thus drug distribution into the brain may be modulated by changes in P-glycoprotein function.

**Rate of Intravenous Administration**

Although the simulations in Fig. 3-2 use a single intravenous bolus, this is very rarely appropriate in practice because side effects related to transiently very high concentrations can result. Rather, drugs are more usually administered orally or as a slower intravenous infusion. Thus, administration of a full loading dose of lidocaine (3 to 4 mg/kg) as a single bolus often results transiently in very high concentrations, with a risk of adverse effects such as seizures. Since the distribution half-life of the drug is 8 min, a more appropriate loading regimen is the same dose, administered as two to four divided boluses every 8 min, or a rapid infusion (e.g., 10 mg/min for 20 min).

Some drugs are so predictably lethal when infused too rapidly that special precautions should be taken to prevent accidental boluses. For example, solutions of potassium for intravenous administration >20

\]

\[
\text{Dose} = 2\times D
\]

**Discontinue drug**

**Figure 3-5** Drug accumulation to steady state. In this simulation, drug was administered (arrows) at intervals = 50% of the elimination half-life. Steady state is achieved during initiation of therapy after ~5 elimination half-lives, or 10 doses. A loading dose did not alter the eventual steady state achieved. A doubling of the dose resulted in a doubling of the steady state but the same time course of accumulation. Once steady state is achieved, a change in dose (increase, decrease, or drug discontinuation) results in a new steady state in ~5 elimination half-lives. [Adapted by permission from DM Roden, in DP Zipes, J Jalife (eds): Cardiac Electrophysiology: From Cell to Bedside, 4th ed. Philadelphia, Saunders, 2003. Copyright 2003 with permission from Elsevier.]
meq/L should be avoided in all but the most exceptional and carefully monitored circumstances. This minimizes the possibility of cardiac arrest, which can occur as a result of accidental increases in infusion rates of more concentrated solutions.

Procainamide, which is almost totally absorbed after oral administration, can be given orally as a single 1000-mg loading dose with little risk of hypotension. However, administration by the intravenous route is more safely accomplished by giving the dose in fractions of about 100 mg at 5-min intervals or, more conveniently, as a 20-mg/min infusion over 50 min to avoid hypotension during the distribution phase.

As these examples illustrate, excessively rapid administration of many drugs can lead to catastrophic consequences that result from high concentrations in the blood during the distribution phase. In contrast, for some centrally active drugs, the higher concentration of drug during the distribution phase after intravenous administration is used to advantage. The use of midazolam for intravenous sedation, for example, depends upon its rapid uptake by the brain during the distribution phase to produce sedation quickly, with subsequent egress from the brain during the redistribution of the drug as equilibrium is achieved.

Similarly, adenosine must be administered as a rapid bolus in the treatment of reentrant supraventricular tachycardias (Chap. 214), to prevent elimination by very rapid (t₁/₂ of seconds) uptake into erythrocytes and endothelial cells before the drug can reach its clinical site of action, the atroventricular node.

**PLASMA PROTEIN BINDING** Many drugs circulate in the plasma partly bound to plasma proteins. Since only unbound (free) drug can distribute to sites of pharmacologic action, drug response is related to the free rather than the total circulating plasma drug concentration. In most cases, the degree of binding is fairly constant across the therapeutic concentration range; in this case, when plasma drug concentration is used to adjust doses, total levels in plasma can be used without resulting in significant error.

**Clinical Implications of Altered Protein Binding** For drugs that are normally highly bound to plasma proteins (>90%), small changes in the extent of binding (e.g., due to disease) produce a large change in the amount of unbound drug, and hence drug effect. The acute-phase reactant α₁-acid glycoprotein binds to basic drugs, such as lidocaine or quinidine, and is increased in a range of common conditions, including myocardial infarction, surgery, neoplastic disease, rheumatoid arthritis, and burns. This increased binding can lead to reduced pharmacologic effects at therapeutic concentrations of total drug. Conversely, conditions such as hypoalbuminemia, liver disease, and renal disease can decrease the extent of drug binding, particularly of acidic and neutral drugs, such as phenytoin. Here, plasma concentration of free drug is increased, so drug efficacy and toxicity are enhanced if total (free + bound) drug is used to monitor therapy.

**CLEARANCE** When drug is eliminated from the body, the amount of drug in the body declines over time. An important concept in quantifying this reduction is to consider that drug concentration at the beginning and end of a time period are unchanged, and that a specific volume of the body has been “cleared” of the drug during that time period. This defines clearance as volume/time. Clearance is a measure of the efficiency of drug removal that encompasses both drug metabolism and excretion.

**Clinical Implications of Altered Clearance** While elimination half-lives determine the time required to achieve steady-state plasma concentrations (C₀), the magnitude of that steady state is determined by clearance (Cl) and dose alone. For a drug administered as an intravenous infusion, this relationship is

\[ C_0 = \text{dosing rate}/Cl \quad \text{or} \quad \text{dosing rate} = Cl 	imes C_0 \]

When drug is administered orally, the average plasma concentration within a dosing interval \( C_{avg,ss} \) replaces \( C_0 \), and bioavailability \( (F) \) must be included:

\[ F \times \text{dosing rate} = Cl \times C_{avg,ss} \]

Genetic variants, drug interactions, or diseases that reduce the activity of drug-metabolizing enzymes or excretory mechanisms may lead to decreased clearance and hence a requirement for downward dose adjustment to avoid toxicity. Genetic variants may reduce expression of CYPs (or other drug-metabolizing enzymes) or may result in normal expression of enzymes that have reduced function; in either case, dose requirements may need to be reduced. Conversely, some drug interactions and genetic variants increase CYP expression, and hence increased drug dosage may be necessary to maintain a therapeutic effect.

Clearance varies among drugs but is constant for most drugs over the therapeutic range of concentrations. In some cases, elimination becomes saturated at high doses, and the process then occurs at a fixed amount per unit time (zero order). With such nonlinear elimination kinetics, an increase in drug dosage is followed by a disproportionate rise in drug concentration, which can carry a risk of toxicity. Drugs that undergo zero-order elimination at therapeutic dosages include phenytoin, theophylline, and ethanol. Monitoring plasma concentrations of these agents is an indispensable guide to adjusting dose.

**THE CONCEPT OF HIGH-RISK PHARMACOKINETICS** Many drugs undergo elimination by multiple drug-metabolizing or excretory pathways. In this case, absence of one pathway (due to a genetic variant or drug interaction) may not have a large impact on drug concentrations or drug actions. However, other drugs utilize a single pathway exclusively for drug elimination. Under this scenario, any condition that inhibits that pathway (be it disease-related, genetic, or due to a drug interaction) can lead to dramatic changes in drug concentrations and hence effect. Examples of this phenomenon are discussed further below and include digoxin toxicity when P-glycoprotein, the major route of digoxin elimination, is inhibited and potentially fatal bone marrow aplasia due to azathioprine or 6-mercaptopurine in patients with genetically determined absence of function of thiopurine S-methyltransferase (TPMT).

A dual-pathway example is the antiarrhythmic flecainide, which is eliminated by both renal excretion and CYP2D6-mediated metabolism. Rare patients with both renal dysfunction and absent CYP2D6 activity (on a genetic basis or because of drug interactions) may develop severe adverse reactions related to high plasma concentrations.

**ACTIVE DRUG METABOLITES** A major role of drug metabolism is generation of more polar compounds that then readily undergo renal or biliary excretion. From an evolutionary point of view, drug metabolism probably developed as a defense against noxious xenobiotics (foreign substances, e.g., from plants) to which our ancestors inadvertently exposed themselves. The organization of the drug uptake and efflux pumps, and the location of drug metabolism in the intestine and liver prior to drug entry to the systemic circulation (Fig. 3-4), support this idea of a primitive protective function.

However, drug metabolites are not necessarily pharmacologically inactive. Metabolites may produce effects similar to, overlapping with, or distinct from those of the parent drug. For example, N-acetylprocainamide (NAPA) is a major metabolite of the antiarrhythmic procainamide. While it exerts antiarrhythmic effects, its electrophysiologic properties differ from those of the parent drug. Indeed, NAPA accumulation is the usual explanation for marked QT prolongation and torsades de pointes ventricular tachycardia (Chap. 214) during therapy with procainamide. Thus, the common laboratory practice of adding procainamide to NAPA concentrations to estimate a total therapeutic effect is inappropriate.

Some drugs are administered in an inactive form and require metabolism to generate active metabolites that mediate the drug effects. Examples include many angiotensin-converting enzyme (ACE) inhibitors and the analgesic codeine (whose active metabolite morphine profoundly underlies the opioid effect during codeine administration). Codeine and procainamide metabolism are also variable on a genetic basis, further contributing to variability in drug effects.
olism has also been implicated in bioactivation of procarcinogens and in generation of reactive metabolites that mediate certain adverse drug effects (e.g., acetaminophen hepatotoxicity, discussed below).

**PRINCIPLES OF PHARMACODYNAMICS**

Once a drug accesses a molecular site of action, it alters the function of that molecular target, with the ultimate result of a drug effect that the patient or physician can perceive. For drugs used in the urgent treatment of acute symptoms, little or no delay is anticipated (or desired) between the drug-target interaction and the development of a clinical effect. Examples include vascular thrombosis, shock, malignant hypertension, status epilepticus, or arrhythmias. For many conditions, however, the indication for therapy is less urgent, and in fact a delay between the interaction of a drug with its pharmacologic target(s) and a clinical effect is common. Pharmacokinetic mechanisms that can contribute to such a delay include uptake into peripheral compartments or generation and accumulation of active metabolites. A common pharmacodynamic mechanism is that the clinical effect develops as a downstream consequence of the initial molecular effect the drug produces. Thus, administration of a proton-pump inhibitor or an H₂-receptor blocker produces an immediate increase in gastric pH but ulcer healing that is delayed. Cancer chemotherapy inevitably produces delayed therapeutic effects, often long after drug is undetectable in plasma and tissue. Translation of a molecular drug action to a clinical effect can thus be highly complex and dependent on the details of the pathologic state being treated. These complexities have made pharmacodynamics and its variability less amenable than pharmacokinetics to rigorous mathematical analysis. Nevertheless, some clinically important principles can be elucidated.

A therapeutic drug effect assumes the presence of underlying pathophysiology. Thus, a drug may produce no action, or a different spectrum of actions, in unaffected individuals compared to patients. Further, concomitant disease can complicate interpretation of response to drug therapy, especially adverse effects. For example, increasing dyspnea in a patient with chronic lung disease receiving amiodarone therapy could be due to drug, underlying disease, or an intercurrent cardiopulmonary problem. Thus the presence of chronic lung disease, and interpretation of the symptom of increasing dyspnea, is one factor that should be considered in selection of antiarrhythmic therapies. Similarly, high doses of anticonvulsants such as phenytoin may cause neurologic symptoms, which may be confused with the underlying neurologic disease.

The concept that a drug interacts with a specific molecular receptor does not imply that the drug effect will be constant over time, even if stable drug and metabolite concentrations are maintained. The drug-receptor interaction occurs in a complex biologic milieu that itself can vary to modulate the drug effect. For example, ion channel blockade by drugs, an important anticonvulsant and antiarrhythmic effect, is often modulated by membrane potential, itself a function of factors such as extracellular potassium or ischemia. Thus, the effects of these drugs may vary depending on the external milieu. Receptors may be up- or downregulated by disease or by the drug itself. For example, β-adrenergic blockers upregulate β-receptor density during chronic therapy. While this effect does not usually result in resistance to the therapeutic effect of the drugs, it may produce severe β agonist–mediated effects (such as hypertension or tachycardia) if the blocking drug is abruptly withdrawn.

**PRINCIPLES OF DOSE SELECTION**

The desired goal of therapy with any drug is to maximize the likelihood of a beneficial effect while minimizing the risk of adverse effects. Previous experience with the drug, in controlled clinical trials or in postmarketing use, defines the relationships between dose (or plasma concentration) and adverse effects and provides a starting point for initiation of drug therapy.

Figure 3-1 illustrates the relationships among dose, plasma concentrations, efficacy, and adverse effects and carries with it several important implications:

1. **The target drug effect should be defined when drug treatment is started.** With some drugs, the desired effect may be difficult to measure objectively, and the onset of efficacy can be delayed for weeks or months; drugs used in the treatment of cancer and psychiatric disease are examples. Sometimes, a drug is used to treat a symptom, such as pain or palpitations, and here it is the patient who will report whether the selected dose is effective. In yet other settings, such as anticoagulation or hypertension, the desired response is readily measurable.

2. **The nature of anticipated toxicity often dictates the starting dose.** If side effects are minor, it may be acceptable to start at a dose high enough to achieve efficacy and downtitrate if side effects occur. However, this approach is rarely if ever justified if the anticipated toxicity is serious or life-threatening; in this circumstance, it is more appropriate to initiate therapy with the lowest dose that may produce a desired effect.

3. **The above considerations do not apply if these relationships between dose and effects cannot be defined.** This is especially relevant to some adverse drug effects (discussed in further detail below) whose development is not readily related to drug dose.

4. **If a drug dose does not achieve its desired effect, a dosage increase is justified only if toxicity is absent and the likelihood of serious toxicity is small.** For example, a small percentage of patients with strong seizure foci require plasma levels of phenytoin >20 μg/mL to control seizures. Dosages to achieve this effect may be appropriate, if tolerated. Conversely, clinical experience with flecaïnide suggests that levels >1000 ng/mL, or dosages >400 mg/d, may be associated with an increased risk of sudden death; thus dosage increases beyond these limits are ordinarily not appropriate, even if the higher dosage appears tolerated.

Other mechanisms that can lead to failure of drug effect should also be considered; drug interactions and noncompliance are common examples. This is one situation in which measurement of plasma drug concentrations, if available, can be especially useful. Noncompliance is an especially frequent problem in the long-term treatment of diseases such as hypertension and epilepsy, occurring in ≥25% of patients in therapeutic environments in which no special effort is made to involve patients in the responsibility for their own health. Multidrug regimens with multiple doses per day are especially prone to noncompliance.

Monitoring response to therapy, by physiologic measures or by plasma concentration measurements, requires an understanding of the relationships between plasma concentration and anticipated effects. For example, measurement of QT interval is used during treatment with sotalol or dofetilide to avoid marked QT prolongation that can herald serious arrhythmias. In this setting, evaluating the electrocardiogram at the time of anticipated peak plasma concentration and effect (e.g., 1 to 2 h postdose at steady state) is most appropriate. Maintained high aminoglycoside levels carry a risk of nephrotoxicity, so dosages should be adjusted on the basis of plasma concentrations measured at trough (predose). On the other hand, ensuring aminoglycoside efficacy is accomplished by adjusting dosage so that peak drug concentrations are above a minimal antibacterial concentration. For dose adjustment of other drugs (e.g., anticonvulsants, antiarrhythmics), concentration should be measured at its lowest during the dosing interval, just prior to a dose at steady state (Fig. 3-5), to ensure a maintained therapeutic effect.

**CONCENTRATION OF DRUGS IN PLASMA AS A GUIDE TO THERAPY**

Factors such as interactions with other drugs, disease-induced alterations in elimination and distribution, and genetic variation in drug disposition combine to yield a wide range of plasma levels in patients given the same dose. Hence, if a predictable relationship can be established between plasma drug concentration and beneficial or adverse drug effect, measurement of plasma levels can provide a valuable tool to guide selection of an optimal dose. This is particularly true when there is a narrow range between the plasma levels yielding therapeutic and adverse ef-
Effects, as with digoxin, theophylline, some antiarrhythmics, aminoglycosides, cyclosporine, and anticonvulsants. The common situation of first-order elimination implies that average, maximum, and minimum steady-state concentrations are related linearly to the dosing rate. Accordingly, the maintenance dose may be adjusted on the basis of the ratio between the desired and measured concentrations at steady state; for example if a doubling of the steady-state plasma concentration is desired, the dose should be doubled.

For drugs that have zero-order kinetics (e.g., phenytoin and theophylline), plasma concentrations change disproportionately more than the alteration in the dosing rate. In this situation, changes in dose should be small to minimize the degree of unpredictability, and plasma concentration monitoring should be used to ensure that dose modification achieves the desired level.

**DETERMINATION OF MAINTENANCE DOSE** An increase in dosage is usually best achieved by changing the drug dose but not the dosing interval, e.g., by giving 200 mg every 8 h instead of 100 mg every 8 h. However, this approach is acceptable only if the resulting maximum concentration is not toxic and the trough value does not fall below the minimum effective concentration for an undesirable period of time. Alternatively, the steady state may be changed by altering the frequency of intermittent dosing but not the size of each dose. In this case, the magnitude of the fluctuations around the average steady-state level will change — the shorter the dosing interval, the smaller the difference between peak and trough levels (Fig. 3–3).

Fluctuation within a dosing interval is determined by the relationship between the dosing interval and the drug’s half-life. If the dosing interval is equal to the drug’s half-life, fluctuation is about twofold, which is usually acceptable. With drugs that have a low therapeutic ratio, dosage changes should be conservative (<50% dose change) and not more frequent than every three to four half-lives. Other drugs, such as many antihypertensives, have little dose-related toxicity so the therapeutic ratio is large. Even if drug is eliminated rapidly, it can be given infrequently. Thus, 75 mg of captopril will result in reduced blood pressure for up to 12 h, even though captopril elimination half-life is about 2 h; this is because the dose raises the concentration of drug in plasma many times higher than the threshold for its pharmacologic effect.

**EFFECTS OF DISEASE ON DRUG CONCENTRATION AND RESPONSE**

**RENAL DISEASE** Renal excretion of parent drug and metabolites is generally accomplished by glomerular filtration and by specific drug transporters, only now being identified. If a drug or its metabolites are primarily excreted through the kidneys and increased drug levels are associated with adverse effects, drug dosages must be reduced in patients with renal dysfunction to avoid toxicity. The antiarrhythmics dofetilide and sotalol undergo predominant renal excretion and carry a risk of QT prolongation and arrhythmias if doses are not reduced in renal disease. Thus, in end-stage renal disease, sotalol can be given as 40 mg after dialysis (every second day), compared to the usual daily dose, 80 to 120 mg every 12 h. The narcotic analgesic meperidine undergoes extensive hepatic metabolism, so that renal failure has little effect on its plasma concentration. However, its metabolite, normeperidine, does undergo renal excretion, accumulates in renal failure, and probably accounts for the signs of central nervous system excitation, such as irritability, twitching, and seizures, that appear when multiple doses of meperidine are administered to patients with renal disease. Protein binding of some drugs (e.g., phenytoin) may be altered in uremia, so measuring free drug concentration may be desirable.

In non-end-stage renal disease, changes in renal drug clearance are generally proportional to those in creatinine clearance, which may be measured directly or estimated from the serum creatinine (Chap. 259). This estimate, coupled with the knowledge of how much drug is normally excreted renally vs nonrenally, allows an estimate of the dose adjustment required. In practice, most decisions involving dosing adjustment in patients with renal failure use published recommended adjustments in dosage or dosing interval based on the severity of renal dysfunction indicated by creatinine clearance. Any such modification of dose is a first approximation and should be followed by plasma concentration data (if available) and clinical observation to further optimize therapy for the individual patient.

**LIVER DISEASE** In contrast to the predictable decline in renal clearance of drugs in renal insufficiency, the effects of hepatitis or cirrhosis on drug disposition range from impaired to increased drug clearance, in an unpredictable fashion. Standard tests of liver function are not useful in adjusting doses. First-pass metabolism may decrease, and thus oral bioavailability increase, as a consequence of disrupted hepatocyte function, altered liver architecture, and portacaval shunts. The oral availability for high-first-pass drugs such as morphine, meperidine, midazolam, and nifedipine is almost doubled in patients with cirrhosis, compared to those with normal liver function. Therefore, the size of the oral dose of such drugs should be reduced in this setting.

**HEART FAILURE AND SHOCK** Under conditions of decreased tissue perfusion, the cardiac output is redistributed to preserve blood flow to the heart and brain at the expense of other tissues (Chap. 216). As a result, drugs may be distributed into a smaller volume of distribution, higher drug concentrations will be present in the plasma, and the tissues that are best perfused (the brain and heart) will be exposed to these higher concentrations. If either the brain or heart is sensitive to the drug, an alteration in response will occur. As well, decreased perfusion of the kidney and liver may impair drug clearance. Thus, in severe congestive heart failure, in hemorrhagic shock, and in cardiogenic shock, response to usual drug doses may be excessive, and dosage reduction may be necessary. For example, the clearance of lidocaine is reduced by about 50% in heart failure, and therapeutic plasma levels are achieved at infusion rates only about half those usually required. The volume of distribution of lidocaine is also reduced, so loading regimens should be reduced.

**DRUG USE IN THE ELDERLY** Ageing results in changes in organ function, especially of the organs involved in drug disposition. Therefore, pharmacokinetics are often different in elderly individuals than in younger adults. In the elderly, multiple pathologies and medications used to treat them result in more drug interactions and adverse effects.

Even in the absence of kidney disease, renal clearance may be reduced by 35 to 50% in elderly patients. Dosage adjustments are therefore necessary for drugs that are eliminated mainly by the kidneys. Because muscle mass and therefore creatinine production are reduced in older individuals, a normal serum creatinine concentration can be present even though creatinine clearance is impaired; dosages should be adjusted on the basis of creatinine clearance, as discussed above. Aging also results in a decrease in the size of and blood flow to the liver and possibly in the activity of hepatic drug-metabolizing enzymes; accordingly, the hepatic clearance of some drugs is impaired in the elderly. As with liver disease, these changes are not readily predicted.

Elderly patients may display altered drug sensitivity. Examples include increased analgesic effects of opioids, increased sedation from benzodiazepines and other CNS depressants, and increased risk of bleeding while receiving anticoagulant therapy, even when clotting parameters are well controlled. Exaggerated responses to cardiovascular drugs are also common because of the impaired responsiveness of normal homeostatic mechanisms. Conversely, the elderly display decreased sensitivity to β-adrenergic receptor blockers.

Adverse drug reactions are especially common in the elderly, because of altered pharmacokinetics and pharmacodynamics, the frequent use of multidrug regimens, and concomitant disease. For example, use of long half-life benzodiazepines is linked to the occurrence of hip fractures in elderly patients, perhaps reflecting both a risk of falls from these drugs (due to increased sedation) and the increased incidence of osteoporosis in elderly patients. In population surveys of the noninstitutionalized elderly, as many as 10% had at least one adverse drug reaction in the previous year.
Accordingly, optimization of drug therapy in the elderly, particularly in frail patients, is often difficult, as these multiple factors accentuate interindividual variability in drug response. Initial doses should be less than the usual adult dosage and should be increased slowly. The number of medications, and doses per day, should be kept as low as possible.

**GENETIC DETERMINANTS OF THE RESPONSE TO DRUGS**

**PRINCIPLES OF GENETIC VARIATION AND HUMAN TRAITS** (See also Chap. 58)

Variants in the human genome resulting in variation in level of expression or function of molecules important for pharmacokinetics and pharmacodynamics are increasingly recognized. These may be mutations (very rare variants, often associated with disease) or polymorphisms, variants that are much more common in a population. Variants may occur at a single nucleotide or involve insertion or deletion of one or more nucleotides. They may be in the exons (coding regions) or introns. Exonic polymorphisms may or may not alter the encoded protein, and variant proteins may or may not display altered function. Similarly, polymorphisms in intronic regions (including those that regulate gene expression) may or may not alter protein level.

As variation in the human genome is increasingly well documented, associations are being described between polymorphisms and various traits (including response to drug therapy). Some of these rely on well-developed chains of evidence, including in vitro studies demonstrating variant protein function, familial aggregation of variant allele with the trait, and association studies in large populations. In other cases, the associations are less compelling. Identifying “real” associations is one challenge that must be overcome before genomics, and in particular the concept of genotyping to identify optimal drugs (or dosages) in individual patients prior to prescribing, can be considered for widespread clinical practice. Nevertheless, the appeal of this approach is considerable.

Rates of drug efficacy and adverse effects often vary among ethnic groups. Many explanations for such differences are plausible; genomic approaches have now established that functionally important variants determining differences in drug response often display differing distributions among ethnic groups. This finding may have importance for drug use among ethnic groups, as well as in drug development.

**GENETICALLY DETERMINED DRUG DISPOSITION AND VARIABLE EFFECTS**

The concept that genetically determined variations in drug metabolism might be associated with variant drug levels, and hence effect, was advanced at the end of the nineteenth century, and the first examples of familial clustering of unusual drug responses due to this mechanism were noted in the mid-twentieth century. Clinically important genetic variants have been described in multiple molecular pathways of drug disposition (Table 3-1). These variants are identified either by directly establishing DNA sequence (genotyping) or by phenotyping: exposing a large group of otherwise healthy subjects to a specific probe substrate and measurement of urinary formation of the metabolite. The heavy arrow indicates a clear antimode, separating poor metabolizer subjects (black), with two loss-of-function CYP2D6 alleles. Individuals with one or two functional alleles are grouped together as extensive metabolizers (blue). Also shown are ultrarapid metabolizers, with 2 to 11 functional copies of the gene (red) and 12 functional copies (green), displaying the greatest enzyme activity.

**FIGURE 3-6** CYP2D6 metabolic activity was assessed in 290 subjects by administration of a test dose of a probe substrate and measurement of urinary formation of the CYP2D6-generated metabolite. The heavy arrow indicates a clear antimode, separating poor metabolizer subjects (black), with two loss-of-function CYP2D6 alleles. Individuals with one or two functional alleles are grouped together as extensive metabolizers (blue). Also shown are ultrarapid metabolizers, with 2 to 11 functional copies of the gene (red) and 12 functional copies (green), displaying the greatest enzyme activity. (Adapted by permission from M-I. Dahl et al: J Pharmacol Exp Ther 274:515, 1995.)

Polymorphisms that reduce transcription of uridine diphosphate glucuronosyltransferase (UGT1A1) cause benign hyperbilirubinemia (Gilbert’s disease; Chap. 284). These have also been associated with diarrhea and increased bone marrow depression with the antineoplastic irinotecan, whose active metabolite is normally detoxified by this enzyme. Slow acetylators have an increased incidence of the drug-induced lupus syndrome during procainamide and hydralazine therapy and of hepatitis with isoniazid. Induction of CYPs (e.g., by rifampin) also increases the risk of isoniazid-related hepatitis, likely reflecting generation of reactive metabolites of acetyldihydrazine, itself an isoniazid metabolite.

Polymorphisms that reduce transcription of uridine diphosphate glucuronosyltransferase (UGT1A1) cause benign hyperbilirubinemia (Gilbert’s disease; Chap. 284). These have also been associated with diarrhea and increased bone marrow depression with the antineoplastic irinotecan, whose active metabolite is normally detoxified by this pathway.

**CYP Variants**

CYP3A4 is the most abundant hepatic and intestinal CYP and is also the enzyme responsible for metabolism of the greatest number of drugs in therapeutic use. CYP3A4 activity is highly variable (up to an order of magnitude) among individuals, but the distribution is unimodal, suggesting that the variability does not arise from variants in the CYP3A4 gene. The mechanisms underlying this variability are not yet well understood. A closely related gene, encoding CYP3A5 (which shares substrates with CYP3A4), does display loss-of-function variants, especially in African-derived populations. CYP3A3 refers to both enzymes.

CYP2D6 accounts for very little total hepatic CYP by weight but is second to CYP3A4 in the number of commonly used drugs that it metabolizes. CYP2D6 is polymorphically distributed, with about 7% of European- and African-derived populations (but very few Asians) displaying the PM phenotype (Fig. 3-6). Over 70 loss-of-function variants in the CYP2D6 gene have been described; the PM phenotype arises in individuals with two such alleles. In addition, individuals with multiple functional copies of the CYP2D6 gene (ultrarapid metabolizers) have been identified, particularly among northern Africans. CYP2D6 represents the main metabolic pathway for a number of drugs...
(Table 3-1). Codeine is biotransformed by CYP2D6 to the potent active metabolite morphine, so its effects are blunted in PMs and exaggerated in ultrarapid metabolizers. With beta blockers metabolized by CYP2D6 (including ophthalmic timolol and the antihypertrophic propranolone), PM subjects display greater signs of beta blockade (including bradycardia and bronchospasms) than EMs. Further, in EM subjects, proprafenone elimination becomes nonlinear at higher doses so, for example, a tripling of the dose may lead to a tenfold increase in drug concentration. The oral hypoglycemic agent phenformin was withdrawn because it occasionally caused profound lactic acidosis; this likely arose as a result of high concentrations in CYP2D6 PMs. Ultrarapid metabolizers may require very high dosages of tricyclic antidepressants to achieve a therapeutic effect, and with codeine may display transient euphoria and nausea due to very rapid generation of morphine.

The PM phenotype for CYP2C19 is common (20%) among Asians, and rarer (3 to 5%) in European-derived populations. The impact of polymorphic CYP2C19-mediated metabolism has been demonstrated with the proton pump inhibitor omeprazole, where ulcer cure rates with “standard” dosages were markedly lower in EM patients (29%) than in PMs (100%). Thus, understanding the importance of this polymorphism would have been important in developing the drug, and knowing a patient’s CYP2C19 genotype should improve therapy.

There are common allelic variants of CYP2C9 that encode proteins with loss of catalytic function. These variant alleles are associated with a requirement for lower maintenance dose of warfarin. In rarer (<2%) individuals homozygous for these variant alleles, maintenance warfarin dosages may be difficult to establish, and the risk of bleeding complications appears increased. Similarly, patients with loss-of-function CYP2C9 alleles display increased rates of neurologic complications with phenytoin and of hypoglycemia with glipizide.

VARIABILITY IN THE MOLECULAR TARGETS WITH WHICH DRUGS INTERACT As molecular approaches identify specific gene products as targets of drug action, polymorphisms that alter the expression or function of these drug targets—and thus modulate their actions in patients—are also being recognized. For example, genome-wide searches in families with premature Alzheimer’s disease have associated variants in the APOE locus with the disease (Chap. 350). The E4 allele of the gene has been associated with a worse prognosis, a finding that has been attributed to reduced expression of choline acetyltransferase. Further, this polymorphism is also linked to response to the acetylcholinesterase inhibitor tacrine. A beneficial response appears to be more common in patients with the prognostically more benign APOE3 allele (Table 3-1). Codeine is biotransformed by CYP2D6 to the potent active metabolite morphine, so its effects are blunted in PMs and exaggerated in ultrarapid metabolizers. With beta blockers metabolized by CYP2D6 (including ophthalmic timolol and the antihypertrophic propranolone), PM subjects display greater signs of beta blockade (including bradycardia and bronchospasms) than EMs. Further, in EM subjects, proprafenone elimination becomes nonlinear at higher doses so, for example, a tripling of the dose may lead to a tenfold increase in drug concentration. The oral hypoglycemic agent phenformin was withdrawn because it occasionally caused profound lactic acidosis; this likely arose as a result of high concentrations in CYP2D6 PMs. Ultrarapid metabolizers may require very high dosages of tricyclic antidepressants to achieve a therapeutic effect, and with codeine may display transient euphoria and nausea due to very rapid generation of morphine.

The PM phenotype for CYP2C19 is common (20%) among Asians, and rarer (3 to 5%) in European-derived populations. The impact of polymorphic CYP2C19-mediated metabolism has been demonstrated with the proton pump inhibitor omeprazole, where ulcer cure rates with “standard” dosages were markedly lower in EM patients (29%) than in PMs (100%). Thus, understanding the importance of this polymorphism would have been important in developing the drug, and knowing a patient’s CYP2C19 genotype should improve therapy.

There are common allelic variants of CYP2C9 that encode proteins with loss of catalytic function. These variant alleles are associated with a requirement for lower maintenance dose of warfarin. In rarer (<2%) individuals homozygous for these variant alleles, maintenance warfarin dosages may be difficult to establish, and the risk of bleeding complications appears increased. Similarly, patients with loss-of-function CYP2C9 alleles display increased rates of neurologic complications with phenytoin and of hypoglycemia with glipizide.

POLYMORPHISMS THAT MODULATE THE BIOLGIC CONTEXT WITHIN WHICH THE DRUG-TARGET INTERACTIONS OCCUR The interaction of a drug with its molecular target is translated into a clinical action in a complex biologic milieu that is itself often perturbed by disease. Thus, polymorphisms that determine variability in this biology may profoundly influence drug response, although the genes involved are not themselves directly targets of drug action. The common insertion/deletion (I/D) polymorphism in the ACE gene determines prognosis in many types of heart disease, including heart failure. In patients with heart failure treated with β-adrenergic blockers, the best response to therapy has been associated with the DD genotype, the group with the worst prognosis. The mechanism underlying this outcome is uncertain, but a direct effect of beta blockers on ACE seems unlikely; rather the I/D genotype likely affects the biology of heart failure to allow an improved response to beta blockers. Similarly, polymorphisms in genes important for lipid homeostasis (such as the ABCA1 transporter and the apolipoprotein E [APOE] genes) are associated with response to HMG-CoA reductase inhibitors. In one large study, the combination of diuretic use combined with a variant in the adducin gene (encoding a cytoskeletal protein important for renal tubular sodium absorption) decreased stroke or myocardial infarction risk, while neither factor alone has an effect. Common polymorphisms in ion channel genes that are not themselves the target of QT-prolonging drugs may nevertheless influence the extent to which those drugs affect the electrocardiogram and produce arrhythmias.

PROSPECTS FOR INCORPORATING GENETIC INFORMATION INTO CLINICAL PRACTICE These and many other examples of associations between specific genotypes and drug responses raise the tantalizing prospect that patients will undergo routine genotyping for loci known to modulate drug levels or response prior to receiving a prescription. The twin goals are to identify patients likely to exhibit adverse effects and those most likely to respond well. Obstacles that must be overcome before this vision becomes a reality include replication of even the most compelling associations, demonstrations of cost-effectiveness, development of readily usable genotyping technologies, and ethical issues involved in genotyping. While these barriers seem daunting, the field is very young and evolving rapidly. Indeed, one major result of understanding of the role of genetics in drug action has been improved screening of drugs during the development process to reduce the likelihood of highly variable metabolism or unanticipated toxicity (such as torsades de pointes).

INTERACTIONS BETWEEN DRUGS Drug interactions can complicate therapy by adversely increasing or decreasing the action of a drug; interactions may be based on changes in drug disposition or in drug response in the absence of changes in drug levels. Interactions must be considered in the differential diagnosis of any unusual response occurring during drug therapy. Prescribers should recognize that patients often come to them with a legacy of drugs acquired during previous medical experiences, often with multiple physicians who may not be aware of all the patient’s medications. A meticulous drug history should include examination of the patient’s medications and, if necessary, calls to the pharmacist to identify prescriptions. It should also address the use of agents not often volunteered during questioning, such as over-the-counter (OTC) drugs, health food supplements, and topical agents such as eye drops. Lists of interactions are available from a number of electronic sources. The practicing physician cannot be expected to memorize these. How-

Pharmacokinetic Interactions Causing Diminished Drug Delivery to Target Sites

**Impaired Gastrointestinal Absorption**

Aluminum ions, present in antacids, can form insoluble chelates with the tetracyclines, preventing their absorption. Kaolin-pectin suspensions bind digoxin, and when the substances are administered together, digoxin absorption is reduced by about one-half. Resins that sequester bile acids in the gut can bind other drugs, such as digoxin. Ketoconazole is a weak base that dissolves well only at acidic pH. Histamine H2 receptor antagonists and proton pump inhibitors reduce gastric acidity and thus impair the dissolution and absorption of ketoconazole.

**Induction of CYP or Transporter Activity**

Expression of some genes responsible for drug elimination, notably CYP3A and MDR1, can be markedly increased by “inducing” drugs, such as rifampin, carbamazepine, phenytoin, St. John’s wort, and glutethimide and by smoking, exposure to chlorinated insecticides such as DDT (CYP1A2), and chronic alcohol ingestion. One mechanism for this coordinate induction of multiple pathways is increased expression of common transcription factors (e.g., hepatocyte nuclear factor 4α).

Administration of inducing agents lowers plasma levels over 2 to 3 weeks as gene expression is increased. This alters the effects of many drugs, including warfarin, quinidine, mexiletine, verapamil, ketoconazole, itraconazole, cyclosporine, dexamethasone, methylprednisolone, prednisolone (the active metabolite of prednisone), oral contraceptive steroids, methadone, and metronidazole. These interactions all have obvious clinical significance. Further, if a drug dose is stabilized in the presence of an inducer which is subsequently stopped, major toxicity can occur as clearance returns to preinduction levels and drug concentrations rise. This is a particular problem with narrow-therapeutic-ratio drugs such as warfarin and some antiarrhythmics. Individuals vary in the extent to which drug metabolism can be induced, likely through genetic mechanisms.

**Inhibition of Cellular Uptake or Binding**

Tricyclic antidepressants, doxepin, and chlorpromazine are potent inhibitors of norepinephrine uptake into adrenergic neurons and prevent the uptake of the guanidinium anti-hypertensive agents (such as guanethidine and guanadrel), thereby abolishing their antihypertensive effects. Similarly, the antihypertensive effect of clonidine is partially antagonized by tricyclic antidepressants.

Pharmacokinetic Interactions Causing Increased Drug Delivery to Target Sites

**Inhibition of Drug Metabolism**

Inhibition of drug metabolism can lead to reduced clearance, prolonged half-life, accumulation of drug during maintenance therapy, and thus adverse effects. In contrast to induction, new protein synthesis is not involved, and the effect develops as drug and any inhibitor metabolites accumulate (a function of their elimination half-lives). Since shared substrates of a single enzyme can compete for access to the active site of the protein, many CYP substrates can also be considered inhibitors. However, some drugs are especially potent as inhibitors (and occasionally may not even be substrates); it is in the use of agents of the latter type that clinicians must be especially alert to the potential for interactions.

Cimetidine (but not other H2-receptor blockers) is a potent inhibitor of the oxidative metabolism of many drugs, including warfarin, quinidine, nifedipine, lidocaine, theophylline, and phenytoin. Severe adverse reactions can develop as a consequence.

The antifungal agents ketoconazole and itraconazole are potent inhibitors of enzymes in the CYP3A family. When fluconazole levels are elevated as a result of higher doses and/or renal insufficiency, this drug can also inhibit CYP3A. The macrolide antibiotics erythromycin and clarithromycin inhibit CYP3A4 to a clinically significant extent, but azithromycin does not. Some of the calcium channel blockers, including diltiazem, nicardipine, and verapamil can also inhibit CYP3A, as can some of the enzyme’s substrates, such as cyclosporine.

Examples of CYP3A substrates also include quinidine, lovastatin, simvastatin, atorvastatin, nifedipine, lidocaine, erythromycin, methylprednisolone, carbamazepine, midazolam, and triazolam.

Phenytoin, an inducer of many systems including CYP3A, inhibits CYP2C9. CYP2C9 metabolism of losartan to its active metabolite is inhibited by phenytoin, with potential loss of antihypertensive effect. Accumulation of the prokinetic drug cisapride and the antihista mine terfenadine due to CYP3A inhibition led to QT prolongation and torsades de pointes. Measures to prevent co-prescription of these agents with CYP3A inhibitors were unsuccessful, and alternative safer agents were developed, so these drugs were eventually withdrawn.

Cyclosporine can cause serious toxicity when its metabolism via CYP3A4 is inhibited by erythromycin, ketoconazole, diltiazem, nicardipine, or verapamil. The risk of myopathy with some HMG-CoA reductase inhibitors (lovastatin, simvastatin, atorvastatin) is thought to be increased by CYP3A4 inhibition. One agent in this class, cerivas-
tatin, was withdrawn because of an especially high incidence of this adverse effect, although cellular studies suggest inhibition of other pathways may have also contributed in this case. The antiviral ritonavir is a very potent CYP3A4 inhibitor that is often added to anti-HIV regimens not because of its antiviral effects but because it decreases clearance, and hence increases efficacy, of other anti-HIV agents. Grapefruit (but not orange) juice inhibits CYP3A, especially at high doses; patients receiving drugs where even modest CYP3A inhibition may increase the risk of adverse effects (e.g., cyclosporine, some HMG-CoA reductase inhibitors) should therefore avoid grapefruit juice.

CYP2D6 is markedly inhibited by quinidine and is also blocked by a number of neuroleptic drugs, such as chlorpromazine and haloperidol, and by fluoxetine. The analgesic effect of codeine depends on its metabolism to morphine via CYP2D6. Thus, quinidine reduces the analgesic efficacy of codeine in EMs. Since desipramine is cleared largely by metabolism via CYP2D6 in EMs, its levels are increased substantially by concurrent administration of quinidine, fluoxetine, or the neuroleptics that inhibit CYP2D6. Clinical consequences of fluoxetine’s interaction with CYP2D6 substrates may not be apparent for weeks after the drug is started, because of its very long half-life and slow generation of a CYP2D6-inhibiting metabolite.

6-Mercaptopurine, the active metabolite of azathioprine, is metabolized not only by TPMT but also by xanthine oxidase. When allopurinol, a potent inhibitor of xanthine oxidase, is administered with standard doses of azathioprine or 6-mercaptopurine, life-threatening toxicity (bone marrow suppression) can result.

**Inhibition of Drug Transport** The best studied example is P-glycoprotein (Fig. 3-4). Quinidine inhibits P-glycoprotein function in vitro, and it now appears that the long-recognized doubling of plasma digoxin when quinidine is coadministered reflects this action in vivo, particularly since the effects of quinine (increased digoxin bioavailability and reduced renal and hepatic secretion) occur at the sites of P-glycoprotein expression. Many other drugs also elevate digoxin concentrations (e.g., amiodarone, verapamil, cyclosporine, itraconazole, and erythromycin), and a similar mechanism seems likely. Reduced CNS penetration of multiple HIV protease inhibitors (with the attendant risk of facilitating viral replication in a sanctuary site) appears attributable to P-glycoprotein-mediated exclusion of the drug from the CNS; thus inhibition of P-glycoprotein has been proposed as a therapeutic approach to enhance drug entry to the CNS.

A number of drugs are secreted by the renal tubular transport systems for organic anions. Inhibition of these systems can cause excessive drug accumulation. Salicylate, for example, reduces the renal clearance of methotrexate, an interaction that may lead to methotrexate toxicity. Renal tubular secretion contributes substantially to the elimination of penicillin, which can be inhibited (to increase its therapeutic effect) by probenecid.

Inhibition of the tubular cation transport system by cimetidine decreases the renal clearance of doxetiletide and of procarcinamide and its active metabolite NAPA.

**DRUG INTERACTIONS NOT MEDIATED BY CHANGES IN DRUG DISPOSITION** Drugs may act on separate components of a common process to generate effects greater than either has alone. For example, although small doses of aspirin (<1 g daily) do not alter the prothrombin time appreciably in patients who are receiving warfarin therapy, aspirin nevertheless increases the risk of bleeding in these patients because it inhibits platelet aggregation. Thus the combination of impaired functions of platelets and of the clotting system, while useful in some patients, also increases the potential for hemorrhagic complications. Similarly, the use of other anticlotting agents (heparin, glycoprotein Ib/IIa inhibitors, clopidogrel) with aspirin improves outcomes in acute coronary syndromes, while exacerbating this bleeding tendency.

Nonsteroidal anti-inflammatory drugs (NSAIDs) cause gastric ulcers, and, in patients treated with warfarin, the risk of bleeding from a peptic ulcer is increased almost threefold by concomitant use of a NSAID. Indomethacin, piroxicam, and probably other NSAIDs antagonize the antihypertensive effects of β-adrenergic receptor blockers, diuretics, ACE inhibitors, and other drugs. The resulting elevation in blood pressure ranges from trivial to severe. This effect is not seen with aspirin and sulindac but has been found with cyclooxygenase-2 inhibitors (celecoxib, rofecoxib).

Torsades de pointes during administration of QT-prolonging antiarrhythmics (quinidine, sotalol, dofetilide) occur much more frequently in those patients receiving diuretics, probably reflecting hypokalemia. In vitro, hypokalemia not only prolongs the QT interval in the absence of drug but also potentiates drug block of ion channels that results in QT prolongation. Also, some diuretics have direct electrophysiologic actions that prolong QT.

The administration of supplemental potassium leads to more frequent and severe hypokalemia when potassium elimination is reduced by concurrent treatment with ACE inhibitors, spironolactone, amiloride, or triamterene.

The pharmacologic effects of sildenafil result from inhibition of the phosphodiesterase type 5 isomorph that inactivates cyclic GMP in the vasculature. Nitroglycerin and related nitrates used to treat angina produce vasodilation by elevating cyclic GMP. Thus, coadministration of these nitrates with sildenafil can cause profound hypotension, which can be catastrophic in patients with coronary disease.

Sometimes, combining drugs can increase overall efficacy and/or reduce drug-specific toxicity. Such therapeutically useful interactions are described in chapters dealing with specific disease entities, elsewhere in this text.

**ADVERSE REACTIONS TO DRUGS** The beneficial effects of drugs are coupled with the inescapable risk of untoward effects. The morbidity and mortality from these untoward effects often present diagnostic problems because they can involve every organ and system of the body and are frequently mistaken for signs of underlying disease. Major advances in the investigation, development, and regulation of drugs ensure in most instances that drugs are uniform, effective, and relatively safe and that their recognized hazards are publicized. However, prior to regulatory approval and marketing, new drugs are tested in relatively few patients who tend to be less sick and to have fewer concomitant diseases than those patients who subsequently receive the drug therapeutically. Because of the relatively small number of patients studied in clinical trials, and the selected nature of these patients, rare adverse effects may not be detected prior to a drug’s approval, and physicians therefore need to be cautious in the prescription of new drugs and alert for the appearance of previously unrecognized adverse events. Often, these adverse reactions are rare, such as hematologic abnormalities, arrhythmias, hepatitis, or renal dysfunction. In these cases, often (but inappropriately) labeled “idiiosyncratic,” elucidating underlying mechanisms can assist development of safer compounds or allow a patient subset at especially high risk to be excluded from drug exposure. National adverse reaction reporting systems, such as those operated by the U.S. Food and Drug Administration (suspected adverse reactions can be reported online at http://www.fda.gov/medwatch/report/hcp.htm) and the Committee on Safety of Medicines in Great Britain, can prove useful. The publication or reporting of a newly recognized adverse reaction can in a short time stimulate many similar such reports of reactions that previously had gone unrecognized.

Occasionally, “adverse” effects may be exploited to develop an entirely new indication for a drug. Unwanted hair growth during minoxidil treatment of severely hypertensive patients led to development of the drug for hair growth. Sildenafil was initially developed as an antianginal, but its effects to alleviate erectile dysfunction not only led to a new drug indication but also to increased understanding of the role of type 5 phosphodiesterase in erectile tissue. These examples further reinforce the concept that prescribers must remain vigilant to the possibility that unusual symptoms may reflect unappreciated drug effects.
The large number and variety of drugs and herbal remedies available OTC as well as by prescription make it impossible for patient or physician to obtain or retain the knowledge necessary to use all drugs well. It is understandable, therefore, that many OTC drugs are used unwisely by the public and that restricted drugs may be prescribed incorrectly by physicians.

Some 25 to 50% of patients make errors in self-administration of prescribed medicines, and these errors can be responsible for adverse drug effects. Elderly patients are the group most likely to commit such errors, perhaps in part because they consume more medicines. One-third or more of patients also may not take their prescribed medications. Similarly, patients commit errors in taking OTC drugs by not reading or following the directions on the containers. Physicians must recognize that providing directions with prescriptions does not always guarantee compliance.

In hospital, drugs are administered in a controlled setting, and patient compliance is, in general, ensured. Errors may occur nevertheless—the wrong drug or dose may be given or the drug may be given to the wrong patient—and improved drug distribution and administration systems are addressing this problem. On the other hand, there are no easy means for controlling how ambulatory patients take prescription or OTC drugs.

**EPIEDEMOLOG**

Patients receive, on average, 10 different drugs during each hospitalization. The sicker the patient, the more drugs are given, and there is a corresponding increase in the likelihood of adverse drug reactions. When <6 different drugs are given to hospitalized patients the probability of an adverse reaction is ~5%, but if >15 drugs are given, the probability is >40%. Retrospective analyses of ambulatory patients have revealed adverse drug effects in 20%. Serious adverse reactions are also well recognized with “herbal” remedies and OTC compounds: examples include kava-associated hepatotoxicity, L-tryptophan-associated eosinophilia-myalgia, and phenylpropanolamine-associated stroke, each of which has caused fatalities.

A 2000 Institute of Medicine report indicated that 7000 Americans die annually because of medication errors, that 2 to 3% of hospital admissions are for illnesses attributed to drugs, that the in-hospital cost was $2 billion, and that this represents a tiny fraction of the overall problem of medication errors and its costs. A small group of widely used drugs accounts for a disproportionate number of reactions. Aspirin and other NSAIDs, analgesics, digoxin, anticoagulants, diuretics, antimicrobials, glucocorticoids, antineoplastics, and hypoglycemic agents account for 90% of reactions, although the drugs involved differ between ambulatory and hospitalized patients.

**ETIOLOGY**

Most adverse drug reactions are preventable, and recent studies using a systems analysis approach suggest that the most common system failure associated with an adverse drug reaction is the failure to disseminate knowledge about drugs to individuals who prescribe and administer them. Most adverse reactions may be classified in two groups. The most frequent ones result from exaggeration of an intended pharmacologic action of the drug, and the underlying mechanisms have been discussed above. Other adverse reactions ensue from toxic effects unrelated to the intended pharmacologic actions. The latter effects are often unpredictable and frequently severe, and result from recognized as well as undiscovered mechanisms.

**TOXICITY UNRELATED TO A DRUG'S PRIMARY PHARMACOLOGIC ACTIVITY**

**Cytotoxic Reactions**

Drug or more commonly reactive metabolites generated by CYPs can covalently bind to tissue macromolecules (such as proteins or DNA) to cause tissue toxicity. Because of the reactive nature of these metabolites covalent binding often occurs close to the site of production; this is typically the liver, although CYPs are found in other tissues as well.

The most common cause of drug-induced hepatotoxicity is acetaminophen overdose. Normally, reactive metabolites are detoxified by combining with hepatic glutathione. When glutathione becomes exhausted, the metabolites bind instead to hepatic protein, with resultant hepatocyte damage. The hepatic necrosis produced by the ingestion of acetaminophen can be prevented, or at least attenuated, by the administration of substances such as N-acetylcysteine that reduce the binding of electrophilic metabolites to hepatic proteins. The risk of hepatic necrosis is increased in patients receiving drugs such as phenobarbital or phenytoin that increase the rate of drug metabolism or ethanol that exhaust glutathione stores. Such toxicity has even occurred with therapeutic dosages, so patients at risk through these mechanisms should be warned.

**Immunologic Mechanisms**

Most pharmacologic agents are small molecules with low molecular weights (<2000) and thus are poor immunogens. Generation of an immune response to a drug therefore usually requires in vivo activation and covalent linkage to protein, carbohydrate, or nucleic acid.

Drug stimulation of antibody production may mediate tissue injury by several mechanisms. The antibody may attack the drug when the drug is covalently attached to a cell, and thereby destroy the cell. This occurs in penicillin-induced hemolytic anemia. Antibody-drug-antigen complexes may be passively adsorbed by a bystander cell, which is then destroyed by activation of complement; this occurs in quinine- and quinine-induced thrombocytopenia. Heparin-induced thrombocytopenia arises when antibodies against complexes of platelet factor 4 peptide and heparin generate immune complexes that activate platelets; thus the thrombocytopenia is accompanied by “paradoxical” thrombosis and is treated with thrombin inhibitors. Drugs or their reactive metabolites may alter a host tissue, rendering it antigenic and eliciting autoantibodies. For example, hydralazine and procainamide (or their reactive metabolites) can chemically alter nuclear material, stimulating the formation of antinuclear antibodies and occasionally causing lupus erythematosus. Autoantibodies can be elicited by drugs that neither interact with the host antigen nor have any chemical similarity to the host tissue; for example, the antihypertensive a-methyl-dopa frequently stimulates the formation of antibodies to host erythrocytes, yet the drug neither attaches to the erythrocyte nor shares any chemical similarities with the antigenic determinants on the erythrocyte. Drug-induced pure red cell aplasia (Chap. 94) is due to an immune-based drug reaction. Red cell formation in bone marrow cultures can be inhibited by phenytoin and purified IgG obtained from a patient with pure red cell aplasia associated with phenytoin.

Serum sickness (Chap. 298) results from the deposition of circulating drug-antibody complexes on endothelial surfaces. Complement activation occurs, chemotactic factors are generated locally, and an inflammatory response develops at the site of complex entrapment. Arthus, urticaria, lymphenadenopathy, glomerulonephritis, or cerebritis may result. Foreign proteins (vaccines, streptokinase, therapeutic antibodies) and antibiotics are common causes. Many drugs, particularly antimicrobial agents, ACE inhibitors, and aspirin, can elicit anaphylaxis, with production of IgE, which binds to mast cell membranes. Contact with a drug antigen initiates a series of biochemical events in the mast cell and results in the release of mediators that can produce the characteristic urticaria, wheezing, flushing, rhinorrhea, and (occasionally) hypotension.

Drugs may also elicit cell-mediated immune responses. Topically administered substances may interact with sulfhydryl or amino groups in the skin and react with sensitized lymphocytes to produce the rash characteristic of contact dermatitis. Other types of rashes may also result from the interaction of serum factors, drugs, and sensitized lymphocytes.

**DIAGNOSIS AND TREATMENT OF ADVERSE DRUG REACTIONS**

The manifestations of drug-induced diseases frequently resemble those of other diseases, and a given set of manifestations may be produced by different and dissimilar drugs. Recognition of the role of a drug or drugs in an illness depends on appreciation of the possible adverse reactions to drugs in any disease, on identification of the temporal relationship between drug administration and development of the illness, and on familiarity with the common manifestations of the drugs. Many associations between particular drugs and specific reactions have been
The time needed for a concentration-dependent adverse effect to disappear depends on the time required for the concentration to fall below the range associated with the adverse effect; that, in turn, depends on the initial blood level and on the rate of elimination or metabolism of the drug. Adverse effects of drugs with long half-lives take a considerable time to disappear.

SUMMARY

Modern clinical pharmacology aims to replace empiricism in the use of drugs with therapy based on in-depth understanding of factor(s) that determine an individual’s response to drug treatment. Molecular pharmacology, pharmacokinetics, genetics, clinical trials, and the educated prescriber all contribute to this process. No drug response should ever be termed “idiosyncratic”; all responses have a mechanism whose understanding will help guide further therapy with that drug or successors. This rapidly expanding understanding of variability in drug actions makes the process of prescribing drugs increasingly daunting for the practitioner. However, fundamental principles should guide this process:

- The benefits of drug therapy, however defined, should always outweigh the risk.
- The smallest dosage necessary to produce the desired effect should be used.
- The number of medications and doses per day should be minimized.
- Although the literature is rapidly expanding, accessing it is becoming easier; tools such as computers and hand-held devices to search databases of literature and unbiased opinion will become increasingly commonplace.
- Genetics play a role in determining variability in drug response and may become a part of clinical practice.
- Prescribers should be particularly wary when adding or stopping specific drugs that are especially liable to provoke interactions and adverse reactions.
- Prescribers should use only a limited number of drugs, with which they are thoroughly familiar.

PATSY BM et al: Diuretic therapy, the alpha-2adrenergic gene variant, and the risk of myocardial infarction or stroke in persons with treated hypertension. JAMA 287:1680, 2002

A primary goal of health care is to prevent disease or to detect it early enough that interventions will be more effective. Strategies for disease screening and prevention are driven by evidence that testing and interventions are practical and effective. Most screening tests are currently based on readily available and inexpensive biochemical (e.g., cholesterol), physiologic (e.g., blood pressure), radiologic (e.g., mammogram), or tissue specimens (e.g., Pap smear). In the future, it is anticipated that genetic testing will play an increasingly important role for predicting disease risk (Chap. 58). However, such tests are not widely used except for individuals at risk for high-penetrance genes based on family or ethnic history (e.g., BRCA1, BRCA2). The identification of low-penetrance but high-frequency genes that cause common disorders such as diabetes or hypertension offers the possibility of new genetic tests. However, any new screening test, whether based on genetic or other methods, must be subjected to rigorous evaluation of its sensitivity, specificity, impact on disease, and cost-effectiveness. Physicians and patients are continuously introduced to new screening tests, often in advance of complete evaluation. For example, the use of whole-body computed tomography imaging has been advocated as a means to screen for a variety of disorders. Though appealing in concept, there is currently no evidence to justify this approach, which is associated with high cost and a substantial risk of false-positive results.

This chapter will review the basic principles of screening and strategies for measuring the impact of screening and prevention and will provide a summary of recommendations for screening and prevention in the primary care setting. Recommendations for specific disorders, such as cardiovascular disease, diabetes, or cancer, are provided in the chapters dedicated to these topics.

**BASIC PRINCIPLES OF SCREENING** In general, screening is most effective when applied to relatively common disorders that carry a large disease burden (Table 4-1). The five leading causes of mortality in the United States are heart diseases, malignant neoplasms, accidents, cerebrovascular diseases, and chronic obstructive pulmonary disease. Thus, many prevention strategies are targeted at these conditions.

A primary goal of screening is the early detection of a risk factor or disease at a stage when it can be corrected or cured. For example, most cancers have a better prognosis when identified as premalignant lesions or when they are still resectable. Similarly, early identification of hypertension or hyperlipidemia allows therapeutic interventions that reduce the risk of cardiovascular or cerebrovascular events. However, early detection does not necessarily influence survival. For example, in some studies of lung cancer screening, tumors are identified at an early stage, but overall mortality does not differ between screened and unscreened populations. The apparent improvement in 5-year survival rates can be attributed to the detection of smaller tumors rather than a real change in clinical course after diagnosis. Similarly, the detection of prostate cancer may not lead to a mortality difference because the disease is often indolent and competing morbidities, such as coronary artery disease, may ultimately cause mortality (Chap. 67).

Disorders with a long latency period increase the potential gains associated with detection. For example, cancer of the cervix has a long latency between dysplasia and invasive carcinoma, providing an opportunity for detection by routine screening. Similarly, an adenoma-polyp progresses to invasive colon cancer over 4 to 12 years, allowing an opportunity to detect early lesions by fecal occult blood testing and endoscopy. On the other hand, breast cancer screening in premenopausal women is more challenging because of the relatively short interval between development of a localized breast cancer and metastasis to regional nodes (estimated to be ~12 months).

**METHODS OF MEASURING HEALTH BENEFITS** It is not practical to perform all possible screening procedures. For example, screening for laryngeal cancer in smokers is not currently recommended. It is necessary to examine the strength of evidence in favor of screening measures relative to the cost and risk of false-positive tests. For example, should ultrasound be used to screen for ovarian cancer in average-risk women? It is currently estimated that the unnecessary laparotomies triggered by finding benign ovarian masses would actually cause more harm than the benefit derived from detecting the occasional curable ovarian cancer.

A variety of end points are used to assess the potential gain from screening and prevention interventions:

1. **The number of subjects screened to alter the outcome in one individual.** It is estimated, for example, that 731 women aged 65 to 69 would need to be screened by dual-energy x-ray absorptiometry (DEXA) and then treated appropriately to prevent one hip fracture from osteoporosis.

2. **The absolute and relative impact of screening on disease outcome.** A meta-analysis of Swedish mammography trials (ages 40 to 70) found that ~1.2 fewer women per thousand would die from breast cancer if they were screened over a 12-year period. By comparison, ~3 lives per 1000 might be saved from colon cancer in a population (ages 50 to 75) screened with annual fecal occult blood testing (FOBT) over a 13-year period. Based on this analysis, colon cancer screening may actually save more women’s lives than mammography. The impact of FOBT (8.8/1000 versus 5.9/1000) might be stated as either 3 lives per 1000, or as a 30% reduction in colon cancer death; thus, it is important to consider both the relative and absolute impact on numbers of lives saved.

3. **The cost per year of life saved.** This is used to assess the effectiveness of many screening and prevention strategies. Typically, strategies that cost <$30,000 to $50,000 per year of life saved are considered “cost effective” (Chap. 2). For example, using alendronate to treat 65-year-old women with osteoporosis for their entire life would need to be screened by dual-energy x-ray absorptiometry (DEXA) and then treated appropriately to prevent one hip fracture from osteoporosis.

4. **Increase in average life expectancy for a population.** Predicted increases in life expectancy for various screening procedures are listed in Table 4-2. It should be noted, however, that the life expectancy increase is an average that applies to a population and not to an individual. In reality, the vast majority of the screened population does not derive any benefit and possibly incurs a slight risk.

from false-positive results. A small subset of patients, however, will benefit greatly from being screened. For example, Pap smears do not benefit the 98% of women who never develop cancer of the cervix. However, for the 2% who would develop localized cervical cancer, Pap smears may add as much as 25 years to their lives. Some studies suggest that a 1-month gain of life expectancy is a reasonable goal for a population-based preventive strategy.

The U.S. Preventive Services Task Force provides recommendations for evidence-based screening (Table 4-3). In addition to these population-based guidelines, it is reasonable to consider families and social history to identify individuals with special risk factors (www.ahrq.gov/clinic/uspstfix.htm).

For example, when there is a significant family history of breast, colon, or prostate cancer, it is prudent to initiate screening about 10 years before the age when the youngest family member developed cancer. Screening should also be considered for many other common disorders pending the development of further evidence. Three examples are screening for diabetes (using fasting blood glucose), domestic violence, and features of depression.

**Cost-Effectiveness**

Screening techniques must be cost effective, if they are to be applied to large populations. Costs include not only the expense of testing but also time away from work and potential risks. When the risk-to-benefit ratio is less favorable, it is useful to provide information to patients and factor their perspectives into the decision-making process. For example, many expert groups, including the U.S. Preventive Services Task Force, recommend an individualized discussion about prostate cancer screening, as the decision-making process is complex and relies heavily on personal issues. Although the early detection of prostate cancer may intuitively seem desirable, risks include false-positive results that can lead to anxiety and unnecessary surgery. Potential complications from surgery and radiation treatment include erectile dysfunction, urinary incontinence, and bowel dysfunction. Some men may decline screening, while others may be more willing to accept the risks of an early detection strategy. Another example of shared decision-making is the choice of colon cancer screening techniques (Chap. 67).

In controlled studies, the use of annual FOBT reduces colon cancer deaths by 15 to 30%. Flexible sigmoidoscopy reduces colon cancer deaths by ~60%. Colonoscopy offers the same, or greater, benefit than flexible sigmoidoscopy, but its use incurs additional costs and risks. These screening procedures have not been directly compared in the same population, but the estimated cost to society is similar—$10,000 to $25,000 per year of life saved. Thus, while one patient may prefer the ease of preparation, less time disruption, and the lower risk of flexible sigmoidoscopy, others may prefer the sedation and thoroughness of colonoscopy.

When considering the impact of screening tests, it is important to recognize that tobacco and alcohol use, diet, and exercise represent the vast majority of factors that influence preventable deaths. Perhaps the single greatest preventive health care measure is to help patients quit smoking (Chap. 375). **COMMONLY ENCOUNTERED ISSUES**

Despite compelling evidence that prevention strategies can have major health care benefits, implementation of these services is challenging because of competing demands on physician and patient time and because of gaps in health care reimbursement. Moreover, efforts to reduce disease risk frequently involve behavior changes (e.g., weight loss, exercise, seatbelts) or managing addictive conditions (e.g., tobacco and alcohol use) that are often recalcitrant to intervention. Public education and economic incentives are often useful, in addition to counseling by health care providers (Table 4-4).

A number of techniques can assist the physician with the growing number of recommended screening tests. An appropriately configured electronic medical record can provide reminder systems that make it easier for physicians to track and meet guidelines. Some systems pro-

* Screening is performed earlier and more frequently when there is a strong family history. Randomized, controlled trials have documented that fecal occult blood testing (FOBT) confers a 15 to 30% reduction in colon cancer mortality. Although randomized trials have not been performed for sigmoidoscopy or colonoscopy, well-designed case-control studies suggest similar or greater efficacy relative to FOBT.

**Note:** Prostate-specific antigen (PSA) testing is capable of enhancing the detection of early-stage prostate cancer, but evidence is inconclusive that it improves health outcomes. PSA testing is recommended by several professional organizations and is widely used in clinical practice, but it is not currently recommended by the U.S. Preventive Services Task Force (Chap. 81).

**Note:** STDs, sexually transmitted diseases.
The study of biologic differences between sexes has emerged as a distinct scientific discipline in the United States. A report from the Institute of Medicine (IOM) found that sex has a broad impact on biologic and disease processes and succinctly concluded—sex matters. The National Institutes of Health established the Office of Research on Women’s Health in 1990 to develop an agenda for future research in the field. In parallel, women’s health is developing as a new clinical discipline with a focus on disorders that are disproportionately represented in women. The integration of women’s health into internal medicine and other specialties has been accompanied by novel approaches to health care delivery, including greater attention to patient education and involvement in disease prevention and medical decision-making.

The IOM report recommended the terms sex difference to describe biologic processes that differ between males and females and gender difference for features related to social influences. This chapter highlights representative examples of sex differences in selected medical areas. Disorders discussed in this section are reviewed in detail in other chapters.

**DISEASE RISK: REALITY AND PERCEPTION** The leading causes of death are the same in women and men: (1) heart disease, (2) cancer, and (3) cerebrovascular disease (Table 5-1; Fig. 5-1). The leading cause of cancer death, lung cancer, is the same in both sexes. Breast cancer is the second leading cause of cancer death in women but with rates that are 35% lower than those for lung cancer. Men are substantially more likely to die from suicide, homicide, and accidents than women.

Women’s risk for many diseases increases at menopause, which occurs at a median age of 51.4 years. In the industrialized world, women spend one-third of their lives in the postmenopausal period. Estrogen levels fall abruptly at menopause, inducing a variety of physiologic and metabolic responses. Rates of cardiovascular disease increase and bone density begins to decrease after menopause. Nevertheless, in the United States women live on average 5.7 years longer than men, with a life expectancy of 79.5 years compared to 73.8 years in men. Elderly women outnumber elderly men, so that age-related conditions, such as hypertension, have a female preponderance.

Women’s perception of disease risk is often inaccurate; <10% know that cardiovascular disease is the leading cause of death in women. The condition that they fear most is breast cancer, despite the fact that death rates from breast cancer have been falling since the 1990s. In any given decade of life, a woman’s risk for breast cancer never exceeds 1 in 34. Although a woman’s lifetime risk of developing breast cancer if she lives past 85 years is about 1 in 9, it is much more likely that she will die from cardiovascular disease than from breast cancer. In other words, many elderly women have breast cancer but die from other causes. Similarly, only 26% of women are aware that lung cancer is the leading cause of cancer death in women. These misconceptions are unfortunate as they perpetuate inadequate attention to modifiable risk factors, such as dyslipidemia, hypertension, and cigarette smoking. Physicians are also less likely to recognize women’s risk for cardiovascular disease. When presented with actors portraying patients with chest pain, physicians’ estimates for probability of coronary heart disease (CHD) were significantly lower for women than for men and were lower for black women than for white women. These perceptions on the part of both the patient and her physician lead to important differences in cardiac care that are discussed below.

**SEX DIFFERENCES IN HEALTH AND DISEASE**

**Alzheimer’s Disease** (See also Chap. 350) Alzheimer’s disease (AD) affects approximately twice as many women as men. Because the risk for AD increases with age, part of this sex difference is accounted for by the fact that women live longer than men. However, additional factors likely contribute to the increased risk for AD in women. There are sex differences in brain size, structure, and functional organization. There is emerging evidence for sex-specific differences in gene expression, not only for genes on the X and Y chromosomes but also for some autosomal genes. Estrogens have pleiotropic genomic and nongenomic effects on
the central nervous system, including neurotrophic actions in key areas involved in cognition and memory. Women with AD have lower endogenous estrogen levels compared to women without AD. These observations have led to the hypothesis that estrogen is neuroprotective. Some studies have suggested that estrogen administration improves cognitive function in non-demented postmenopausal women as well as in women with AD, and several observational studies have suggested that postmenopausal hormone therapy (PHT) may decrease the risk of AD. However, recent placebo-controlled trials have found no improvement in disease progression or cognitive function after up to 15 months of PHT in women with AD. The findings in these observational studies may be confounded by the fact that PHT users are better educated and have higher socioeconomic status, both of which are associated with a decreased risk of AD. An ancillary study of the Women’s Health Initiative (WHI) randomized clinical trial, the WHI Memory Study, is prospectively evaluating the impact of PHT on cognitive function and the development of AD in women 65 to 79 years of age at the time of enrollment. The results of this study should be available in 2007.

**Coronary Heart Disease** (See also Chap. 226) There are major sex differences in CHD, the leading cause of death in men and women in the United States. CHD death rates have been falling in men over the past 30 years but they have been increasing in women.

CHD presents differently in women, who are usually 10 to 15 years older than their male counterparts and are more likely to have comorbidities, such as hypertension, congestive heart failure, and diabetes. In the Framingham study, angina was the most frequent initial symptom of CHD in women, whereas myocardial infarction was the most frequent initial presentation in men. Women more often have atypical symptoms, such as nausea, vomiting, indigestion, and upper back pain.

Women with myocardial infarction are more likely to present with cardiac arrest or cardiogenic shock, whereas men are more likely to present with ventricular tachycardia. Further, younger women with myocardial infarction are more likely to die than men of similar age, with women under <50 experiencing twice the mortality rate of men, even after adjustment for differences in disease severity and management. Indeed, the younger the woman, the greater the risk of death from myocardial infarction compared to men (Fig. 5-2).

Physicians are less likely to suspect heart disease in women with chest pain and are less likely to perform diagnostic and therapeutic cardiac procedures in women. In addition, there are sex differences in the accuracy of certain diagnostic procedures. The exercise electrocardiogram has substantial false-positive as well as false-negative rates in women compared to men. Women are less likely to receive therapies such as angioplasty, thrombolytic therapy, coronary artery bypass grafts, beta-blockers, or aspirin. There are also sex differences in outcomes when women with CHD do receive therapeutic interventions. Women undergoing coronary artery bypass graft surgery have more advanced disease, a higher perioperative mortality rate, less relief of angina, and less graft patency; however, 5- and 10-year survival rates are similar. Women undergoing percutaneous transluminal coronary angioplasty have lower rates of initial angiographic and clinical success than men, but they also have a lower rate of restenosis and a better long-term outcome. Women may benefit less and have more frequent serious bleeding complications from thrombolytic therapy than do men. Factors such as older age, more comorbid conditions, and more severe CHD in women at the time of events or procedures appear to account in part for the observed sex differences.

Elevated cholesterol levels, hypertension, smoking, obesity, low high-density lipoprotein (HDL) cholesterol levels, diabetes, and lack of physical activity are important risk factors for CHD in both men and women. Total triglyceride levels are an independent risk factor for CHD in women but not in men. Low HDL-cholesterol and diabetes are more important risk factors for CHD in women than in men. Smoking is an important risk factor for CHD in women—it accelerates atherosclerosis, exerts direct negative effects on cardiac function, and is associated with an earlier age of menopause. Cholesterol-lowering drugs are equally effective in men and women for primary and sec-

The WHI trial randomized 16,608 women 50 to 79 years of age: 8,506 to estrogen plus progestin and 8,102 to placebo. It was halted in May 2002 after an average follow-up of 5.2 years because women receiving PHT had an increased risk of invasive breast cancer, and an overall assessment of outcomes showed more risk than benefit. Compared to women in the placebo group, women in the PHT group had a 26% higher rate of breast cancer, a 29% higher rate of CHD, a 41% higher rate of stroke, and a greater than twofold increase in pulmonary embolism (Table 5-2). There was no difference in the rate of endometrial cancer in the PHT group compared to the placebo group. There was a 33% reduction in the rate of hip fractures and a 37% reduction in the rate of colon cancer in the PHT group. Despite these beneficial effects, the global index of outcomes showed that the PHT group had a 15% higher rate of adverse events compared to the placebo group. Nevertheless, the absolute risk of PHT is relatively small. In 10,000 women receiving PHT compared to those receiving placebo, one would predict that over 1 year there might be eight more invasive breast cancers, seven more CHD events, eight more strokes, eight more pulmonary embolic events, but six fewer colon cancers and five fewer hip fractures. An estrogen-only arm of this study is ongoing.

Why did the results of these randomized clinical trials differ so markedly from those of observational studies of PHT? Women placed on PHT tend to have higher socioeconomic status, more education, lower body weight and blood pressure, and more favorable lipid profiles than nonusers—all factors that independently decrease the risk of CHD. This phenomenon has been called the healthy user effect. Physicians may also choose to prescribe PHT to women they deem to be healthier. Women at risk for certain conditions, such as breast cancer, may not be placed on PHT, which could decrease the number of PHT-associated cases of breast cancer in observational studies. In addition, individuals who continue to take medication, including placebo, have decreased overall mortality. This phenomenon is known as compliance bias and could contribute to the better outcomes for PHT users in observational studies. It is also possible that the type of PHT was a factor in the paradoxical results of the randomized clinical trials. Combined continuous estrogen plus progestin was used in both trials, because it was the most widely prescribed preparation and it does not induce menstrual bleeding (although many women do experience irregular bleeding early in therapy), permitting blinding of the trial. The progestin used was medroxyprogesterone acetate, which has been shown to have a number of adverse metabolic effects, such as antagonizing the beneficial effects of estrogen on lipids and insulin sensitivity. Progestins may also abolish the beneficial direct vascular actions of estrogen and increase the risk for breast cancer. The estrogen-alone component of the WHI will determine whether the progestin accounted for the increased risk of PHT.

The oral route of administration results in first-pass hepatic metabolism that induces the production of several clotting factors. It remains possible that more physiologic PHT, such as transdermal estradiol, may not have the adverse effects of other forms of PHT. This hypothesis needs to be tested in randomized clinical trials.

**Diabetes Mellitus** (See also Chap. 323) Women are more sensitive to insulin than men. Despite this, the prevalence of type 2 diabetes mellitus (DM) is higher in women, in part related to the higher prevalence of obesity among women. Polycystic ovary syndrome and gestational diabetes mellitus—common conditions in premenopausal women—are associated with a significantly increased risk for type 2 DM. Premenopausal women with DM lose the cardioprotective effect of female sex and have identical rates of CHD to those in males. This finding is partially explained by the coexistence of several CHD risk factors: obesity, hypertension, and dyslipidemia. Premenopausal women with DM also have impaired endothelial function and reduced coronary vasodilatory responses, which may predispose to cardiovascular complications.

**Hypertension** (See also Chap. 230) After age 60 years, hypertension is more common in U.S. women than in men, largely because of the high prevalence of hypertension in older age groups and the longer survival of women. Isolated systolic hypertension is present in 30% of women >60 years. Sex hormones affect blood pressure. Both nortriptyline and hypertensive women have higher blood pressure levels during the follicular than during the luteal phase. In the Nurses Health Study, the relative risk of hypertension was 1.8 in current users of oral contraceptives, but this risk is lower with the newer low-dose contraceptive preparations. PHT is not associated with hypertension. Among secondary causes of hypertension, there is a female preponderance of renal artery fibromuscular dysplasia.

The benefits of treatment for hypertension have been dramatic in both women and men. In a meta-analysis of the effects of hypertension treatment, the Individual Data Analysis of Antihypertensive Intervention Trial found a reduction of risk for stroke and for major cardiovascular events in women. The effectiveness of various antihypertensive drugs appears to be comparable in women and men; however, women may experience more side effects. For example, women are more likely to develop cough with angiotensin-converting enzyme inhibitors.

**Autoimmune Disorders** (See also Chap. 299) Most autoimmune disorders occur more commonly in women than in men; these include autoimmune thyroid and liver diseases, lupus, rheumatoid arthritis, scleroderma, multiple sclerosis, and idiopathic thrombocytopenic purpura. However, there is no sex difference in the incidence of type 1 DM, and ankylosing spondylitis occurs more commonly in men. There are relatively few differences in bacterial disease infection rates in men and women. In general, sex differences in viral diseases can be accounted for by differences in behaviors, such as exposures or rates of immunization. There are, however, sex differences in HIV infection (see below). Sex differences in both immune responses and adverse reactions to vaccines have been reported. For example, there is a female preponderance of postvaccination arthritis.

The mechanisms for these sex differences remain obscure. Adaptive immune responses are more robust in women than in men, which may be explained by the stimulatory actions of estrogens and the inhibitory actions of androgens on the cellular mediators of immunity. Consistent with an important role for gonadal hormones, there is variation in immune responses during the menstrual cycle, and the activity of certain autoimmune disorders is altered by castration or pregnancy (e.g., rheumatoid arthritis and multiple sclerosis may remit during pregnancy). Nevertheless, the majority of studies show that exogenous estrogens and progestins in the form of PHT or oral contraceptives do not alter autoimmune disease incidence or activity. Exposure to fetal antigens, including circulating fetal cells that persist in certain tissues, has been speculated to increase the risk of autoimmune responses. There is clearly an important genetic component to autoimmunity, as indicated by the familial clustering and HLA association of many such disorders. However, HLA types are not sexually dimorphic.

**HIV Infection** (See also Chap. 173) AIDS is an important cause of death in younger women (Fig. 5-1). Heterosexual contact with an at-risk partner is the fastest-growing transmission category, and women are twice as likely as men to be infected by a partner. Women are also more likely to be infected by multiple variants of the virus than men. Women with HIV have more rapid decreases in their CD4 cell counts than men. Compared with men, HIV-infected women more frequently develop candidiasis, but Kaposi’s sarcoma is less common than in men. Other sexually transmitted diseases, such as chlamydial infection and gonorrhea, are important causes of infertility in women, and papilloma virus infection predisposes to cervical cancer.

**Osteoporosis** (See also Chap. 333) Osteoporosis is much more prevalent in postmenopausal women than in age-matched men, and osteoporotic hip fractures are a major cause of morbidity in elderly women. Men accumulate more bone mass, and lose bone more slowly, than women. Sex differences in bone mass are found as early as infancy. Calcium intake, vitamin D, and estrogen all play important roles in bone formation and bone loss. Particularly during adolescence, calcium intake is an important determinant of peak bone mass. Vitamin D deficiency is surprisingly common in elderly women, occurring in >40% of women living in northern latitudes. Receptors for estrogens and androgens have been identified in bone. Estrogen deficiency is associated with increased osteoclast activity and a decreased number of bone-forming units, leading to net bone loss. The aromatase enzyme, which converts androgens to estrogens, is also present in bone. Recent studies show that estrogen is an important determinant of bone mass in men (derived from the aromatization of androgens) as well as in women.

**Pharmacology** On average, women have lower body weights, smaller organs, higher percent body fat, and lower total body water than men. There are also important sex differences in drug action and metabolism that are not accounted for by these differences in body size and composition. Gonadal steroids alter the binding and metabolism of a number of drugs. Further, menstrual cycle phase and pregnancy can alter drug action. Women require lower doses of neuroleptics to control schizophrenia. Women awaken from anesthesia faster than men given the same doses of anesthetics. Women also take more medications than men, including over-the-counter formulations and supplements. The greater use of medications combined with these biologic differences may account for the reported higher frequency of adverse drug reactions in women than in men.

**Psychological Disorders** (See also Chap. 371) Depression, anxiety, and affective and eating disorders (bulimia and anorexia nervosa) are more common in women than in men. Epidemiologic studies from both developed and developing nations consistently find major depression to be twice as common in women as in men, with the sex difference becoming evident in early adolescence. Depression occurs in 10% of women during pregnancy and in 10 to 15% of women during the postpartum period. There is a high likelihood of recurrence of postpartum depression with subsequent pregnancies. The incidence of major depression diminishes after age 45 years and does not increase with the onset of menopause. Depression in women appears to have a worse prognosis than in men; episodes last longer and there is a lower rate of spontaneous remission. Schizophrenia and bipolar disorders occur at equal rates in men and women, although there may be sex differences in symptoms.

Both biologic and social factors account for the greater prevalence of depressive disorders in women. Men have higher levels of the neurotransmitter serotonin. Gonadal steroids also affect mood, and fluctuations during the menstrual cycle have been linked to symptoms of premenstrual syndrome.

**Substance Abuse and Tobacco** (See also Chaps. 372 and 375) Substance abuse is more common in men than women. However, one-third of Americans who suffer from alcoholism are women. Women alcoholics are less likely to be diagnosed than men. A greater proportion of men than women seek help for alcohol and drug abuse. Men are more likely to go to an alcohol or drug treatment facility, while women tend to approach a primary care physician or mental health professional for
help under the guise of a psychosocial problem. Late-life alcoholism is more common in women than men. On average, alcoholic women drink less than alcoholic men but exhibit the same degree of impairment. Blood alcohol levels are higher in women than in men after drinking equivalent amounts of alcohol, adjusted for body weight. This greater bioavailability of alcohol in women is due both to the smaller volume of distribution and the slower gastric metabolism of alcohol secondary to lower activity of gastric alcohol dehydrogenase than in men. In addition, alcoholic women are more likely to abuse tranquilizers, sedatives, and amphetamines. Women alcoholics have a higher mortality rate than do nonalcoholic women and alcoholic men. Women also appear to develop alcoholic liver disease and other alcohol-related diseases with shorter drinking histories and lower levels of alcohol consumption. Alcohol abuse also poses special risks to a woman, adversely affecting fertility and the health of the baby (fetal alcohol syndrome). Even moderate alcohol use increases the risk of breast cancer, hypertension, and stroke in women.

More men than women smoke tobacco, but the prevalence of smoking is declining faster in men than women. Smoking markedly increases the risk of cardiovascular disease in premenopausal women and is also associated with a decrease in the age of menopause. Women who smoke are more likely to develop chronic obstructive pulmonary disease and lung cancer than men and at lower levels of tobacco exposure.

Violence Against Women (See also Chap. 371) Domestic violence is the most common cause of physical injury in women, exceeding the combined incidence of all other types of injury (such as from rape, mugging, and auto accidents). Sexual assault is one of the most common crimes against women. One in five adult women in the United States reports having experienced sexual assault during her lifetime. Adult women are much more likely to be raped by a spouse, ex-spouse, or acquaintance than by a stranger. Domestic violence may be an unrecognized feature of certain clinical presentations such as chronic abdominal pain, headaches, substance abuse, and eating disorders, in addition to more obvious manifestations such as trauma.

SUMMARY Women’s health has become a mature discipline over the past decade. The importance of sex differences in biologic processes is now recognized. It is clear that understanding the mechanisms of these differences will have an impact not only on women’s but also on men’s health. For example, estrogen is now recognized as an important regulator of bone density in men as well as in women. Elucidating the biology of sex hormone action has resulted in the design of drugs with tissue-specific hormone agonist and antagonist effects. These discoveries will make it feasible to selectively modulate the actions of sex hormones in both women and men to prevent and treat disease.

ACKNOWLEDGMENT The author wishes to acknowledge the contributions of Dr. Anthony Komaroff and Dr. Celeste Robb-Nicholson to this chapter in previous editions of the text.

6 MEDICAL DISORDERS DURING PREGNANCY

Robert L. Barbieri, John T. Repke

Approximately 4 million births occur in the United States each year. A significant proportion of these are complicated by one or more medical disorders. Two decades ago, many medical disorders were contraindications to pregnancy. Advances in obstetrics, neonatology, obstetric anesthesiology, and medicine have increased the expectation that pregnancy will result in an excellent outcome for both mother and fetus despite most of these conditions. Successful pregnancy requires important physiologic adaptations, such as a marked increase in cardiac output. Medical problems that interfere with the physiologic adaptations of pregnancy increase the risk for poor pregnancy outcome; conversely, in some instances pregnancy may adversely impact an underlying medical disorder.

HYPERTENSION (See also Chap. 230) In pregnancy, cardiac output increases by 40%, most of which is due to an increase in stroke volume. Heart rate increases by approximately 10 beats per minute during the third trimester. In the second trimester of pregnancy, systemic vascular resistance decreases and this is associated with a fall in blood pressure. During pregnancy, a blood pressure of 140/90 mmHg is considered to be abnormally elevated and is associated with a marked increase in perinatal morbidity and mortality. In all pregnant women, the measurement of blood pressure should be performed in the sitting position, because for many the lateral recumbent position is associated with a blood pressure lower than that recorded in the sitting position. The diagnosis of hypertension requires the measurement of two elevated blood pressures, at least 6 h apart. Hypertension during pregnancy is usually caused by preeclampsia, chronic hypertension, gestational hypertension, or renal disease.

Preeclampsia Approximately 5 to 7% of all pregnant women develop preeclampsia, the new onset of hypertension (blood pressure > 140/90 mmHg), proteinuria (>300 mg/24 h), and pathologic edema during gestation. Although the precise placental factors that cause preeclampsia are unknown, the end result is vasospasm and endothelial injury in multiple organs. Excessive placental secretion of an fms-like tyrosine kinase 1 may contribute to the endothelial dysfunction, hypertension, and proteinuria observed in preeclampsia. Glomerular endothelial cells demonstrate swelling and encroachment on the vascular lumen. Preeclampsia is associated with abnormalities of cerebral circulatory autoregulation, which increase the risk of stroke at normal blood pressures. Risk factors for the development of preeclampsia include nulliparity, diabetes mellitus, a history of renal disease or chronic hypertension, a prior history of preeclampsia, extremes of maternal age (>35 years or <15 years), obesity, factor V Leiden mutation, angiotensinogen gene T235, antiphospholipid antibody syndrome, and multiple gestation.

There are no well-established strategies for the prevention of preeclampsia. Clinical trials have demonstrated that low-dose aspirin treatment does not prevent preeclampsia in either low- or high-risk women. Two meta-analyses reported that dietary calcium supplementation appeared to be effective in reducing the risk of developing preeclampsia. Subsequently, however, a large randomized clinical trial in...
low-risk women did not demonstrate a protective effect of calcium supplementation. Therefore, calcium supplementation may be considered in women at high risk for preeclampsia (see above). The observation that dietary intervention may reduce the risk of hypertension in men and nonpregnant women raises the possibility that dietary manipulations will be discovered that reduce the risk of preeclampsia.

Severe preeclampsia is the presence of new-onset hypertension and proteinuria accompanied by central nervous system dysfunction (headaches, blurred vision, seizures, coma), marked elevations of blood pressure (>160/110 mmHg), severe proteinuria (>5 g/24 h), oliguria or renal failure, pulmonary edema, hepatic cellular injury (ALT > 2 × the upper limits of normal), thrombocytopenia (platelet count < 100,000/μL), or disseminated intravascular coagulation. Women with mild preeclampsia are those with the diagnosis of new-onset hypertension, proteinuria, and edema without evidence of severe preeclampsia. The HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome is a special subgroup of severe preeclampsia and is a major cause of morbidity and mortality in this disease. The presence of platelet dysfunction and coagulation disorders further increases the risk of stroke.

Preeclampsia resolves within a few weeks after delivery. For pregnant women with preeclampsia prior to 37 weeks’ gestation, delivery reduces the mother’s morbidity but exposes the fetus to the risk of premature delivery. The management of preeclampsia is challenging because it requires the clinician to balance the health of both mother and fetus simultaneously and to make management decisions that afford both the best opportunities for infant survival. In general, prior to term, women with mild preeclampsia can be managed conservatively with bed rest, close monitoring of blood pressure and renal function, and careful fetal surveillance. For women with severe preeclampsia, delivery is recommended after 32 weeks’ gestation. This reduces maternal morbidity and slightly increases the risks associated with prematurity for the newborn. Prior to 32 weeks’ gestation, the risks of prematurity for the fetus are great, and some authorities recommend conservative management to allow for continued fetal maturation. Expectant management of severe preeclampsia remote from term affords some benefits for the fetus with significant risks for the mother. Such management should be restricted to tertiary care centers where maternal-fetal medicine, neonatal medicine, and critical care medicine expertise are available.

The definitive treatment of preeclampsia is delivery of the fetus and placenta. For women with severe preeclampsia, aggressive management of blood pressures > 160/110 mmHg reduces the risk of cerebrovascular accidents.

Intravenous labetalol or hydralazine are the drugs most commonly used to manage preeclampsia. Alternative agents such as calcium channel blockers may be used. Elevated arterial pressure should be reduced slowly to avoid hypotension and a decrease in blood flow to the fetus. Angiotensin-converting enzyme (ACE) inhibitors as well as angiotensin-receptor blockers should be avoided in the second and third trimesters of pregnancy because of their adverse effects on fetal development. Pregnant women treated with ACE inhibitors often develop oligohydramnios, which may be caused by decreased fetal renal function.

Magnesium sulfate is the treatment of choice for the prevention and treatment of eclamptic seizures. Two large randomized clinical trials have demonstrated the superiority of magnesium sulfate over phenytoin and diazepam, and a recent large randomized clinical trial has demonstrated the efficacy of magnesium sulphate in reducing the risk of seizures and possible reducing the risk of maternal death. Magnesium may prevent seizures by interacting with N-methyl-D-aspartate (NMDA) receptors in the central nervous system. Given the difficulty of predicting eclamptic seizures on the basis of disease severity, it is recommended that once the decision to proceed with delivery is made, all patients carrying a diagnosis of preeclampsia be treated with magnesium sulfate (see Guideline).

### Chronic Essential Hypertension

Pregnancy complicated by chronic essential hypertension is associated with intrauterine growth restriction and increased perinatal mortality. Pregnant women with chronic hypertension are at increased risk for superimposed preeclampsia and abruptio placenta. Women with chronic hypertension should have a thorough prepregnancy evaluation, both to identify remediable causes of hypertension and to ensure that the prescribed antihypertensive agents are not associated with an adverse outcome of pregnancy (e.g., ACE inhibitors, angiotensin-receptor blockers). a-Methyldopa and labetalol are the most commonly used medications for the treatment of chronic hypertension in pregnancy. Baseline evaluation of renal function is necessary to help differentiate the effects of chronic hypertension versus superimposed preeclampsia should the hypertension worsen during pregnancy. There are no convincing data that demonstrate that treatment of mild chronic hypertension improves perinatal outcome.

### Gestational Hypertension

This is the development of elevated blood pressure during pregnancy or in the first 24 h post partum in the absence of preexisting chronic hypertension and other signs of preeclampsia. Uncomplicated gestational hypertension that does not progress to preeclampsia has not been associated with adverse pregnancy outcome or adverse long-term prognosis.

### Renal Disease

(See also Chaps. 259 and 267) Normal pregnancy is characterized by an increase in glomerular filtration rate and creatinine clearance. This occurs secondary to a rise in renal plasma flow and increased glomerular filtration pressures. Patients with underlying renal disease and hypertension may expect a worsening of hypertension during pregnancy. If superimposed preeclampsia develops, the additional endothelial injury results in a capillary leak syndrome that may make the management of these patients challenging. In general, patients with underlying renal disease and hypertension benefit from more aggressive management of blood pressure than those with gestational hypertension. Preconception counseling is also essential for these patients so that accurate risk assessment can occur prior to the establishment of pregnancy and important medication changes and adjustments can be made. In general, a prepregnancy serum creatinine level <133 μmol/L (<1.5 mg/dL) is associated with a favorable prognosis. When renal disease worsens during pregnancy, close collaboration between the nephrologist and the maternal-fetal medicine specialist is essential so that decisions regarding delivery can be weighed in the context of sequelae of prematurity for the neonate versus long-term sequelae for the mother with respect to future renal function.

### Post-Transplant

Successful pregnancy after renal transplantation has been reported increasingly. Predictors for success include a normal functioning transplanted kidney, absence of rejection for at least 2 years prior to the pregnancy, absence of hypertension, and preferably minimal doses of immunosuppressant medications. Pregnancies in
women using cyclosporine are more likely to be complicated by renal insufficiency and/or the development of hypertension. Such patients require very careful maternal and fetal surveillance. Nearly half of these pregnancies deliver preterm, and 20% of neonates are small for their gestational age. Rejection occurs in ~10% of pregnancies, and ~15% of patients will have deterioration in their renal function that persists after delivery. While pregnancy is generally well tolerated in renal transplant recipients, controversy remains as to whether or not deterioration of graft function is accelerated by pregnancy. More aggressive management of blood pressure has been suggested in this group of patients in an effort to protect the grafted kidney.

**Systemic Lupus Erythematosus (SLE)** Another subset of patients with chronic renal disease and hypertension are those patients whose pregnancies are complicated by SLE (Chap. 300). In the past, SLE was considered to be a contraindication to pregnancy. With improved understanding of the effects of SLE on pregnancy, and vice versa, and with improved pharmacologic methods for managing SLE, successful pregnancy outcome is likely. Good prognostic factors for establishment of pregnancy in the presence of SLE are as follows:

1. Disease quiescence > 6 months
2. Normal blood pressure (with or without medication)
3. Normal renal function ([creatinine < 133 μmol/L (< 1.5 mg/dL)]
4. Absence of antiphospholipid antibodies
5. Minimal or no need for immunosuppressive drugs
6. Absence of prior adverse reproductive outcome

Previously a point of controversy, there is now increasing consensus that pregnancy and the postpartum period are times of increased lupus activity. In severe flares early in gestation, pregnancy termination is often recommended. If pregnancy termination is not an option, then medical therapy to manage the lupus flare should not be influenced by the pregnancy, provided informed consent for treatment is obtained from the patient. Pulsed glucocorticoid therapy, azathioprine, hydroxychloroquine, and cyclophosphamide have all been used successfully in pregnancy.

**CARDIAC DISEASE**

**Valvular Heart Disease** (See also Chap. 219) This is the most common cardiac problem complicating pregnancy.

**MITRAL STENOSIS** This is the valvular disease most likely to cause death during pregnancy. The pregnancy-induced increase in blood volume, cardiac output, and tachycardia can cause pulmonary edema in women with mitral stenosis. Pregnancy associated with long-standing mitral stenosis may result in pulmonary hypertension. Sudden death has been reported when hypovolemia has been allowed to occur in this condition. Careful control of heart rate, especially during labor and delivery, minimizes the impact of tachycardia and reduced ventricular filling times on cardiac function. Pregnant women with mitral stenosis are at increased risk for the development of atrial fibrillation and other tachyarrhythmias. Medical management of severe mitral stenosis and atrial fibrillation with digoxin and beta blockers is recommended. Balloon valvulotomy can be carried out during pregnancy.

**MITRAL REGURGITATION AND AORTIC REGURGITATION** These are both generally well tolerated during pregnancy. The pregnancy-induced decrease in systemic vascular resistance reduces the risk of cardiac failure with these conditions. As a rule, mitral valve prolapse does not present problems for the pregnant patient, and aortic stenosis, unless very severe, is well tolerated. In the most severe cases of aortic stenosis, limitation of activity or balloon valvuloplasty may be indicated.

For women with artificial valves contemplating pregnancy, it is important that warfarin be stopped and heparin initiated prior to conception. Warfarin therapy during the first trimester of pregnancy has been associated with fetal chordosplasia punctata. In the second and third trimester of pregnancy, warfarin may cause fetal optic atrophy and mental retardation. For women with prosthetic heart valves, prophylaxis against thrombosis with low-molecular-weight heparin (LMWH) is not recommended due to reports of valvular thrombosis despite adequate anticoagulation. Prophylaxis with unfractionated heparin is recommended for this group of women.

**Congenital Heart Disease** (See also Chap. 218) The presence of a congenital cardiac lesion in the mother increases the risk of congenital cardiac disease in the newborn. Prenatal screening of the fetus for congenital cardiac disease with ultrasound is recommended. Atrial or ventricular septal defect is usually well tolerated during pregnancy in the absence of pulmonary hypertension, provided that the woman’s pregravid pregnancy cardiac status is favorable. Use of air filters on intravenous sets during labor and delivery in patients with intracardiac shunts is generally recommended.

**Other Cardiac Disorders** Supraventricular tachycardia (Chap. 214) is a common cardiac complication of pregnancy. Treatment is the same as in the nonpregnant patient, and fetal tolerance of medications such as adenosine and calcium channel blockers is acceptable. When necessary, electrocardioversion may be performed and is generally well tolerated by mother and fetus.

Peripartum cardiomyopathy (Chap. 221) is a rare disorder of pregnancy associated with myocarditis, and its etiology remains unknown. Treatment is directed toward symptomatic relief and improvement of cardiac function. Many patients recover completely; others are left with a progressive dilated cardiomyopathy. Recurrence in a subsequent pregnancy has been reported, and women should be counseled to avoid pregnancy after a diagnosis of peripartum cardiomyopathy.

**Specific High-Risk Cardiac Lesions**

**Marfan Syndrome** (See also Chap. 342) This is an autosomal dominant disease, associated with a high risk of maternal morbidity. Approximately 15% of pregnant women with Marfan syndrome develop a major cardiovascular manifestation during pregnancy, with almost all women surviving. An aortic root diameter <40 mm is considered to be associated with a favorable outcome of pregnancy. Prophylactic therapy with beta blockers has been advocated, although large-scale clinical trials in pregnancy have not been performed.

**Pulmonary Hypertension** (See also Chap. 220) Maternal mortality in the setting of severe pulmonary hypertension is high, and primary pulmonary hypertension is a contraindication to pregnancy. Termination of pregnancy may be advisable in these circumstances to preserve the life of the mother. In the Eisenmenger syndrome, i.e., the combination of pulmonary hypertension with right-to-left shunting due to congenital abnormalities (Chap. 218), maternal and fetal death occur frequently. Systemic hypotension may occur after blood loss, prolonged Valsalva maneuver, or regional anesthesia; sudden death secondary to hypotension is a dreaded complication. Management of these patients is challenging, and invasive hemodynamic monitoring during labor and delivery is generally recommended.

In patients with pulmonary hypertension, vaginal delivery is less stressful hemodynamically than Cesarean section, which should be reserved for accepted obstetric indications.

**Deep Venous Thrombosis and Pulmonary Embolism** (See also Chaps. 232 and 244) A hypercoagulable state is characteristic of pregnancy, and deep venous thrombosis (DVT) is a common complication. Indeed, pulmonary embolism is the most common cause of maternal death in the United States. In pregnant women, DVT occurs much more commonly in the left leg than in the right leg, due to the compression of the left iliac vein by the right iliac artery and the uterus. Activated protein C resistance caused by the factor V Leiden mutation increases the risk for DVT and pulmonary embolism during pregnancy. Approximately 25% of women with DVT during pregnancy carry the factor V Leiden allele. The presence of the factor V Leiden mutation also increases the risk for severe preeclampsia. If the fetus carries a factor V Leiden mutation, the risk of extensive placental infarction is very high. Additional genetic mutations associated with DVT during pregnancy include the prothrombin G20210A mutation (heterozygotes and homozygotes) and the methylentetrahydrofolate reductase C677T mutation (homozygotes).
TREATMENT

Aggressive diagnosis and management of DVT and suspected pulmonary embolism optimize the outcome for mother and fetus. In general, all diagnostic and therapeutic modalities afforded the nonpregnant patient should be utilized in pregnancy. Anticoagulant therapy with LMWH or unfractionated heparin is indicated in pregnant women with DVT. LMWH may be associated with an increased risk of epidural hematoma in women receiving an epidural anesthetic in labor. One approach to this problem is to switch from LMWH heparin to unfractionated heparin about 2 weeks before the anticipated delivery date. Warfarin therapy is contraindicated in the first trimester due to its association with fetal chondrodysplasia punctata. In the second and third trimesters, warfarin may cause fetal optic atrophy and mental retardation. When DVT occurs in the postpartum period, LMWH therapy for 7 to 10 days may be followed by warfarin therapy for 3 to 6 months. Warfarin is not contraindicated in breast-feeding women.

ENDOCRINE DISORDERS  Diabetes Mellitus (See also Chap. 323) In pregnancy, the fetoplacental unit induces major metabolic changes, the purpose of which is to shunt glucose and amino acids to the fetus while the mother uses ketones and triglycerides to fuel her metabolic needs. These metabolic changes are accompanied by maternal insulin resistance, caused in part by placental production of steroids, a growth hormone variant, and placental lactogen. Although pregnancy has been referred to as a state of accelerated starvation, it is better characterized as accelerated ketosis. In pregnancy, after an overnight fast, plasma glucose is lower by 0.8 to 1.1 mmol/L (15 to 20 mg/dL) than in the nonpregnant state. This is due to the use of glucose by the fetus. In early pregnancy, fasting may result in circulating glucose concentrations in the range of 2.2 mmol/L (40 mg/dL) and may be associated with symptoms of hypoglycemia. In contrast to the decrease in maternal glucose concentration, plasma hydroxybutyrate and acetoadacetate levels rise to two to four times normal after a fast.

TREATMENT

Pregnancy complicated by diabetes mellitus is associated with higher maternal and perinatal morbidity and mortality rates. Preconception counseling and treatment are important for the diabetic patient contemplating pregnancy. Optimizing preconception glucose control and attention to other dietary needs such as appropriate levels of folate can significantly reduce the risk of congenital fetal malformations. Folate supplementation reduces the incidence of fetal neural tube defects, which occur with greater frequency in fetuses of diabetic mothers. In addition, optimizing glucose control during key periods of organogenesis reduces other congenital anomalies including sacral agenesis, caudal dysplasia, renal agenesis, and ventricular septal defect.

Once pregnancy is established, glucose control should be managed more aggressively than in the nonpregnant state. In addition to dietary changes, this requires more frequent blood glucose monitoring and often involves additional injections of insulin or conversion to an insulin pump. Fasting blood glucose levels should be maintained at <5.8 mmol/L (<105 mg/dL) with no values exceeding 7.8 mmol/L (140 mg/dL). Commencing in the third trimester, regular surveillance of maternal glucose control as well as assessment of fetal growth (obstetric sonography) and fetoplacental oxygenation (fetal heart rate monitoring or biophysical profile) optimize pregnancy outcome. Pregnant diabetic patients without vascular disease are at greater risk for delivering a macrosomic fetus, and attention to fetal growth via clinical and ultrasound examinations is important. Fetal macrosomia is associated with an increased risk of maternal and fetal birth trauma. Pregnant women with diabetes have an increased risk of developing preeclampsia, and those with vascular disease are at greater risk for developing intrauterine growth restriction, which is associated with an increased risk of fetal and neonatal death. Excellent pregnancy outcomes in patients with diabetic nephropathy and proliferative retinopathy have been reported with aggressive glucose control and intensive maternal and fetal surveillance.

TREATMENT

Glycemic control may become more difficult to achieve as pregnancy progresses. Because of delayed pulmonary maturation of the fetuses of diabetic mothers, early delivery should be avoided unless there is biochemical evidence of fetal lung maturity. In general, efforts to control glucose and maintain the pregnancy until the estimated date of delivery result in the best overall outcome for both mother and newborn.

Gestational Diabetes  All pregnant women should be screened for gestational diabetes unless they are in a low-risk group. Women at low risk for gestational diabetes are those <25 years of age; those with a body mass index <25 kg/m², no maternal history of macrosomia or gestational diabetes, and no diabetes in a first-degree relative; and those not members of a high-risk ethnic group (African American, Hispanic, Native American). A typical two-step strategy for establishing the diagnosis of gestational diabetes involves administration of a 50-g oral glucose challenge with a single serum glucose measurement at 60 min. If the plasma glucose is < 7.8 mmol/L (<140 mg/dL), the test is considered normal. Serum glucose > 7.8 mmol/L (>140 mg/dL) warrants administration of a 100-g oral glucose challenge with serum glucose measurements obtained in the fasting state, and at 1, 2, and 3 h. Normal values are plasma glucose concentrations <5.8 mmol/L (<105 mg/dL), 10.5 mmol/L (190 mg/dL), 9.1 mmol/L (165 mg/dL), and 8.0 mmol/L (145 mg/dL), respectively.

Pregnant women with gestational diabetes are at increased risk of preeclampsia, delivering infants who are large for their gestational age, and birth lacerations. Their fetuses are at risk of hypoglycemia and birth trauma (brachial plexus) injury.

TREATMENT

Gestational diabetes is first treated with dietary measures. Inability to maintain fasting glucose concentrations <5.8 mmol/L (<105 mg/dL) or 2-h postprandial glucose concentrations <6.7 mmol/L (<120 mg/dL) should prompt initiation of insulin therapy. Patients with a diagnosis of gestational diabetes will benefit from postpartum follow-up as they are at increased risk for developing type 2 diabetes.

Thyroid Disease (See also Chap. 320) In pregnancy, the estrogen-induced increase in thyroxine-binding globulin causes an increase in circulating levels of total T₄ and total T₃. The normal range of circulating levels of free T₄, free T₃, and thyroid stimulating hormone (TSH) remain unaltered by pregnancy.

The thyroid gland normally enlarges during pregnancy. Maternal hyperthyroidism occurs at a rate of approximately 2 per 1000 pregnancies and is generally well tolerated by pregnant women. Clinical signs and symptoms should alert the physician to the occurrence of this disease. Many of the physiologic adaptations to pregnancy may mimic subtle signs of hyperthyroidism. Although pregnant women are able to tolerate mild hyperthyroidism without adverse sequelae, more severe hyperthyroidism can cause spontaneous abortion or premature labor, and thyroid storm is associated with a significant risk of maternal mortality.

TREATMENT

Hyperthyroidism in pregnancy should be aggressively evaluated and treated. The treatment of choice is propylthiouracil. Because it crosses the placenta, the minimum effective dose should be used to maintain free T₃ in the upper normal range. Methimazole crosses the placenta to a greater degree than propylthiouracil and has been associated with fetal aplasia cutis. Radioiodine should not be used during pregnancy, either for scanning or treatment, because of effects on the fetal thyroid. In emergent circumstances, additional treatment with beta blockers and a saturated solution of potassium iodide may be necessary. Hyperthyroidism is most difficult to control in the first trimester of pregnancy and easiest to control in the third trimester.

The goal of therapy for hypothyroidism is to maintain the serum
TSH in the normal range, and thyroxine is the drug of choice. Children born to women with an elevated serum TSH (and a normal total thyroxine) during pregnancy have impaired performance on neuropsychologic tests. During pregnancy, the dose of thyroxine required to keep the TSH in the normal range rises. In one study, the mean replacement dose of thyroxine required to maintain the TSH in the normal range was 0.1 mg daily before pregnancy, and it increased to 0.15 mg daily during pregnancy.

HEMATOLOGIC DISORDERS Pregnancy has been described as a state of physiologic anemia. Part of the reduction in hemoglobin concentration is dilutional, but iron and folate deficiencies are the major causes of correctable anemia during pregnancy. Folic acid food supplementation implemented in 1998 has reduced the risk of fetal neural tube defects. In populations at high risk for hemoglobinopathies (Chap. 91), hemoglobin electrophoresis should be performed as part of the prenatal screen. Hemoglobinopathies can be associated with increased maternal and fetal morbidity and mortality. Management is tailored to the specific hemoglobinopathy and is generally the same for both pregnant and nonpregnant women. Prenatal diagnosis of hemoglobinopathies in the fetus is readily available and should be discussed with prospective parents either prior to or early in pregnancy.

Thrombocytopenia occurs commonly during pregnancy. The majority of cases are benign gestational thrombocytopenias, but the differential diagnosis should include immune thrombocytopenia (Chap. 101) and preeclampsia. Maternal thrombocytopenia may also be caused by catastrophic obstetric events such as retention of a dead fetus, sepsis, abruptio placenta, and amniotic fluid embolism.

NEUROLOGIC DISORDERS Headache appearing during pregnancy is usually due to migraine (Chap. 14), a condition that may worsen, improve, or be unaffected by pregnancy. A new or worsening headache, particularly if associated with visual blurring, may signal eclampsia (above) or pseudotumor cerebri (benign intracranial hypertension; Chap. 25); diplopia due to a sixth nerve palsy suggests pseudotumor cerebri. The risk of seizures in patients with epilepsy increases in the postpartum period but not consistently during pregnancy; management is discussed in Chap. 348. The risk of stroke is generally thought to increase during pregnancy because of a hypercoagulable state; however, studies suggest that the period of risk occurs primarily in the postpartum period and that both ischemic and hemorrhagic strokes may occur at this time. Guidelines for use of heparin therapy are summarized above (see “Deep Venous Thrombosis and Pulmonary Embolism”); warfarin is teratogenic and should be avoided. The onset of a new movement disorder during pregnancy suggests chorea gravidarum, a variant of Sydenham’s chorea associated with rheumatic fever and streptococcal infection (Chap. 121); the chorea may recur with subsequent pregnancies. Patients with preexisting multiple sclerosis (Chap. 359) experience a gradual decrease in the risk of relapses as pregnancy progresses and, conversely, an increase in attack risk during the postpartum period. Beta interferons should not be administered to pregnant MS patients, but moderate or severe relapses can be safely treated with pulse glucocorticoid therapy. Finally, certain tumors, particularly pituitary adenoma and meningioma (Chap. 358), may manifest during pregnancy because of accelerated growth, possibly driven by hormonal factors.

Peripheral nerve disorders associated with pregnancy include Bell’s palsy (idiopathic facial paralysis, Chap. 363), which is approximately threefold more likely to occur during the third trimester and immediate postpartum period than in the general population. Therapy with glucocorticoids should follow the guidelines established for nonpregnant patients; however, acyclovir should probably be avoided, particularly during the first two trimesters. Entrapment neuropathies (Chap. 363) are common in the later stages of pregnancy, presumably as a result of fluid retention. Carpal tunnel syndrome (median nerve) presents as pain and paresthesia in the hand, often worse at night, and later with weakness in the thenar muscles. Treatment is generally conservative; wrist splints may be helpful, and glucocorticoid injections or surgical section of the carpal tunnel can usually be postponed. Meralgia paresthetica (lateral femoral cutaneous nerve) consists of pain and numbness in the lateral aspect of the thigh without weakness. Patients are usually reassured to learn that these symptoms are benign and can be expected to remit spontaneously after the pregnancy has been completed.

Judicious use of neuroimaging procedures is reasonable during pregnancy. Some centers require that formal consent be obtained from pregnant patients before magnetic resonance imaging (MRI) scans are administered. Experimental data indicate that high-field-strength MRI may be teratogenic to rodents; however, studies in pregnant MRI technicians have failed to show any risk to the fetus, even with chronic exposure. The paramagnetic MRI contrast agent gadolinium is usually not administered, particularly during the first trimester, because it crosses the blood-brain barrier. Computed tomography scanning of the brain is also considered safe, particularly as the procedure is fast, little radioactive scatter is produced, and pelvic contents are easily shielded; iodinated contrast media should be avoided whenever possible.

GASTROINTESTINAL AND LIVER DISEASE Up to 90% of pregnant women experience nausea and vomiting during the first trimester of pregnancy. Occasionally, hyperemesis gravidarum requires hospitalization to prevent dehydration, and sometimes parenteral nutrition is required. Crohn’s disease may be associated with exacerbations in the second and third trimesters. Ulcerative colitis is associated with disease exacerbations in the first trimester and during the early postpartum period. Medical management of these diseases during pregnancy is identical to the management in the nonpregnant state (Chap. 276).

Exacerbation of gall bladder disease is commonly observed during pregnancy. In part this may be due to pregnancy-induced alteration in the metabolism of bile and fatty acids. Intrahepatic cholestasis of pregnancy is generally a third-trimester event. Profound pruritus may accompany this condition, and it may be associated with increased fetal mortality. It has been suggested that placental bile salt deposition may contribute to progressive uteroplacental insufficiency. Therefore, regular fetal surveillance should be undertaken once the diagnosis of intrahepatic cholestasis is made. Favorable results with ursodiol have been reported.

Acute fatty liver is a rare complication of pregnancy. Frequently confused with the HELLP syndrome (see “Preeclampsia,” above) and severe preeclampsia, the diagnosis of acute fatty liver of pregnancy may be facilitated by imaging studies and laboratory evaluation. Acute fatty liver of pregnancy is generally characterized by markedly increased levels of bilirubin and ammonia and by hypoglycemia. Management of acute fatty liver of pregnancy is supportive; recurrence in subsequent pregnancies has been reported.

All pregnant women should be screened for hepatitis B. This infection is important for pediatricians after delivery of the infant. All infants receive hepatitis B vaccine. Infants born to mothers who are carriers of hepatitis B surface antigen should also receive hepatitis B immune globulin as soon after birth as possible and preferably within the first 72 h.

INFECTIONS Other than bacterial vaginosis, the most common bacterial infections during pregnancy involve the urinary tract (Chap. 269). Many pregnant women have asymptomatic bacteriuria, most likely due to stasis caused by postgestational effects on ureteral and bladder smooth muscle and to compression effects of the enlarging uterus. In itself, this condition is not associated with an adverse outcome of pregnancy. However, if asymptomatic bacteriuria is left untreated, symptomatic pyelonephritis may occur. Indeed, ~75% of cases of pregnancy-associated pyelonephritis are the result of untreated asymptomatic bacteriuria. All pregnant women should be screened with a urine culture for asymptomatic bacteriuria at the first prenatal visit. Subsequent screening with nitrite leukocyte esterase strips is indicated in high-risk women, such as those with sickle cell trait or a history of urinary tract infections. All women with positive screens should be treated.
Because of the association between bacterial vaginosis and preterm delivery, screening for bacterial vaginosis has been used in an effort to reduce risk. However, standard treatment for bacterial vaginosis does not reduce the risk of preterm delivery.

Abdominal pain and fever during pregnancy create a clinical dilemma. The diagnosis of greatest concern is intrauterine amniotic infection. While amniotic infection most commonly follows rupture of the membranes, this is not always the case. In general, antibiotic therapy is not recommended as a temporizing measure in these circumstances. If intrauterine infection is suspected, induced delivery with concomitant antibiotic therapy is generally indicated. Intrauterine amniotic infection is most often caused by pathogens such as Escherichia coli and group B streptococcus. In high-risk patients at term or in premature patients, routine intrapartum prophylaxis of group B streptococcal (GBS) disease is recommended. Penicillin G and ampicillin are the drugs of choice. In penicillin-allergic patients, clindamycin is recommended. Recently, it has been reported that universal screening of pregnant women for GBS disease may be superior to treatment based on presence of risk factors alone.

Postpartum infection is a significant cause of maternal morbidity and mortality. While rare after vaginal delivery, postpartum endomyometritis develops in 5% of patients having elective repeat cesarean section and in 25% of patients after emergency cesarean section following prolonged labor. Prophylactic Antibiotics should be given to all patients undergoing cesarean section. As most cases of postpartum endomyometritis are polymicrobial, broad-spectrum antibiotic coverage with a penicillin, aminoglycoside, and metronidazole is recommended (Chap. 148). Most cases resolve within 72 hours. Women who do not respond to antibiotic treatment for postpartum endomyometritis should be evaluated for septic pelvic thrombophlebitis. Imaging studies may be helpful in establishing the diagnosis, which is primarily a clinical diagnosis of exclusion. Patients with septic pelvic thrombophlebitis generally have tachycardia out of proportion to their fever and respond rapidly to intravenous administration of heparin.

All patients are screened prenatally for gonorrhea and chlamydial infections, and the detection of either should result in prompt treatment. Ceftriaxone and azithromycin are the agents of choice (Chaps. 128 and 160).

**Viral Infections**

**CYTOMEGALOVIRUS INFECTION** Viral infection in pregnancy presents a significant challenge. The most common cause of congenital viral infection in the United States is cytomegalovirus (CMV) (Chap. 166). As many as 50 to 90% of women of childbearing age have antibodies to CMV, but only rarely does CMV reactivation result in neonatal infection. More commonly, primary CMV infection during pregnancy creates a risk of congenital CMV. No currently accepted treatment of CMV during pregnancy has been demonstrated to protect the fetus effectively. Moreover, it is impossible to predict which fetus will sustain life-threatening CMV infection. Severe CMV disease in the newborn is characterized most often by petechiae, hepatosplenomegaly, and jaundice. Chorioretinitis, microcephaly, intracranial calcifications, hepatitis, hemolytic anemia, and purpura may also develop. Central nervous system involvement, resulting in the development of psychomotor, ocular, auditory, and dental abnormalities over time, has been described.

**RUBELLA** (See also Chap. 177) Rubella virus is a known teratogen; first-trimester rubella carries a high risk of fetal anomalies, though the risk decreases significantly later in pregnancy. Congenital rubella may be diagnosed by percutaneous umbilical blood sampling with the detection of IgM antibodies in fetal blood. All pregnant women should be screened for their immune status to rubella. Indeed, all women of childbearing age, regardless of pregnancy status, should have their immune status for rubella verified and be immunized if necessary. The incidence of congenital rubella in the United States is extremely low.

**HERPESVIRUS** (See also Chap. 163) The acquisition of genital herpes during pregnancy is associated with spontaneous abortion, prematurity, and congenital and neonatal herpes. A recent cohort study of pregnant women without evidence of previous herpes infection demonstrated that ~2% of the women acquired a new herpes infection during the pregnancy. Approximately 60% of the newly infected women had no clinical symptoms. Infection occurred equally in all three trimesters. If herpes seroconversion occurred early in pregnancy, the risk of transmission to the newborn was very low. In women who acquired genital herpes shortly before delivery, the risk of transmission was high. The risk of active genital herpes lesions at term can be reduced by prescribing acyclovir for the last 4 weeks of pregnancy to women who have had their first episode of genital herpes during the pregnancy. However, whether or not this strategy results in less viral shedding or enhanced fetal protection at delivery remains to be determined.

Herpesvirus infection in the newborn can be devastating. Disseminated neonatal herpes carries with it high mortality and morbidity rates from central nervous system involvement. It is recommended that pregnant women with active genital herpes lesions at the time of presentation in labor be delivered by cesarean section.

**PARVOVIRUS** (See also Chap. 168) Parvovirus infection (human parvovirus B19) may occur during pregnancy. It rarely causes sequelae, but susceptible women infected during pregnancy may be at risk for fetal hydrops secondary to erythroid aplasia and profound anemia.

**TOXOPLASMOsis** (See also Chap. 198) In the United States, approximately 70% of women of childbearing age are susceptible to Toxoplasma. Most primary infections of toxoplasmosis in the United States come from eating undercooked meat. The diagnosis of congenital toxoplasmosis is possible through sampling of fetal umbilical blood. If there is no evidence of placental/fetal infection, single-drug treatment with spiramycin is recommended. Triple-drug therapy with spiramycin, pyrimethamine, and sulfadiazine is recommended if there is evidence of fetal infection and the woman does not wish to terminate the pregnancy or cannot terminate it because of advanced gestational age. Prenatal treatment has been shown to reduce the number of infants with severe infection.

**HUMAN IMMUNODEFICIENCY VIRUS (HIV)** (See also Chap. 173) The predominant cause of HIV infection in children is transmission of the virus from the mother to the newborn during the perinatal period. Exposures, which increase the risk of mother-to-child transmission, include vaginal delivery, preterm delivery, trauma to the fetal skin, and maternal bleeding. Additionally, recent infection with high maternal viral load, low maternal CD4+ T cell count, prolonged labor, prolonged length of membrane rupture, and the presence of other genital tract infections, such as syphilis or herpes, increase the risk of transmission. Breast feeding may also transmit HIV to the newborn and is therefore contraindicated in most developed countries for HIV-infected mothers. There is no clear evidence to suggest that the course of HIV disease is altered by pregnancy. There is also no clear evidence to suggest that uncomplicated HIV disease adversely impacts pregnancy other than by its inherent infection risk.

**TREATMENT**

The majority of cases of mother-to-child (vertical) transmission of HIV-1 occur during the intrapartum period. Mechanisms of vertical transmission include infection after rupture of the membranes and direct contact of the fetus with infected secretions or blood from the maternal genital tract. In women with HIV infection who are not receiving antiretroviral therapy, the rate of vertical transmission is approximately 25%. Cesarean section and treatment with zidovudine, administered both before and during delivery, decrease the rate of vertical transmission. In a meta-analysis, zidovudine treatment of both the mother during the prenatal and intrapartum periods and the neonate at birth reduced the risk of vertical transmission to 7.3%. The combination of elective cesarean section plus zidovudine treatment reduced the risk of vertical transmission to 2%. The role of multiple drug ther-
apy during pregnancy has not yet been established, pending safety data for the neonate.

SUMMARY Maternal mortality has decreased steadily during the past 60 years. The maternal death rate has decreased from nearly 600/100,000 live births in 1935 to 0.01%. The most common causes of maternal death in the United States today are, in decreasing order of frequency, thromboembolic disease, hypertension, ectopic pregnancy, and hemorrhage. With improved diagnostic and therapeutic modalities as well as advances in the treatment of infertility, more patients with medical complications will be seeking, and be in need of, complex obstetric care. Improving outcome of pregnancy in these women will be best obtained by assembling a team of internists and specialists in maternal-fetal medicine (high-risk obstetrics) to counsel these patients about the risks of pregnancy and to plan their treatment prior to conception. The importance of preconception counseling cannot be overstated. It is the responsibility of all physicians caring for women in the reproductive age group to assess their patient’s reproductive plans as part of their overall health evaluation.

FURTHER READING

Most individuals will require surgery at some point in their lifetimes. In the United States, surgeons performed 18 million inpatient operations in 2000; ambulatory surgery accounted for a substantial number of additional procedures. Preoperative medical consultation is, therefore, a common activity for practicing internists. However, many internists may be uncomfortable in this role as the process of preoperative risk stratification is not intuitive and relies heavily on a highly specialized literature that is not common knowledge among practicing clinicians.

The role of the medical consultant is to determine the presence of known or unrecognized comorbid disease or other factors that may increase risk of morbidity or mortality from baseline and to recommend strategies to reduce the risk and optimize the patient’s condition before operation. This knowledge informs the discussion of risks and benefits for the patient and surgeon. Such consultations may range from the routine evaluation of a healthy patient before minor surgery to confirmation of high risk in a moribund patient undergoing emergency surgery for a life-threatening illness. Overall morbidity and mortality from surgery is low. Studies have demonstrated surgical mortality rates of 1% across all procedures for unselected patients. Mortality of the subset of patients undergoing ambulatory surgery is substantially lower. Surgeons select patients for ambulatory surgery when the combination of a lower risk procedure and few patient-related comorbidities suggests a low risk of adverse outcomes. Mortality in this group of patients is approximately 0.01%.

The most important contributions to postoperative morbidity and mortality are cardiac and pulmonary complications; each occurs in approximately 5% of all patients undergoing an operation. This chapter will review preoperative risk assessment and risk-reduction strategies for healthy patients and for the major categories of adverse outcomes and medical comorbidities—cardiac complications, pulmonary complications, and diabetes mellitus. Two other important perioperative considerations, venous thromboembolism prophylaxis (Chaps. 232 and 244) and endocarditis prophylaxis (Chap. 109), are discussed elsewhere in this text.

ANESTHETIC PHYSIOLOGY Modern anesthesia is extremely safe. Mortality among healthy patients undergoing surgery is low; estimates range from 0.01 to 0.03%. Patient- and procedure-related factors are more important contributors to perioperative morbidity than is anesthesia itself. Inhalational anesthetic agents have predictable physiologic effects. All inhalational anesthetic agents are myocardial depressants. While not clinically significant in healthy patients, this effect leads to a dependence on cardiac preload that may cause an accentuated response to the induction of anesthesia in patients who are volume-depleted due to illness or overdiuresis or who have left ventricular dysfunction. Anesthesia leads to a decrease in lung volumes. Both vital capacity and functional residual capacity decrease by one-third in abdominal surgery. This results from diaphragmatic dysfunction, decreased mucociliary clearance, loss of sighing breaths, and depression of the ventilatory response to hypoxemia and hypercarbia. This decrease in lung volumes may lead to atelectasis and is a principal factor leading to the development of postoperative pulmonary complications.

Controversy has long existed regarding the relative safety of general versus spinal or epidural anesthesia in patients at risk for postoperative cardiac or pulmonary complications. In a recent large meta-analysis of randomized controlled trials of anesthetic technique, patients who were randomized to spinal or epidural anesthesia as a component of their anesthesia had significantly lower rates of venous thromboembolism, pneumonia, respiratory depression, myocardial infarction, or death than patients receiving general anesthesia exclusively; relative risk reductions ranged from 30 to 55%. Clinicians should recommend spinal or epidural anesthesia, when possible, for patients at high risk for postoperative medical complications.

EVALUATION OF THE HEALTHY PATIENT Given the very low risk of complications among healthy patients undergoing surgery, additional clinical evaluation only rarely identifies patients at higher than average risk. Furthermore, due to the low prior probability of adverse events, most abnormal results from potential preoperative tests are false-positive tests. These results often contribute little to the estimation of risk, may increase patient and physician anxiety, lead to additional invasive tests that carry risk, and may increase medicolegal liability due to the possibility of abnormal test results that are ignored. A careful screening history and physical examination are the most important parts of the preoperative assessment of patients who report that they are healthy.

The history should focus on symptoms that suggest the possibility of occult cardiac or pulmonary disease. Many institutions have developed simple preoperative screening questionnaires for this purpose;
several of these instruments have been validated and shown to correctly identify most patients at higher than average risk. For example, in one study of a screening questionnaire, clinical evaluation by an anesthesiologist determined that only 2% of patients had negative responses to the questionnaire yet would have benefited from a more detailed clinical evaluation. Table 7-1 lists the questions on this validated questionnaire.

It is particularly important to query the patient about exercise capacity and to determine the reason for exercise intolerance, if present. For example, one report confirmed that a patient’s self-report of the inability to walk at least four blocks on level ground or to climb at least two flights of stairs predicts a twofold increase in cardiac and all serious postoperative complications. One should inquire specifically about chest pain or shortness of breath with activity and about chronic cough. The history should also include a review of medications (both prescription and over the counter), any previous operations or important medical problems, alcohol use, the possibility of pregnancy in reproductive-age women, previous adverse responses to anesthesia or surgery, and a family history of anesthetic reactions (that might suggest malignant hyperthermia).

Age appears to be a minor risk factor for both pulmonary and cardiac complications. Most of the risk attributed to age can be explained by medical comorbidities that are more common with advancing age. In the few studies that have looked at this question, younger and older patients with a similar burden of medical comorbidities appear to have a similar risk of postoperative complications. While counterintuitive, obesity does not appear to be a risk factor for cardiac or pulmonary complications or perioperative mortality.

Clinicians should not routinely obtain laboratory testing before surgery. Rather, tests should be requested selectively based on patient- or procedure-related factors that predict a higher likelihood of an abnormal result that may potentially influence perioperative management. Many studies have shown the very limited value of preoperative testing (laboratory testing, urinalysis, electrocardiogram, and chest radiograph) of healthy patients. In most reports, <1% of all routine preoperative tests are abnormal and could potentially influence management; most of these can be predicted by clinical evaluation. Among patients undergoing low-risk surgery, such as cataract surgery, there is no difference in morbidity or mortality between patients who undergo routine preoperative testing and those who do not undergo such testing. When clinicians do choose to obtain preoperative tests, tests obtained within the previous 4 months may be safely used as preoperative tests, assuming there has been no change in the patient’s clinical condition. Table 7-2 lists recommendations for specific tests in healthy patients based on the incidence of abnormalities that influence management and the predictive value of an abnormal test. The positive and negative likelihood ratios refer to the change in the odds of an adverse postoperative event if the test result is abnormal or normal, respectively.

### CARDIAC RISK ASSESSMENT

Cardiac complications are the most important source of perioperative morbidity and may occur even in patients previously unknown to have heart disease. Therefore, an assessment of cardiac risk must be part of every preoperative evaluation. In general, low-risk patients may proceed without further evaluation; high-risk patients will require treatment to reduce the risk of complications regardless of the results of preoperative cardiac testing; and intermediate-risk patients will benefit most from additional testing to stratify risk before surgery.

#### CARDIAC RISK INDICES

In most cases, one can confidently estimate risk through a careful history and physical examination and application of a cardiac risk index. The science of cardiac risk stratification began with the landmark study of Goldman and colleagues in 1977 that identified risk factors among the history, physical examination, electrocardiogram, general medical status, and type of surgical procedure. More recently, the revised cardiac risk index of Lee and colleagues has been shown to outperform the original index and other available risk-stratification tools and is now the preferred tool for initial risk stratification before noncardiac surgery (Table 7-3). This index resulted from a multivariate analysis of patients undergoing elective noncardiac surgery and includes six independent factors that predict risk of postoperative cardiac complications. As all of these factors were associated with a similar odds ratio for complications (range, 1.9 to 3.2), each factor is assigned one point in the revised cardiac risk index. Predictive factors include high-risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular procedures), ischemic heart disease, a history of congestive heart failure, a history of symptomatic cerebrovascular disease, insulin therapy for diabetes mellitus, or a preoperative serum creatinine > 177 μmol/L (2.0 mg/dL). Risk classes result from the total number of points (of six possible points). Risk increases substantially when two points exist; the greatest risk is for patients with three or more points.

Several factors that increase the likelihood of coronary artery disease (CAD) nonetheless do not increase the risk of postoperative cardiac complications. Factors that do not appear to increase risk include obesity, stable hypertension with a diastolic blood pressure of <110 mmHg, elevated cholesterol, bundle branch block, and cigarette smoking.

After application of the revised cardiac risk index (Table 7-3) to

*Patients who answer yes to any of questions #1–8, 10–14, 16, 19–25, or 30 should receive a complete history and physical examination as part of the preoperative evaluation.

stratify risk, clinicians should apply one of the established cardiac risk guidelines to determine the optimal strategy for additional testing and risk reduction strategies. Both the American College of Physicians (ACP) and the American Heart Association/American College of Cardiology (AHA/ACC) have published guidelines that suggest criteria for additional cardiac testing for selected patients before surgery and treatment strategies to reduce risk in high-risk patients. The ACP guideline is more clinically based and easier to use but does not incorporate the revised cardiac risk index, which was published after its release (Fig. 7-1). One can use elements of the ACP guideline along with more recent data to suggest that the first step would be to apply the revised cardiac risk index. Low-risk patients (class I) undergoing nonvascular surgery may proceed without additional evaluation. Additional noninvasive cardiac testing is appropriate for intermediate-risk patients (class II) undergoing vascular surgery. All high-risk patients (classes III and IV) should receive treatment to reduce risk (discussed below).

The AHA/ACC guideline is more complicated and relies on three separate factors: (1) clinical predictors (such as those in the revised cardiac risk index; Table 7-3), (2) functional capacity, and (3) procedure-specific risks. Examples of major clinical predictors include unstable coronary syndromes, recent myocardial infarction with evidence of ischemic risk, and decompensated congestive heart failure. Functional capacity is considered poor if patients are unable to perform activities requiring expenditure of at least four metabolic equivalents (METs). Examples in daily life include climbing one flight of stairs, doing light housework, or walking at least two blocks on level ground. Procedure-specific risks go beyond the high-risk categories defined in the revised cardiac risk index to identify low- and intermediate-risk procedures. This guideline recommends noninvasive cardiac testing for any patient with at least two of the following: (1) intermediate clinical predictors, (2) poor functional capacity, and (3) high-risk surgery.

**EVALUATION BEFORE VASCULAR SURGERY** Cardiac risk indices are unable to identify a subset of patients at low risk for cardiac complications after vascular surgery. This is due to the observation that the risk factors for peripheral vascular disease and CAD are the same. Therefore, patients undergoing arterial surgery are much more likely to have CAD than are patients undergoing general surgical procedures such as cholecystectomy, for example. As the prior probability of CAD is higher among such patients (92% in one angiographic study), even patients with low scores on cardiac risk indices have substantial risk for postoperative cardiac complications. Additional testing is necessary to estimate risk in these patients. Pharmacologic stress tests have been used widely to estimate cardiac risk before vascular surgery. Dipyridamole-thallium testing and dobutamine stress echocardiography have been studied most extensively. The test characteristics of the two tests are similar. Each has a negative predictive value of 95 to 100% but a positive predictive value for postoperative cardiac complications of only 10 to 20% for patients undergoing major vascular operations. As the predictive performances of these two tests are similar, clinicians may consider them to be interchangeable, and the selection of one test over the other depends on local availability and expertise.

Given the low predictive value when used in unscreened patients before vascular surgery, clinicians may incorporate clinical factors to identify an intermediate probability group that will benefit most from noninvasive testing. Several strategies exist; the most widely used are the “Eagle” criteria that include Q waves on the electrocardiogram, age > 70 years, angina, ventricular ectopy requiring treatment, and diabetes requiring treatment. Patients who have none of these factors have a low risk of adverse events and can proceed without further evaluation. Those with three to five factors are at high risk and need no risk refinement by further study. Those with one to two factors benefit the most from noninvasive testing.

STRATEGIES TO REDUCE CARDIAC RISK  After identifying patients whose risk of postoperative cardiac complications is above average, one must identify interventions and strategies to reduce risk, assuming that the risk is not so high that one would consider cancelation of surgery. As a recent myocardial infarction increases the risk of adverse events, one should delay elective surgery until at least 6 months after myocardial infarction. If an operation is necessary during this interval, a functional test such as an exercise test may stratify risk and identify a subset of patients with good exercise capacity and no inducible ischemia who may consider proceeding to surgery. Active congestive heart failure increases risk, and appropriate treatment of pulmonary congestion, including diuretic therapy, will reduce this risk. One should not diurese to the point of orthostatic hypotension as this may increase the risk of hypotension with anesthetic induction.

The risk attributed to aortic stenosis is controversial. While this was an important factor in the original Goldman cardiac risk index, recent retrospective uncontrolled studies suggest that even patients with critical aortic stenosis may undergo noncardiac surgery with an acceptable degree of risk. One should evaluate the severity of aortic stenosis in all patients suspected of having symptoms caused by their valvular disease. The indication for surgical treatment of aortic stenosis is the same as for patients who are not contemplating noncardiac surgery.

When risk is due to a high-risk operation, and few opportunities exist to otherwise reduce risk, clinicians may consider the possibility of an alternate lower risk procedure, if such a procedure exists.

Perioperative Beta Blockers  The most important recent observation in the field of perioperative cardiac risk is that perioperative beta blockers markedly reduce the risk of cardiac complications in selected patients. Four separate large-scale randomized trials have now addressed the benefit of this intervention. In two of the trials, all patients had either known CAD or at least two of the following risk factors: age ≥ 65 years, hypertension, current cigarettes use, total cholesterol ≥ 6.2 mmol/L (≥ 240 mg/dL), and diabetes mellitus. Many patients in clinical practice would meet these broad inclusion criteria. The other trials evaluated patients undergoing vascular surgery with at least one additional risk factor or preoperative ischemia demonstrated by Holter monitoring. The results of these trials show reductions in the rate of postoperative myocardial infarction and cardiac death from 55 to 93%. The number of such patients needed to treat to prevent one event range from 2.5 to 8.3, indicating a strong effect on reducing risk.

FIGURE 7-1  American College of Physicians’ guidelines for cardiac evaluation before noncardiac surgery. A. Guidelines for all adults facing surgery. B. Guidelines for high-risk patients. *Clinicians may use the revised cardiac risk index (Table 7-3) in place of the modified cardiac risk index for this guideline, which has been shown since the 1997 publication of the ACP guideline to be a superior tool for risk stratification. In addition, broader use of perioperative beta blockers is supported by recent studies, as described in the text. ACP, American College of Physicians; CHF, congestive heart failure; DSE, dobutamine stress echocardiography; DTI, dipyridamole-thallium imaging. (Reprinted with permission from American College of Physicians: Ann Intern Med 127: 309, 1997.)
Patient selection for perioperative beta-blocker use remains the subject of study. At this point, it is wise to use perioperative beta blockers for any patient at increased risk for postoperative cardiac complications, which includes any patient who meets the above criteria or has at least one risk factor according to the revised cardiac risk index (Table 7-3).

**Coronary Revascularization Before Noncardiac Surgery** While the data showing benefit of perioperative beta blockers are compelling, evidence for clear benefit of coronary revascularization to reduce the risk of subsequent noncardiac surgery is mostly lacking. No prospective trials address this question. Retrospective data exist among patients who were recruited and studied for another reason and in whom complications for incidental noncardiac surgery were determined. For example, among patients with stable CAD who had been randomly allocated to either coronary bypass surgery or medical therapy, and who subsequently underwent noncardiac surgery, the relative reduction in risk attributed to the coronary bypass surgery was similar to the risk of the coronary bypass surgery itself (2 to 3% mortality). The cardiac risk of sequential coronary bypass followed by noncardiac surgery is therefore similar to that of proceeding directly to the noncardiac surgery.

Percutaneous revascularization fares no better. While risk of treatable cardiac complications such as congestive heart failure appears to be reduced among patients with CAD who undergo percutaneous coronary angioplasty before noncardiac surgery, no difference exists in the rates of cardiac death or myocardial infarction between such patients and medically treated patients with CAD who undergo subsequent noncardiac surgery. Furthermore, patients treated with potent antiplatelet agents in the period after intracoronary stenting have an increased risk of cardiac or bleeding complications in the month after stenting and should not undergo elective noncardiac surgery during this interval.

Since the benefit of coronary revascularization to reduce the risk of noncardiac surgery is small and is inferior to that of perioperative beta blockers, clinicians may reserve this strategy for patients who have an independent indication for revascularization separate from their need for noncardiac surgery.

**PREOPERATIVE PULMONARY EVALUATION**

While estimation of cardiac risk is rightfully a major focus of the preoperative evaluation, clinicians may be surprised to learn that postoperative pulmonary complications are as prevalent as cardiac complications and contribute equally to morbidity, mortality, and length of hospital stay. Therefore, estimation of the risk of pulmonary complications is a necessary part of the preoperative evaluation. Important postoperative pulmonary complications include pneumonia, respiratory failure with prolonged mechanical ventilation, atelectasis, bronchospasm, and exacerbation of underlying chronic obstructive pulmonary disease.

**PATIENT-RELATED RISK FACTORS** One may group risk factors for pulmonary complications into patient- and procedure-related (Table 7-4). The most important patient-related factor is chronic obstructive pulmonary disease, which increases the risk of pulmonary complications fourfold. The risk varies according to the severity of the underlying lung disease. On physical examination, decreased breath sounds, prolonged expiration, rales, wheezes, and rhonchi each predict a sixfold increase in the risk of postoperative pulmonary complications. In contrast, well-controlled asthma does not appear to increase the risk of pulmonary complications. Smoking is a risk factor even for patients with no resulting chronic lung disease; the reported relative risks for complications range from 1.5 to 4. However, patients who have reduced their cigarette use or stopped completely in the 2 months before surgery have a higher risk than current smokers. This may relate to an increase in cough and sputum production that is common in the first weeks to months after cigarette cessation.

The risk of viral respiratory infections is unknown but probably small. Bacterial lower respiratory infections, including bronchitis and pneumonia, do increase the risk of pulmonary complications. In these settings, clinicians should delay elective surgery and treat the underlying infection.

Metabolic factors shown to increase risk include renal insufficiency (BUN > 10.7 mmol/L (>30 mg/dL) and albumin < 30 g/L (<3.0 g/dL). Poor functional capacity, known to increase risk for cardiac complications, is also a risk factor for postoperative pulmonary complications. Advanced age is a modest risk factor of approximately twofold; other patient- and procedure-related risk factors are more important than age. Surprisingly, obesity, even morbid obesity, does not increase the risk for pulmonary complications. However, obstructive sleep apnea, which is more common among obese patients, does increase the risk for airway management problems in the immediate postoperative period (such as hypoxemia and reintubation) and may increase the risk of pulmonary complications, though this latter observation is not well established.

**PROCEDURE-RELATED RISK FACTORS** In contrast to cardiac complications, procedure-related factors are more important than patient-related factors in predicting the risk of pulmonary complications. The most important factor is the surgical site. Risk increases as the incision approaches the diaphragm. The highest risk is for upper abdominal, thoracic, and abdominal aortic aneurysm surgery. Depending on the series, studies have shown complication of rates of 20 to 40% for these procedures. There is lower risk for lower abdominal surgery and peripheral vascular surgery. Laparoscopic abdominal surgeries carry a much lower risk of pulmonary complications (1%). Pulmonary complications are rare for surgeries outside of the chest and abdomen. Other procedure-related factors include prolonged surgical duration (>3 h), general anesthesia, emergency surgery, and the use of long-acting neuromuscular blockers such as pancuronium during anesthesia.

**PREOPERATIVE PULMONARY FUNCTION TESTING** (See also Chap. 234) The role of preoperative pulmonary function testing is debated. While such testing is necessary before planned lung resection (this is not the subject of this chapter), its value before other high-risk surgeries is less clear. The most commonly performed tests in this setting are simple spirometry including forced expiratory capacity in 1 s (FEV₁) and forced vital capacity (FVC). Advocates of testing suggest that clinical decision-making and patient selection for surgery may be influenced by such test results. However, most reports demonstrate that clinical factors (as described above in patient- and procedure-related risk factor sections) are as or more helpful in the estimation of risk than spirometry. Preoperative spirometry could be potentially useful were it to identify either high-risk patients who would escape clinical detection or those patients whose risk of proceeding to surgery would be prohibitive. Neither of these criteria is met.

Several reports have shown that clinical factors correctly identify

| **TABLE 7-4** Risk Factors for Postoperative Pulmonary Complications |
|------------------|------------------|
| **Patient-Related Risk Factors** | **Procedure-Related Risk Factors** |
| Chronic obstructive pulmonary disease | Surgical site: |
| Cigarette use < 8 weeks before surgery | Thoracic surgery |
| ASA class > 2 | Abdominal aortic aneurysm surgery |
| Goldman class 2–4 a | Upper abdominal surgery |
| Age > 60 | Neurosurgery |

| Blood urea nitrogen > 30 mg/dL | Pancuronium use |
| Abnormal chest radiograph lasting > 3 hours | Emergency surgery |

a Goldman cardiac risk index. Of four classes possible; class 4 represents the highest risk.

*Note:* ASA, American Society of Anesthesiologists.

patients at high risk for postoperative pulmonary complications and that there is no substantial incremental value of preoperative spirometry as a risk-stratification tool. While abnormal spirometry, in some studies, does predict risk, these patients would have been identified based on clinical criteria alone. As to prohibitive risk, it is now clear that even patients with spirometric values previously thought to represent an absolute contraindication to surgery (e.g., FEV₁ < 1 L or 50% predicted) can proceed to surgery with an acceptable degree of risk if the indication for surgery is compelling and if every effort is made to reduce postoperative pulmonary complications (see below). Evidence for the benefit of preoperative arterial blood gas analysis is even weaker and is based on small case series. No reports have shown that such studies are superior to clinical evaluation before high-risk nonpulmonary surgery. There is, therefore, no role for routine preoperative arterial blood gas analysis in high-risk patients.

STRATEGIES TO REDUCE POSTOPERATIVE PULMONARY COMPlications

Most risk-reduction strategies follow logically from the above risk factors. One should recommend cigarette cessation for at least 8 weeks before elective surgery. Cessation for briefer periods may increase risk. Clinicians should treat patients with chronic obstructive pulmonary disease or asthma in the usual fashion so as to maximally reduce airflow obstruction. The treatment strategies are identical to those used in patients who are not preparing for surgery. Patients with asthma should be free of wheezes and have a peak flow of at least 80% of the predicted value or of personal best. Antibiotics should be reserved for patients with bacterial lower respiratory tract infection, as their indiscriminate use does not reduce risk. Intraoperative strategies include epidural or spinal anesthesia when feasible, the avoidance of pancuronium as a neuromuscular blocker in high-risk patients, and the use of shorter duration or laparoscopic procedures.

Postoperative strategies include lung expansion maneuvers and pain control. Lung expansion maneuvers reduce risk by minimizing the expected fall in lung volumes (particularly for thoracic and upper abdominal surgery) that contribute importantly to the risk of complications. These strategies include deep breathing exercises (a component of chest physical therapy) and incentive spirometry and effort-independent strategies such as continuous positive airway pressure (CPAP) (Chap. 252). Deep breathing exercises and incentive spirometry are equally effective; each reduces risk by one half. CPAP should be reserved for patients who cannot cooperate with the other maneuvers as it is more costly and carries some risk of barotrauma.

Pain control strategies decrease splinting and improve the ability to take deep breaths; they reduce pulmonary complications by these mechanisms. Epidural analgesia with local anesthetics reduces complication rates in patients undergoing abdominal, thoracic, and aortic surgery. Intercostal nerve blocks may also be beneficial, but the effect did not reach statistical significance in a large well-designed meta-analysis.

DIABETES MELLITUS

(See also Chap. 323)

The most important perioperative risk attributable to diabetes mellitus is that of cardiac complications. This is due to the higher prevalence of CAD, both known and clinically inapparent, among patients with diabetes than among the general population. Therefore, the principal goal of the preparation of patients with diabetes before surgery is a careful assessment of cardiac risk, as described above. Diabetes also increases the risk of surgical wound infections. For the subset of patients with diabetic neuropathy, there is additional risk for aspiration of gastric contents during anesthesia if gastroparesis is present, and for blood pressure lability during surgery if autonomic neuropathy exists.

Strategies to control blood sugar in the perioperative period must balance the risk of hyperglycemia due to the stress of surgery and anesthesia and the need for patients to fast before surgery that may increase the risk of hypoglycemia. One achieves this balance through frequent monitoring and the use of short-acting insulin as needed to achieve blood sugar goals. Optimal perioperative blood sugars are between 100 and 200 mg/dL. Patients who are diet-controlled may proceed to surgery without additional treatment of blood sugar other than careful perioperative monitoring of blood sugar by fingerstick. Those who receive oral hypoglycemic agents should hold their medication on the morning of surgery (with the exception of metformin, which should be stopped the day before to minimize the risk of lactic acidosis). One treats these patients as needed with short-acting insulin on a sliding scale based on frequent monitoring. Intravenous fluids for oral agent– and insulin-treated patients should include glucose to decrease the risk for lipolysis and ketone production.

Controversy exists as to whether patients with insulin-requiring diabetes should be treated with a continuous insulin infusion in the perioperative period versus the conventional use of one-half of the patient’s usual morning long-acting insulin dose on the morning of surgery followed by a sliding scale of regular insulin based on frequent monitoring. Patients undergoing coronary bypass grafting have a lower incidence of sternal wound infections when managed with continuous infusion insulin to achieve tight perioperative blood sugar control. Among seriously ill patients who require prolonged mechanical ventilation after surgery, intensive continuous infusion insulin to achieve near-normal blood sugars reduces overall mortality when compared to a less intensive continuous infusion insulin strategy. Until further data are available, it is reasonable to recommend continuous infusion insulin in the perioperative period for patients undergoing prolonged major surgery, cardiac surgery, or emergent surgery with metabolic abnormalities or who will require prolonged mechanical ventilation after surgery.

LEE TH et al: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. Circulation 100: 1043, 1999

Of all the people who have ever lived to age 65, more than half are now alive. This statistic has important demographic and economic implications, and its impact on medical care is also substantial.

BIOLOGY OF AGING

Numerous molecular concomitants of aging have been described. For instance, there is an increase in chromosome structural abnormalities, DNA cross-linking, and frequency of single-strand breaks; a decline in DNA methylation; and loss of DNA telomeric sequences. The primary structure of proteins is unaltered, but there is an increase in posttranslational changes, deamidation, oxidation, cross-linking, and...
nonenzymatic glycation. Mitochondrial structure deteriorates, albeit not universally.

However, the biologic changes are clearer than the mechanisms that mediate them. In fact, although the senescent phenotype appears to be ubiquitous, biologists disagree about whether senescence even exists beyond zoos and civilized societies and whether it occurs at all in many species. There is little evolutionary rationale for a process that happens after reproduction is complete, particularly one associated with such a long and complex course. In nature, senescence is most notable for its absence; nearly all animals die of predation, disease, or environmental hazards rather than aging. The argument that different species have different maximum life spans can be explained without invoking a specific aging process; while growth and development are based on a genetic template, aging may reflect merely the accumulation of random damage rather than a specific mechanism.

If aging exists as a distinct process, there is consensus that the mechanisms are likely multifactorial, environmentally influenced, and species-specific, if not organ- and cell-specific, making the paucity of available human data particularly problematic. As a result, there are nearly as many theories of aging as investigators. Most theories overlap or are not mutually exclusive, and none is completely compatible with the dearth of data. As a group, the theories can be divided into two broad categories, based on whether they attribute aging to a genetic program or to progressive and random damage to homeostatic systems.

**GENETIC THEORIES OF AGING** Enthusiasm for genetic theories of aging is fueled by several observations, including the dramatic species-specific differences in maximal life span, the strong correlation with survival among monozygotic compared to dizygotic twins, and the fact that single mutations can prolong life span by >50% in some nematodes, flies, and mice. However, all genetic theories must account for the fact that evolutionary selection pressure is minimal following completion of reproduction. Three genetic theories have recently been advanced, but few relevant data have yet been accrued. The first theory suggests that, since animals usually succumb to natural forces long before reaching their maximal life span, aging might reflect mutations that impair long-term survival. These mutations would accumulate in the genome because there is no selection pressure to delete them. A second theory, “pleiotropic antagonism,” proposes that aging may be caused by the late and deleterious effects of genes that are conserved because of the survival advantages they confer prior to reproduction. The third theory applies to ecological niches where extrinsic hazards are relatively low. In such an environment, evolution might select for mutations that retard the aging process since these might allow an animal to produce and protect many more litters. In support of this theory, the rate of aging in an isolated clan of Virginia opossums was calculated to be roughly half of that seen in their less fortunate cousins.

**The Random Damage Theories** These are based on the possibility that the balance between ongoing damage and repair is disrupted. The theories differ in the emphasis placed on increased damage (e.g., by free radicals, oxidation, or glycation) versus deficient repair, as well as in the mechanisms that might mediate each. However, all share the observation that cell and organ repair capacity declines with age. Some 40 years ago, Hayflick and Moorhead observed that the number of replications among cultured cells is finite. Subsequent research revealed that this replicative senescence was due to arrest of the cell cycle at the G1/S phase, the point at which DNA synthesis begins. Recently, cell replication has also been linked to the length of telomeric DNA. Present at the termini of chromosomes, telomeric DNA prevents chromosomal instability, fragmentation, and rearrangement; anchors chromosomes to nuclear matrix; and provides a buffer between coding regions of DNA and the ends of the chromosomes. In addition, telomeric DNA is necessary for cell division. With each cell division, however, roughly 50 of the total 2000 base pairs of the telomere are lost. Telomeric shortening might thus result in loss of gene accessibility, which is necessary to repair ongoing cell damage caused by metabolism. Together with cytoplasmic factors mediating arrest of DNA synthesis, telomeric shortening could also limit the cell’s ability to divide and thereby replace cells lost to apoptosis.

Many mechanisms previously postulated to mediate aging have not been borne out, including the somatic mutation theory (in which aging would result from cumulative spontaneous mutations), the error catastrophe theory (in which aging would result from errors in the synthesis of proteins critical to the synthesis of genetic material or protein-synthesizing machinery), and the intrinsic mutagenesis theory (in which aging is the result of ongoing intrinsic DNA rearrangements).

To date, the only intervention known to delay aging is caloric restriction. The salutary effect of restricting caloric intake by 30 to 40% has been documented in multiple species, from single-celled organisms to rodents. In rodents, it not only increases average life expectancy and maximum life span but also delays the onset of some typical age-associated diseases as well as deterioration of physiologic systems (e.g., immune responsiveness, glucose metabolism, muscle atrophy). Moreover, its impact is evident in both mitotic and postmitotic cells, in gene expression, and in protein turnover and cross-linking. Although the mechanism is still not determined, it is specific to caloric restriction rather than to reduction of any dietary component (e.g., fat intake) or supplements with vitamins or antioxidants. Unfortunately, adequate data from primates are still limited, and the effect of caloric restriction in humans is still unknown.

**PRINCIPLES OF GERIATRIC MEDICINE** Despite the biologic controversy, from a physiologic standpoint human aging is characterized by progressive constriction of the homeostatic reserve of every organ system. This decline, often referred to as homeostasis, is evident by the third decade and is gradual and progressive, although the rate and extent of decline vary. The decline of each organ system (Table 8-1) appears to occur independently of changes in other organ systems and is influenced by diet, environment, and personal habits as well as by genetic factors.

Several important principles follow from these facts: (1) Individuals become more dissimilar as they age, belying any stereotype of aging; (2) an abrupt decline in any system or function is always due to disease and not to “normal aging”; (3) “normal aging” can be attenuated by modification of risk factors (e.g., increased blood pressure, smoking, sedentary lifestyle); and (4) “healthy old age” is not an oxymoron. In fact, in the absence of disease, the decline in homeostatic reserve causes no symptoms and imposes few restrictions on activities of daily living regardless of age.

Appreciation of these facts may make it easier to understand the striking increases that have occurred in life expectancy. Average life expectancy is now 18 years at age 65, 11 years at age 75, 6 years at age 85, 4 years at age 90, and 2 years at age 100. Moreover, the bulk of these years is characterized by a lack of significant impairment (Table 8-2). Even beyond age 85, only 30% of people are impaired in any activity required for daily living and only 20% reside in a nursing home. Yet, as individuals age they are more likely to suffer from disease, disability, and the side effects of drugs, all of which, when combined with the decrease in physiologic reserve, make the older person more vulnerable to environmental, pathologic, and pharmacologic challenges.

The following concepts underlie the remainder of the chapter:

1. Disease presentation is often atypical in the elderly, especially in those >75 to 80 years old. Homeostatic strain caused by onset of a new disease often leads to symptoms associated with a different organ system, particularly one compromised by preexisting disease. For example, fewer than one-fourth of older patients with hyperthyroidism present with goiter, tremor, and exophthalmos; more likely are atrial fibrillation, confusion, depression, syncope, and weakness. Significantly, because the “weakest link” is so often the brain, the lower urinary tract, or the cardiovascular system, a limited number of presenting symptoms predominate—acute confusion, depression, incontinence, falling, and syncope—no matter

* Changes generally observed in healthy elderly subjects free of symptoms and detectable disease in the organ system studied. The changes are usually important only when the system is stressed or other factors are added (e.g., drugs, disease, or environmental challenge); they rarely result in symptoms otherwise.

what the underlying disease. Thus for the most common geriatric syndromes, regardless of the presenting symptom, the differential diagnosis is often usually similar. The corollary is equally important: The organ system usually associated with a particular symptom is less likely to be the source of that symptom in older individuals than in younger ones. Compared with middle-aged individuals, for example, acute confusion in older patients is less often due to a new brain lesion, depression to a psychiatric disorder, incontinence to bladder dysfunction, falling to a neuropathy, or syncope to heart disease.

2. Because of decreased physiologic reserve, older patients often develop symptoms at an earlier stage of their disease (Fig. 8-1). For example, heart failure may be precipitated by mild hyperthyroidism, cognitive dysfunction by mild hyperparathyroidism, urinary retention by mild prostatic enlargement, and nonketotic hyperosmolar coma by

* For independent noninstitutionalized elderly men and women in Massachusetts. Longevity and disability-free longevity are surprisingly long and must be incorporated into treatment decisions. All figures rounded to nearest year. See text for more recent data on longevity alone.

FIGURE 8-1  Even mild organ system dysfunction may cause symptoms if compensatory mechanisms are impaired. (From NM Resnick: JAMA 276:1932, 1996.)
mild glucose intolerance. Paradoxically, therefore, treatment of the underlying disease may be easier because it is frequently less advanced at the time of presentation. A corollary is that drug side effects can occur with drugs and drug doses unlikely to produce side effects in younger people. For instance, a sedating antihistamine (e.g., diphenhydramine) may cause confusion, loop diuretics may precipitate urinary incontinence, digoxin may induce depression even with normal serum levels, and over-the-counter sympathomimetics may precipitate urinary retention in men with mild prostatic obstruction.

Unfortunately, the predisposition to develop symptoms at an earlier stage of disease is often offset by two factors. First, symptoms may present later if there is functional limitation in another system. Coronary artery disease or aortic stenosis may not cause symptoms as early in patients whose mobility is compromised by arthritis. Second, a change in illness behavior occurs with age. Raised at a time when symptoms and debility were accepted as normal consequences of aging, the elderly are less likely to seek attention until symptoms become disabling. Thus, any symptom, particularly those associated with a change in functional status, must be taken seriously and evaluated promptly.

3. Since many homeostatic mechanisms may be compromised concurrently, there are usually multiple abnormalities amenable to treatment, and small improvements in each may yield dramatic benefits overall. For instance, cognitive impairment in patients with Alzheimer’s disease may respond much better to interventions that alleviate comorbidity than to prescription of a cholinesterase inhibitor (Fig. 8-2). Similar approaches apply to most other geriatric syndromes, including falls, incontinence, depression, delirium, syncope, and fracture. In each case, substantial functional improvement can result from treating the contributing factors even if—as in Alzheimer’s disease—the disease itself is largely untreatable.

4. Many findings that are abnormal in younger patients are relatively common in older people—e.g., bacteriuria, premature ventricular contractions, low bone mineral density, impaired glucose tolerance, and uninhibited bladder contractions. However, they may not be responsible for a particular symptom but only be incidental findings that result in missed diagnoses and misdirected therapy. For instance, the finding of bacteriuria should not lead the examiner to look for a source of fever in an acutely ill older patient, nor should an elevated random blood sugar—especially in an acutely ill patient—be incriminated as the cause of neuropathy. On the other hand, certain other abnormalities must not be dismissed as due to old age—e.g., there is no anemia, impotence, depression, or confusion of old age.

5. Because symptoms in older people are often due to multiple causes, the diagnostic “law of parsimony” often does not apply. For instance, fever, anemia, retinal embolus, and a heart murmur prompt almost a reflex diagnosis of infective endocarditis in a younger patient but may reflect aspirin-induced blood loss, a cholesterol embolus, insignificant aortic sclerosis, and a viral illness in an older patient. Moreover, even when the diagnosis is correct, treatment of a single disease in an older patient is unlikely to result in cure. For instance, in a younger patient, incontinence due to involuntary bladder contractions is treated effectively with a bladder relaxant medication. However, in an older patient with the same condition but who also has fecal impaction, treatment may involve enemas that take the patient several hours, and suffers from arthritis-associated impairments of mobility and manual dexterity, treatment of the bladder spasms alone is unlikely to restore continence. On the other hand, disimpaction, discontinuation of the offending medications, and treatment of the arthritis are likely to restore continence without the need for a bladder relaxant. Failure to recognize these principles often leads to prescribing “ineffective” therapy and to unjustified therapeutic nihilism toward older patients.

6. Because the older patient is more likely to suffer the adverse consequences of disease, treatment—and even prevention—may be equally or even more effective. For instance, the survival benefits of exercise, as well as thrombolysis and beta-blocker therapy after a myocardial infarction, are as impressive in older patients as in younger ones; and treatment of hypertension and transient ischemic attacks, as well as immunization against influenza and pneumococcal pneumonia, are more effective in older patients. A proactive approach is even more effective in acute care, in which it decreases the risk of delirium by 30 to 60%. In the outpatient setting, such an approach can delay functional decline and institutionalization. In addition, prevention in older patients must often be seen in a broader context. For instance, although interventions to increase bone density may be limited in older patients, fracture may still be prevented by efforts to improve balance, strengthen legs, reduce peripheral edema, treat other contributing medical conditions, replete nutritional deficits, eliminate environmental hazards, and remove adverse medications—not so much those that affect bone metabolism, but rather those that induce orthostasis, confusion, and extrapyramidal stiffness.

In summary, optimal treatment of the older patient generally requires treating much more than the organ system usually associated with the disease or symptom, and often permits ignoring that system entirely.

**EVALUATION** Evaluation of the older patient can be time-consuming, even when it is tailored to the problem. Yet, such initial investment can reduce subsequent morbidity and resource utilization and enhance patient and physician satisfaction. Additionally, the assessment can often be accomplished over several visits. Moreover, much can be gleaned from questionnaires filled out by the patient or caregiver in advance as well as from observation. For instance, greeting the patient in the waiting room allows the physician to note affective and cognitive response, the strength of the handshake, the ease of rising from a chair without using the arms, the length and steadiness of the stride, and the ability to follow directions to the examining room and to sit down safely in the examining room chair. Observing the patient dress or undress can also enhance detection of impaired cognition, fine motor skills, balance, and judgment. Such observations often provide more information than standard examinations and can shorten the clinical evaluation.

**HISTORY-TAKING IN ELDERLY PATIENTS** Most older patients are able to provide a reliable medical history; however, a multitude of complaints may make obtaining a history more difficult. If the patient is unable to comprehend or communicate, data should be sought from family, friends, and caregivers. The history should also include drug and alcohol ingestion, dietary patterns, falling, incontinence, sexual dysfunction, depression, and anxiety.
Advance Directives  All older patients should be asked whether they have drafted advance health care directives, and, if they have, a copy should be placed in the record. Such directives may consist of a health care proxy or durable power of attorney for health care, in which patients designate a surrogate decision-maker who makes health care decisions if the patient cannot, and/or a living will or medical directive, in which patients specify their desires for treatment in specific situations if they cannot communicate at the critical time. Whether or not the patient has formally drafted these directives, it is useful to indicate in the record who should make health care decisions if the patient is no longer able to do so. Patients should then be encouraged to discuss their thoughts with the physician as well as the designated proxy. It is not feasible to cover all possible future complications in such discussions. Ascertainment of preferences on specific interventions, such as resuscitation or intubation, is also difficult because preferences will likely differ depending on prognosis. For instance, a patient may not be interested in feeding tube placement following a massive stroke with little chance of recovery but would prefer the same intervention if it is short-term and helps ensure more rapid and complete recovery from an intercurrent illness such as pneumonia. More useful is a discussion that uses open-ended questions and empathic comments to elicit the patient’s values and goals. Moreover, for any given condition, preferences may differ depending on baseline clinical status. For robust elderly individuals, recovery is a realistic goal, albeit the odds of complications are higher than for younger individuals. For the frail elderly patient with comorbidity that impairs functional status, reduction or alleviation of symptoms may be the goal. For patients with advanced dementia or terminal illness, maximizing comfort may be the most appropriate strategy. In each situation, however, early elicitation of a patient’s preferences and values—when the patient can still state them—can often help both physicians and families in subsequent difficult decisions by giving surrogate decision-makers the sense that they are doing as the patient would have wanted.

PHYSICAL EXAMINATION  Certain features of the examination should receive special attention, depending in part on clues from the history. Weight and postural blood pressure should be measured at most visits. Vision and hearing should be checked; if hearing is impaired, excess cerumen should be removed from the external auditory canals prior to audiologic referral. Denture fit should be assessed, and the oral cavity should be inspected with the dentures removed. Although thyroid disease becomes more common with age, the sensitivity and specificity of related findings are substantially lower than in younger individuals; consequently, the physical examination can rarely corroborate or exclude thyroid dysfunction in older patients. The breasts should not be overlooked, since older women are more likely to have breast cancer and less likely to do breast self-examination. The systolic murmur of aortic sclerosis is common and may be difficult to differentiate from aortic stenosis, especially since the presence of a fourth heart sound in an elderly person does not imply significant cardiac disease, and the carotid upstroke normally increases owing to age-related arterial stiffening.

In inactive patients and those with fecal or urinary incontinence, one should check for fecal impaction. In patients with urinary incontinence—especially men—a distended bladder must be looked for, since it may be the only finding in urinary retention; perineal sensation and the bulbocavernosus reflex should also be tested. Patients who fall should be observed standing up from a chair, bending down, reaching up, walking 3 m (10 ft), turning, returning, and sitting again; abnormalities of gait and balance should be evaluated with the patient’s eyes open and closed and in response to a sternal push. It should be appreciated that “frontal release signs” (e.g., “snout,” “glabellar,” or pal-momental reflexes) and absent ankle jerks and vibratory sense in the feet may be normal in the elderly.

MENTAL STATUS EXAMINATION  In addition to evaluating mood and affect, some form of cognitive testing is essential in all elderly patients, even if it involves only checking different components of the history for consistency. People with mild degrees of dementia usually retain their social graces and may mask intellectual impairment by a cheerful and cooperative manner. Thus, the examiner should always probe for content. For patients who follow the news, one can ask what stories they are particularly interested in and why; the same applies to reading, social events—even the soap operas on television.

If there is any suspicion of a cognitive deficit after this kind of conversational probing, further questioning is indicated. An examination that tests only orientation as to person, place, and time is insufficient to detect mild or moderate intellectual impairment. As a quick screen, simply assessing orientation and asking the patient to draw a clock with the hands at a set time (e.g., 10 min before 2:00) can be very informative regarding cognitive status, visuospatial deficits, ability to comprehend and execute instructions in logical sequence, and presence or absence of perseveration. For slightly more detailed examinations, many practical mental status tests are available. The most widely used is the Mini-Mental Status Examination of Folstein (Chap. 257), which provides a numerical score that can be obtained in 5 to 10 min. Regardless of the test employed, the total score is less useful diagnostically than is knowledge of the specific domain of the deficit. As a general rule, disproportionate difficulty with immediate recall (e.g., of a list of three items) suggests depression, while predominant difficulty with recalling the items 5 min later suggests dementia. For patients with deficits of attention—recognized by inability to spell simple words backwards, repeat five digits, or recite the months of the year backwards—delirium is probably present, and the accuracy of the remainder of the test is dubious. However, the test can be interpreted accurately only in the context of a comprehensive evaluation.

EVALUATION OF FUNCTIONAL CAPACITY  Medical problem lists, a standard tool for assessing and following younger patients, often prove inadequate for older patients. Heart failure, stroke, and prostate cancer can describe a bedbound institutionalized person as well as a Supreme Court justice. Thus, it is essential to ascertain the patient’s degree of functional incapacity owing to both medical and psychosocial problems. The functional assessment includes determination of the patient’s ability to perform basic activities of daily life (ADL), which are those needed for personal self-care, as well as the ability to perform more complex tasks required for independent living, the instrumental activities of daily living (IADL). ADLs include bathing, dressing, toileting, feeding, getting in and out of chairs and bed, and walking. IADLs include shopping, cooking, money management, housework, using a telephone, and traveling outside the home. For frail patients, an assessment in the home by a trained observer may be required, but for most patients a questionnaire dealing with these activities can be completed by the family or patient. In either case, the physician must determine the cause of any impairment and whether it can be treated. Assessment should conclude with determination of the socioeconomic circumstances and social support systems.

MANAGEMENT OF COMMON GERIATRIC CONDITIONS

Diseases more common in the elderly are covered elsewhere in the text. The medical problems discussed below do not usually present as clear-cut organ-specific diagnoses and are most common in the frail elderly, especially those over 80 years of age.

INTELLECTUAL IMPAIRMENT  The predominant causes of impaired mental function in older patients are delirium, dementia, and depression. Each condition is covered elsewhere in the text in detail (Chaps. 257 and 350), but their management in the elderly is discussed here. Differentiating the causes of impaired mental function is important, but in older patients they frequently coexist. Thus, the most important first step is to search for and correct all factors that may contribute to cognitive impairment, even in patients with dementia (Fig. 8-2). Evidence of dangerous behavior should also be sought (e.g., leaving the stove on, wandering, and getting lost), and plans should be devised to deal with it. Although there is no definitive treatment for Alzheimer’s
disease, it is important to detect. Such knowledge allows the physician to discontinue all unnecessary medications, identify and treat new intercurrent illness, and search for alternative ways to obtain the interval history and to ensure that the patient’s medications are taken correctly. In addition, the physician should help the family and patient predict and deal with the disease; indeed, the family often needs the physician’s support more than the patient does.

**TREATMENT**

Community services should be suggested as needed, including a visiting nurse, a home health aide to assist with personal hygiene, a home-maker to assist with housework, meal delivery, transportation services, day health centers, and respite care to ease the burden on family members. Support groups such as the Alzheimer’s Association are often of value to the family and help them to anticipate problems. Signs of patient abuse by an over-stressed caregiver should be watched for. Legal counsel should be recommended to help the patient and family devise plans for ongoing management and ultimate disposition of assets. Assessment of driving safety may be warranted and can often be completed at a driving school or rehabilitation center. Advance directives should be sought as soon as possible while the patient can still participate.

Cholinesterase inhibitors (e.g., donepezil, galantamine, and rivastigmine) can slow clinical progression and ameliorate behavior. However, they are expensive, their efficacy is modest, their utility for more than a year is largely unstudied, and their side effects (nausea, diarrhea, insomnia, dizziness, and confusion) are common, particularly at the higher dosages often needed. Thus, goals should be agreed upon prior to therapy. If they are not met within 3 to 6 months at maximum dosage, consideration may be given to discontinuing therapy. Patients should be monitored for decline when cholinesterase inhibitors are stopped, since this may point to a previously unrecognized therapeutic benefit.

Finally, abrupt worsening of mentation or the onset of disruptive behavior should always prompt a search for new illness or medication. Exacerbation of cognitive dysfunction may occur with mild infections (e.g., subungal toe abscess, vaginitis, or pressure ulcer); with “therapeutic” levels of many drugs; with use of nonprescribed drugs or alcohol; with modest abnormalities of serum sodium, calcium, glucose, or thyroxine; with mild hypoxia; with borderline nutritional deficiencies; with subdural hematoma or “minor” stroke; and with the development of fecal impaction, urinary retention, pain, or change in environment, particularly in frail older patients. However, if a cause is not found and behavior does not respond to environmental manipulation (e.g., ignoring the behavior, distracting the patient, addressing situational “triggers,” and providing a calm environment), low doses of an antipsychotic medication may be helpful (e.g., haloperidol, 0.25 to 2 mg/d orally; see below). Of note, feeding tubes inserted into patients with advanced dementia do not prolong life, prevent aspiration, or promote healing of pressure ulcers.

**DEPRESSION** Depression of significant degree occurs in 5 to 10% of community-dwelling elderly but is often overlooked. At highest risk are individuals with recent medical illness (e.g., stroke or fracture), bereavement, lack of social supports, recent nursing home admission, or psychiatric history (including alcohol abuse). The diagnosis requires the presence of a depressed mood for at least two consecutive weeks plus at least four of the following eight symptoms: sleep disturbance, lack of interest, feelings of guilt, decreased energy, decreased concentration, decreased appetite, psychomotor agitation/retardation, and suicidal ideation. Also helpful diagnostically are a personal or family history of depression, anhedonia (loss of pleasure), and past response to an antidepressant. It is essential to bear in mind that depression in older patients is often caused or contributed to by drugs or a systemic illness. It is also important to recognize that the risk of suicide is highest in older adults. Although “subsyndromal” depression (fewer than four of the above symptoms) also causes substantial morbidity and health resource utilization, it appears to be less responsive than major depression to therapy.

**TREATMENT**

For the hospitalized patient in whom acute depression delays recovery or rehabilitation—when correction of medical and pharmacologic contributing factors is ineffective and there is no prior history of mania or major depression—methylphenidate, 5 to 10 mg at 8 A.M. and noon (to avoid insomnia) is often very effective, with benefits discernible within a few days. For patients with major depression, there is no ideal antidepressant drug. All are about equally effective, but the side effects differ (see below and Chap. 371). Consequently, one should become familiar with more than one agent with proven efficacy in older adults (e.g., sertraline, citalopram, bupropion, venlafaxine, mirtazapine, and nortriptyline). Because of its potent anticholinergic and orthostatic side effects, amitriptyline should be avoided whenever possible in older patients. Initial low dosages should be increased slowly to avoid serious side effects; low doses of each medication (e.g., nortriptyline, 10 to 30 mg daily; desipramine, 25 to 75 mg daily; or sertraline 50 to 150 mg daily) are often effective in the elderly, especially when combined with psychotherapy. All of the selective serotonin reuptake inhibitors (SSRIs) and venlafaxine may cause hyponatremia due to the syndrome of inappropriate diuretic hormone (SIADH), and all, like the tricyclic antidepressants, may cause falls. Adverse drug reactions should not be assumed to be due to the aging process.

Treatment should be continued for up to a year after remission of the first episode of depression because relapse rates are higher in the elderly. Consideration for indefinite antidepressant therapy should be given to patients with two or more relapses. For those with psychotic depression, refractory depression, or depression where a definitive, rapid response is required (e.g., extreme frailty, actively suicidal), electroconvulsive therapy is usually well tolerated and highly effective in elderly patients.

**URINARY INCONTINENCE**

**Transient Incontinence** (Table 8-3) Because urinary incontinence requires adequate mobility, mentation, motivation, and manual dexterity—in addition to integrated control of the lower urinary tract—problems outside the bladder can result in incontinence.

1. Delirium. A clouded sensorium impedes recognition of both the need to void and the location of the nearest toilet; once delirium clears, incontinence resolves.

2. Infection. Symptomatic urinary tract infection commonly causes or contributes to incontinence; asymptomatic infection does not.

3. Atrophic urethritis/vaginitis. Atrophic urethritis/vaginitis, characterized by the presence of vaginal telangiectasia, petechiae, erythema, or friability, commonly contributes to incontinence in women and responds to a several-month course of low-dose estrogen or vaginal estrogen creams.

</tbody>
</table>

Note: CHF, congestive heart failure.
Examples include nifedipine, nicardipine, isradipine, felodipine, nimodipine.

Stool impaction. This is a common cause of urinary incontinence, especially in hospitalized or immobile patients. Although the mechanism is unknown, a clue to its presence is the coexistence of both urinary and fecal incontinence. Disimpaction restores continence.

Established Incontinence (Table 8-3) The causes of established incontinence include irreversible functional deficits, such as end-stage Alzheimer’s disease, and intrinsic lower urinary tract dysfunction. Lower urinary tract dysfunction should be sought after transient causes have been excluded.

DETRUSOR OVERACTIVITY This disorder (involuntary bladder contraction) accounts for two-thirds of geriatric incontinence in both sexes, regardless of whether patients are demented. Detrusor overactivity can be diagnosed presumptively in a woman when leakage occurs in the absence of stress maneuvers or urinary retention and is preceded by the abrupt onset of an intense urge to urinate that cannot be forestalled. In men, the symptoms are similar, but since detrusor overactivity often coexists with urethral obstruction, urodynamich testing should be done if prescription of a bladder relaxant is planned. Because detrusor overactivity may also be due to bladder stones or tumor, the abrupt onset of otherwise unexplained urge incontinence—especially if accompanied by perineal/suprapubic discomfort or sterile hematuria—should prompt cystoscopy and cystologic examination.

STRESS INCONTINENCE This disorder, the second most common cause of established incontinence in older women (it is rare in men), is characterized by symptoms and evidence of instantaneous leakage of urine in response to stress. Leakage is worse or occurs only during the day unless another abnormality (e.g., detrusor overactivity) is also present. On examination, with the bladder full and the perineum relaxed, instantaneous leakage upon coughing strongly suggests stress incontinence, especially if it reproduces symptoms and if urinary retention has been excluded by a postvoiding residual determination; a several-second delay suggests that leakage is instead caused by an involuntary bladder contraction induced by coughing.

Surgery is the most effective treatment. For women who can comply indefinitely, pelvic muscle exercises are an option for mild to moderate stress incontinence, but they often require specialized training using vaginal cones or biofeedback. Occasionally, a pessary or even a tampon (for women with vaginal stenosis) provides some relief.

URETHRAL OBSTRUCTION Rarely present in women, urethral obstruction (due to prostatic enlargement, urethral stricture, bladder neck contracture, or prostate cancer) is the second most common cause of established incontinence in older men. It can present as dribbling incontinence after voiding, urge incontinence due to detrusor overactivity (which coexists in two-thirds of cases), or overflow incontinence due to urinary retention. Renal ultrasound is recommended to exclude hydronephrosis in men whose postvoiding residual volume exceeds 100 to 200 mL; in older men for whom surgery is planned, urodynamich confirmation of obstruction is strongly advised.
men; such testing is not usually required in women, in whom obstruction is rare.

### TREATMENT

Surgical decompression is the most effective treatment for obstruction, especially if there is urinary retention. For a nonoperative candidate, intermittent or indwelling catheterization is used; a condom catheter is contraindicated when urinary retention is present. For a man with prostatic obstruction who is not in retention, treatment with an α-adrenergic antagonist (e.g., terazosin, 5 to 10 mg daily, or tamsulosin, 0.4 to 0.8 mg daily) may lessen symptoms in a few weeks. The 5α-reductase inhibitor finasteride may ameliorate symptoms in a third or more of patients, but its impact is less and not apparent for many months. Combined treatment with finasteride and either terazosin or tamsulosin has proved no better than treatment with an alpha blocker alone in most men.

**DETRUSOR UNDERACTIVITY** Whether idiopathic or due to sacral lower motor nerve dysfunction, this is the least common cause of incontinence (<10% of cases). When it causes incontinence, detrusor underactivity is associated with urinary frequency, nocturia, and frequent leakage of small amounts. The elevated postvoiding residual volume (generally ≥450 mL) distinguishes it from detrusor overactivity and stress incontinence, but only urodynamic testing (rather than cystoscopy or intravenous urography) differentiates it from urethral obstruction in

40% of admissions to nursing homes. Resultant hip problems and fear of falls are major causes of loss of independence.

Subdural hematoma is a treatable but easily overlooked complication of falls that must be considered in any elderly patient presenting with new neurologic signs, including confusion alone, even in the absence of a headache. Dehydration, electrolyte imbalance, pressure sores, rhabdomyolysis, and hypothermia may also occur and endanger the patient’s life following a fall.

The risk of falling is related to the number of contributory conditions. Because the relationship is multiplicative rather than additive, however, even minor improvement in a number of these factors will reduce the risk substantially. In addition, gait training by a physical therapist often alleviates fear of falling. For those willing to wear them, hip pads have proved effective in two European trials, but the efficacy and acceptability of pads available in the United States are not yet established. Ensuring the availability of phones at floor level, a portable phone, or a lightweight radio call system is also important, as is establishment of the availability of phones at floor level, a porch or rubber mat in tub or shower; shower chair with handheld shower; nonskid rug; raised toilet seat; door locks removed to ensure access in an emergency.

**IMMOBILITY**
The main causes of immobility are weakness, stiffness, pain, imbalance, and psychological problems. Weakness may result from disuse of muscles, malnutrition, electrolyte disturbances, anemia, neurologic disorders, or myopathies. The most common cause of stiffness in the elderly is osteoarthritis; however, Parkinson’s disease, rheumatoid arthritis, gout, pseudogout, and antipsychotic drugs such as haloperidol may also contribute. Pain, whether from bone (e.g., osteoporosis, osteomalacia, Paget’s disease, metastatic bone cancer, trauma), joints (e.g., osteoarthritis, rheumatoid arthritis, gout), bursa, muscle (e.g., polymyalgia rheumatica, intermittent claudication, or “pseudoclaudication”), or foot problems may immobilize the patient.

Imbalance and fear of falling are major causes of immobilization. Imbalance may result from general debility, neurologic causes (e.g., stroke; loss of postural reflexes; peripheral neuropathy due to diabetes mellitus, alcohol, or malnutrition; and vestibulocerebellar abnormalities), orthostatic or postprandial hypotension, or drugs (e.g., diuretics, antihypertensives, neuroleptics, and antidepressants) or may occur following prolonged bed rest. Psychological conditions such as severe anxiety or depression may also contribute to immobilization.

Consequences In addition to thrombophlebitis and pulmonary embolus, there are multiple hazards of bed rest in the elderly. Deconditioning of the cardiovascular system occurs within days and involves fluid shifts, fluid loss, decreased cardiac output, decreased peak oxygen uptake, and increased resting heart rate. Striking changes also occur in skeletal muscle. At the cellular level, intracellular ATP and glycogen concentrations decrease, rates of protein degradation increase, and contractile velocity and strength decline, while at the whole-muscle level, atrophy, weakness, and shortening are seen. Pressure sores are another serious complication; mechanical pressure, moisture, friction, and shearing forces all predispose to their development. As a result, within days of being confined to bed, the risk of postural hypotension, falls, and skin breakdown rises. Moreover, these changes usually take weeks to months to reverse.

The most important step is preventive—to avoid bedrest whenever possible. When it cannot be avoided, several measures can be employed to minimize its consequences. Patients should be positioned as close to the upright position as possible several times a day. Range-of-motion exercises should begin immediately, and the skin over pressure points should be inspected frequently. Isometric and isotonic exercises should be performed while the patient is in bed, and whenever possible patients should assist their own positioning, transferring, and self-care. As mobility becomes feasible, graduated ambulation should begin. For individuals confined to a wheelchair, ring-shaped devices (“donuts”) should not be used to prevent pressure ulcers since they cause venous congestion and edema and actually increase the risk.

If a pressure ulcer develops, therapy depends on its stage. Stage 1 ulcers are characterized by nonblanchable erythema of intact skin; stage 2 lesions involve an ulcer of the epidermis, dermis, or both; stage 3 ulcers extend to the subcutaneous tissue; and stage 4 lesions involve muscle, bone, and/or the supporting tissues. For stage 1 lesions, eliminating excess pressure and ensuring adequate nutrition and hygiene are sufficient. For the remaining types, the caregiver must also ensure that the wound stays clean and moist; thus, if saline dressings are used they should be changed when they are damp rather than dry. Synthetic dressings are more expensive than saline but are more effective because they require fewer changes (with less disruption of reepithelialization) and protect against contamination. Because bacterial colonization of pressure ulcers is universal, swab cultures should not be performed and topical treatment should be considered only for patients whose ulcers have not healed after 2 weeks of therapy. By contrast, associated cellulitis, osteomyelitis, or sepsis requires systemic therapy after cultures of blood and the wound border (by needle aspiration or biopsy) have been obtained. Surgical or enzymatic debridement is required for stage 3 and 4 lesions. In addition to a daily multivitamin, prescribing vitamin C (500 mg twice daily) is also useful. For debilitated patients, special mattresses are beneficial, including those that reduce pressure (e.g., static air mattress or foam) and those that relieve it (e.g., dynamic units that sequentially inflate and deflate).

In addition to treating all identified factors that contribute to immobility, consultation with a physical therapist should be sought. Installing handrails, lowering the bed, and providing chairs of proper height with arms and rubber skid guards may allow the patient to be safely mobile in the home. A properly fitted cane or walker may be helpful.
IATROGENIC DRUG REACTIONS For several reasons, older patients are two or three times more likely to have adverse drug reactions (Chap. 3). Drug clearance is often markedly reduced. This is due to a decrease in renal plasma flow and glomerular filtration rate and a reduced hepatic clearance. The last is due to a decrease in activity of the drug-metabolizing microsomal enzymes and an overall decline in blood flow to the liver with aging. The volume of distribution of drugs is also affected, since the elderly have a decrease in total-body water and a relative increase in body fat. Thus, water-soluble drugs become more concentrated, and fat-soluble drugs have longer half-lives. In addition, serum albumin levels decline, particularly in sick patients, so that there is a decrease in protein binding of some drugs (e.g., warfarin, phenytoin), leaving more free (active) drug available. Thus, a lower/total serum drug level, as assessed by routine assays, may be an appropriate level in older patients.

In addition to impaired drug clearance, which alters pharmacokinetics, older patients have altered responses to similar serum drug levels, a phenomenon known as altered pharmacodynamics. They are more sensitive to some drugs (e.g., opiates, anticoagulants) and less sensitive to others (e.g., β-adrenergic agents). Finally, the older patient with multiple chronic conditions is likely to be taking several drugs, including nonprescribed agents. Thus, adverse drug reactions and dosage errors are more likely to occur, especially if the patient has visual, hearing, or memory deficits. Nonetheless, because undertreatment of older patients is as problematic as overtreatment, these caveats should not deter prescription of appropriate therapy.

Precautions to Avoid Drug Toxicity Before initiating treatment, the physician should first ensure that the symptom requiring treatment is not itself due to another drug. For example, antipsychotic agents can cause symptoms that mimic depression (flat affect, restlessness, and pacing); such symptoms should prompt lowering of the dose rather than initiation of an antidepressant. In addition, drug therapy should be employed only after nonpharmacologic means have been considered or tried and only when the benefit clearly outweighs the risk.

Once pharmacotherapy has been decided upon, it should begin at less than the usual adult dosage and the dose should be increased slowly. However, given the marked variability in pharmacokinetics and pharmacodynamics in the elderly, dose escalation should continue until either a successful endpoint is reached or an intolerable side effect is encountered. The final dosage schedule should be kept as simple as possible, and the number of pills should be kept as low as possible. Serum drug levels are often useful in older patients, especially for monitoring drugs with narrow therapeutic indices such as phenytoin, theophylline, quinidine, aminoglycosides, lithium, and psychotropic agents such as nortriptyline. However, toxicity can occur even with “normal” therapeutic levels of some drugs (e.g., digoxin, phenytoin). Potential drug interactions should be searched for at every visit.

Over-the-Counter Counter Agents Nearly three-quarters of the elderly regularly use nonprescribed drugs, many of which cause significant symptoms and/or interact with other medications. Frequent offenders include nonprescribed agents for insomnia (most of which are anticholinergics), and nonsteroidal anti-inflammatory drugs (NSAIDs), which can hamper control of hypertension in addition to causing renal dysfunction and gastrointestinal bleeding. Gingko biloba, increasingly used as “nostrums” rather than drugs, the physician must ask about them directly.

Sedative-Hypnotics If nonpharmacologic treatment of insomnia is unsuccessful, low-dose and short-term or intermittent use of an intermediate-acting agent whose metabolism is not affected by age (e.g., oxazepam, 10 to 30 mg/d) may be useful. Because of the increased risk of confusion and other adverse effects, benzodiazepines with either short (e.g., triazolam) or long duration of action (e.g., flurazepam and diazepam) should be avoided. Barbbiturates should be avoided for the same reasons. A tricyclic antidepressant should not be prescribed for insomnia unless the patient is depressed.

Antibiotics Serum creatinine is not a good index of renal function in old people; however, when it is elevated, special care must be taken with the administration of drugs normally excreted by the kidneys. Concentrations of relevant antibiotics should be measured directly.

Cardiac Drugs In older patients, digitalis, procainamide, and quinidine have prolonged half-lives and narrow therapeutic windows; toxicity is common at the usual dosages. For example, digoxin toxicity—especially anorexia, confusion, or depression—can occur even with therapeutic digoxin levels.

H1 Receptor Antagonists Most of these agents interfere with hepatic metabolism of other drugs, and all can produce confusion in the elderly. Because they are renally excreted, lower doses should be used to minimize the risk of toxicity in older individuals.

Antipsychotics and Tricyclic Antidepressants These drugs can produce anticholinergic side effects in old people (e.g., confusion, urinary retention, constipation, dry mouth). These can be minimized by switching to a nonanticholinergic agent (e.g., sertraline or citalopram) or one with less anticholinergic effect (e.g., olanzapine, nortriptyline). In general, the least potent agents for psychosis (e.g., chlorpromazine) have the most sedating and anticholinergic effects and are the most likely to induce postural hypotension. By contrast, the most potent antipsychotic agents (e.g., haloperidol) have the least sedating, anticholinergic, and hypotensive side effects but cause extrapyramidal side effects, including dystonia, akathisia, rigidity, and tardive dyskinesia. The newer potent antipsychotics (e.g., risperidone, olanzapine, quetiapine, and clozapine) are relative exceptions to this rule. More specific for seroton inn than dopamine D2 receptors, these medications may be safer for older demented patients, especially those with hallucinations associated with Lewy body dementia or in those receiving therapy for Parkinson’s disease. Unfortunately, even these newer drugs lose their specificity at the higher doses that are commonly required in clinical practice. Thus all of these agents are potentially toxic. Moreover, since both depression and agitation often remit spontaneously, cautious discontinuation of these drugs should be considered periodically.

Glauc um Medications Both topical beta blockers and carbonic anhydrase inhibitors can cause systemic side effects. The latter can cause malaise and anorexia independent of the induced metabolic acidosis.

Anticoagulants Elderly patients benefit from anticoagulation as much as do younger individuals but are more vulnerable to serious bleeding and drug interactions. Hence, more careful monitoring and aiming for the lower boundary of the therapeutic window are advisable.

Analgesics Both propoxyphene and meperidine are associated with a disproportionate risk of delirium, and propoxyphene also increases the risk of hip fracture. Of the NSAIDs, indomethacin is most likely to induce confusion, fluid retention, and gastrointestinal bleeding. Each of these agents should be avoided in the elderly. Cyclooxygenase-2 (COX-2) inhibitors are safer than nonselective NSAIDs for older adults. However, they are more expensive and can cause fluid retention with consequent worsening of hypertension and nocturnal incontinence.

Avoidance of Over-treatment Drugs are frequently not indicated in some common clinical situations. For instance, antibiotics need not be given for asymptomatic bacteriuria unless obstructive uropathy, other anatomic abnormalities, or stones are also present. Ankle edema is often due to venous insufficiency, drugs such as NSAIDs or some calcium antagonists, or even inactivity or malnutrition in chairbound patients. Diuretics are usually not indicated unless edema is associated with heart failure. Fitted, pressure gradient stockings are often helpful. For claudication, regular exercise should be prescribed beforeicosartan. Finally, since older patients generally tolerate aspirin and other NSAIDs less well than do younger patients, localized pain should be
treated when possible with local measures such as injection, physical therapy, heat, ultrasound, or transcutaneous electrical stimulation (Chap. 11).

PREVENTION
Much can be done to prevent the progression and even the onset of disease in older persons. Even when the relative benefit of an intervention is less than in younger adults, its absolute impact is often greater in the elderly because their baseline risk is higher. However, while reductions of morbidity and morbidity are valuable goals for older adults, prevention must also encompass preservation of function and quality of life. Moreover, because preventive interventions are often associated with discomfort, risk, and expense, it is important to ensure that the patient believes the benefit is worth the effort.

Certain recommendations are straightforward. Dietary inadequacies should be corrected. Daily calcium intake should approximate 1500 mg, and most elderly people should take 400 to 800 IU of vitamin D daily (contained in one to two multivitamin tablets). Tobacco and alcohol use should be minimized, since the benefits of discontinuing these accrue even to individuals over age 65. Because of the prevalence, functional impact, and ease of treatment, glaucoma should be screened for, and visual and auditory impairment should be corrected. Dentures should be assessed for their fit, and oral lesions beneath them should be detected. Because thyroid dysfunction is more prevalent in the elderly, difficult to detect clinically, and treatable, serum levels of thyroid-stimulating hormone should be measured at least once in asymptomatic older people and probably every 3 to 5 years thereafter. All older women should be screened for osteoporosis. The importance of reviewing all of a patient’s medications and discontinuing them whenever feasible cannot be overemphasized.

Exercise should be encouraged not only because of its beneficial effects of blood pressure, cardiovascular conditioning, glucose homeostasis, bone density, insomnia, functional status, and even longevity, but also because it may improve mood and social interaction, reduce constipation, and prevent falls. Resistance training should be encouraged as much as a walking program. Sophisticated screening tests are generally not required. Spinal flexion exercises should be avoided in patients with osteopenia.

Immunizations for influenza, pneumococcal pneumonia, and tetanus should be current. Purified protein derivative (PPD) testing should be done on residents of chronic care facilities and on others at high risk of tuberculosis; those who have recently converted probably should be treated. Since responsiveness wanes with age, the test, if negative, should be repeated in a week.

Hypertension, whether isolated systolic hypertension or combined systolic and diastolic hypertension, should be treated as outlined in Chap. 230.

Serum cholesterol should be measured in patients with established coronary heart disease. Older adults with cardiovascular risk factors experience a similar benefit from statin therapy as younger adults (Chap. 225). Low-dose aspirin is likely useful for primary prevention among those at highest risk for coronary and cerebrovascular disease, but the relative risks and benefits must be considered on an individual basis.

Cancer screening is warranted. A Papanicolaou test should be done in women who have not had one before, since the incidence of cervical carcinoma and associated death increases with age; it should be repeated triennially in all older women unless two previous tests have been normal. Screening for colon cancer is warranted until a minimum age of 80 to 85, at least in community-dwelling elderly, although the optimal method is unclear. Because older women with breast cancer are more likely to die of it than with it, screening mammography is indicated every 1 to 2 years, at least until age 75, and thereafter if a positive finding would result in therapeutic intervention.

Perhaps the most valuable preventive measure in the elderly is to take a careful history, focusing not only on the “chief complaint” but also on common and often hidden conditions such as falls, confusion, depression, alcohol abuse, sexual dysfunction, and incontinence. In addition, one should always anticipate the complications for which the specific patient is at risk and take steps to avert them. For instance, a patient with cognitive impairment who smokes is at risk not only for lung cancer but also for starting a fire, and a patient who requires narcotics is at risk for fecal impaction, delirium, urinary retention, and confusion. Community-dwelling patients who are at highest risk of rapid deterioration and institutionalization and who should be monitored more closely include those over age 80, those who live alone, those who are bereaved or depressed, and those who are intellectually impaired.

9 Palliative and End-of-Life Care
Ezekiel J. Emanuel, Linda L. Emanuel

Epidemiology
In 2000, 2,403,351 people died in the United States (Table 9-1). Over 70% of all deaths occur in people >65 years of age. The epidemiology of mortality is similar in most developed countries; cardiovascular diseases and cancer are the predominant killers, a marked change since 1900, when heart disease caused ~8% of all deaths and cancer accounted for <4% of all deaths. In 2000, AIDS accounted for <1% of all deaths, although among those aged 35 to 44, it remains a leading cause of death.

While precise statistics are not available, it is estimated that in developed countries ~70% of all deaths are preceded by a disease or condition such that it is reasonable to plan for dying in the foreseeable future. Cancer has served as the paradigm for terminal care, but it is not the only type of illness with a recognizable and predictable terminal phase. Since congestive heart failure, chronic obstructive pul-
is a focus on four broad domains: (1) physical symptoms; (2) mental or psychological symptoms; (3) social needs that include interpersonal relationships, caregiving, and economic concerns; and (4) existential or spiritual needs.

A whole-person assessment screens for and evaluates needs in each of these four domains. Goals for care are established in discussion with the patient and/or family based on the assessment in each of these domains. Interventions are aimed at improving or managing symptoms and needs. While physicians are responsible for certain especially technical interventions, and for coordinating the interventions, they cannot be responsible for providing all of them. Since failing to address any one of the domains is likely to preclude a good death, a well coordinated, effectively communicating interdisciplinary team takes on special importance in end-of-life care.

HOSPICE AND THE PALLIATIVE CARE FRAMEWORK

Central to this type of care is an interdisciplinary team approach that typically encompasses pain and symptom management, spiritual and psychological care for the patient, and support for family caregivers.

Terminally ill patients have a wide variety of advanced diseases, often with multiple symptoms demanding relief, and require noninvasive therapeutic regimens to be delivered in a commodious care setting. Fundamental to ensuring quality palliative and end-of-life care is the ability to care for all four domains of distress.

Communication Foremost is to ensure empathetic and effective communication. When an illness is life-threatening, there are many
emotionally charged and potentially conflict-creating moments, collectively called “bad news” situations, in which good communication skills are essential. These moments include communicating to the patient and/or family about a terminal diagnosis, the patient’s prognosis, any treatment failures, deemphasizing efforts to cure and prolong life while focusing more on symptom management and palliation, and more private physical space to communicate with physicians, and decisions for patients in the intensive care unit (ICU) desired better well the physician was prepared to deliver bad news but also the setting interventions. In addition, families identify as important not only how well the physician was prepared to deliver bad news but also the setting in which it was delivered. For instance, 27% of families making critical decisions for patients in the intensive care unit (ICU) desired better and more private physical space to communicate with physicians, and 48% found having clergy present reassuring.

Just as surgeons plan and prepare for major operations or investigators rehearse a presentation of research results, physicians and health care providers caring for patients with advanced illness must develop a practiced approach to sharing important information and planning interventions. In addition, families identify as important not only how well the physician was prepared to deliver bad news but also the setting in which it was delivered. For instance, 27% of families making critical decisions for patients in the intensive care unit (ICU) desired better and more private physical space to communicate with physicians, and 48% found having clergy present reassuring.

An organized and effective procedure for communicating bad news with seven steps goes by the acronym P-SPIKES: (1) prepare for the discussion, (2) set up a suitable environment, (3) begin the discussion by finding out what the patient and/or family understand, (4) determine how they will comprehend new information best and how much they want to know, (5) provide needed new knowledge accordingly, (6) allow for emotional responses; and (7) share plans for the next steps in care. Table 9-2 provides a summary of these steps along with suggested phrases and underlying rationales for each.

### Continuous Goal Assessment

Major barriers to ensuring quality palliative and end-of-life care include difficulty in providing an accurate prognosis and emotional resistance of patients and their families to accepting the implications of a poor prognosis. A practical solution to these barriers is to integrate palliative care with curative care regardless of prognosis. With this approach, palliative care no longer conveys the message of failure, having no more treatments, or “giving up hope.” Fundamental to integrating palliative care with curative therapy is to include continuous goal assessment as part of the routine patient reassessment that occurs at most patient-physician encounters.

Goals for care are numerous, ranging from cure of a specific dis-

*Source: Adapted from Buckman.*
Patients also wish to discuss advance care planning with their family. Diversity barriers prevent this. While 80% of Americans endorse advance care planning and completing living wills, only 20% have actually done so. Most patients expect physicians to initiate advance care planning and will wait for physicians to broach the subject. Raising the topic can be done efficiently as a routine matter that is charged and allows them to tell their patients truthfully that they have done this themselves.

Steps in effective advance care planning center on (1) introducing the topic, (2) structuring a discussion, (3) reviewing plans that have been discussed by the patient and family, (4) documenting the plans, (5) updating them periodically, and (6) implementing the advance care directive (Table 9-3). The main barriers to advance care planning are problems in raising the topic and structuring a succinct discussion. Raising the topic can be done efficiently as a routine matter that is recommended for all patients, analogous to purchasing insurance or estate planning. It can be reassuring and effective if the physician has completed his or her own advance care directive.

Structuring a focused discussion is the central skill. Identify the health care proxy and recommend his or her involvement in the advance care planning process. Select a worksheet, preferably one that has been evaluated and demonstrated to produce reliable and valid expressions of patient preferences, and orient the patient and proxy to it. Such worksheets exist both for general and disease-specific situations. Discuss with the patient and proxy one scenario as an example to demonstrate how to think about the issues. It is often helpful to begin with a scenario in which the patient is likely to have settled preferences, such as being in a persistent vegetative state. Once the

**Useful Phrases or Points to Make**

- I’d like to talk with you about something I try to discuss with all my patients. It’s called advance care planning. In fact, I feel that this is such an important topic that I have done this myself. Are you familiar with advance care planning or living wills?
- Have you thought about the type of care you would want if you ever became too sick to speak for yourself? That is the purpose of advance care planning.
- There is no change in health that we have not discussed. I am bringing this up now because it is sensible for everyone, no matter how well or ill, old or young.
- Have many copies of advance care directives available, including in the waiting room, for patients and families.
- Use a structure worksheet with typical scenarios. Begin the discussion with persistent vegetative state and consider other scenarios, such as recovery from and acute event with serious disability, asking the patient about his or her preferences regarding specific interventions, such as ventilators, nasogastric feedings, and CPR proceeding to less-invasive interventions, such as blood transfusions and antibiotics.

*Note: CPR, cardiopulmonary resuscitation.*
patient’s preferences for interventions in this scenario are determined, suggest that the patient and proxy discuss and complete the worksheet for the others. If appropriate, suggest they involve family members in the discussion. On a return visit, go over the patient’s preferences, checking and resolving any inconsistencies. After having the patient and proxy sign the document, place it in the medical chart and be sure that copies are provided to relevant family members and care sites. Since patients’ preferences can change, these documents need to be reviewed periodically or after an illness episode or personal experience.

**TYPES OF DOCUMENTS**  
Advance care planning documents are of two broad types. The first includes living wills or instructional directives; these are advisory documents that describe the types of decisions that should direct care. Some are more specific, delineating different scenarios and interventions for the patient to choose from. Among these, some are for general use and others are designed for use by patients with a specific type of disease, such as cancer or HIV. Less specific directives can be general statements of not wanting life-sustaining interventions or forms that describe the values that should guide specific terminal care decisions. Health care proxy designation directives appoint an individual to make decisions. The choice is not either-or; a combined directive that both directs care and designates a proxy is often utilized, and the directive should clearly indicate whether the specified patient preferences or the proxy’s choice should take precedence if they conflict.

A potentially misleading distinction relates to statutory as opposed to advisory documents. Statutory documents are drafted to fulfill relevant state laws. They tend to be written with the goal of protecting the clinician from legal action if they follow the patient’s stated wishes. Advisory documents are drafted to reflect the patient’s wishes. Both are legal, the first under state law, and the latter under common or constitutional law.

**LEGAL ASPECTS**  
As of 2003, 47 states and the District of Columbia had enacted living will legislation. Many states have their own statutory forms. Massachusetts, Michigan, and New York do not have living will laws. However, like all other states except Alaska, these states have enacted durable power of attorney for health care laws that permit patients to designate a proxy decision maker with authority to terminate life-sustaining treatments. Only in Alaska does the law prohibit proxies from terminating life-sustaining treatments.

The U.S. Supreme Court has ruled that patients have a constitutional right to decide about accepting and terminating medical interventions, including life-sustaining interventions, and that mentally incompetent patients can exercise this right by providing “clear and convincing evidence” of their preferences. Since advance care directives permit patients to provide such evidence, commentators agree that they are constitutionally protected. Most commentators believe that a state is required to honor any clear advance care directive. Many states explicitly honor out-of-state directives. If a patient is not using a statutory form, then a statutory form should be attached to the advance care directive being used.

**INTERVENTIONS**  
**PHYSICAL SYMPTOMS AND THEIR MANAGEMENT**  
Great emphasis has been placed on addressing dying patients’ pain. Some institutions have made it a fifth vital sign. While good end-of-life care requires good pain management, it also requires more. The frequency of symptoms varies by disease and other factors. The most common physical and psychological symptoms among all terminally ill patients include pain, fatigue, insomnia, anorexia, dyspnea, depression, anxiety, and nausea and vomiting. In the last days of life, terminal delirium is also common. Assessments of patients with advanced cancer have shown that patients experienced an average of 11.5 different physical and psychological symptoms (Table 9-4). Evaluations to determine the etiology of these symptoms should be limited to the history and physical examination. Only in rare cases will radiologic or other diagnostic examinations provide sufficient benefit in directing optimal palliative care to warrant the risks, discomfort, and inconvenience to the seriously ill patient. Only a few of the common symptoms presenting difficult management issues will be addressed in this chapter.

**ETIOLOGY**  
Nociceptive pain is the result of direct mechanical or chemical stimulation of nociceptors and normal neural signaling to the brain. It tends to be localized, aching, throbbing, and cramping. The classic example is bone metastases. Visceral pain is caused by nociceptors in gastrointestinal, respiratory, and other organ systems. It is a deep or colicky type of pain classically associated with pancreatitis, myocardial infarction, or tumor invasion of viscer.a Neurotic pain arises from disordered, ectopic nerve signals. It is burning or shocklike pain. Classic cases are post-stroke pain and tumor invasion of the brachial plexus. Well-recognized pain syndromes are associated with peripheral neuropathy after chemotherapy or surgery.

**ASSESSMENT**  
Pain is a subjective experience. Depending upon the patient’s circumstances, perspective, and physiologic condition, the same insult can produce different levels of reported pain and need for pain relief. Systematic assessment includes eliciting the following: (1) periodicity—continuous, with or without exacerbations, or incident; (2) location; (3) intensity; (4) modifying factors; (5) effects of treatments; (6) functional impact; and (7) impact on patient. Several validated pain assessment measures may be used, such as the Visual Analogue Scale, the Brief Pain Inventory, and the pain component of the Memorial Symptom Assessment Scale. Frequent reassessments are essential to assess the effects of interventions.

**INTERVENTIONS**  
Interventions for pain must be tailored to each individual with the goal of preempting chronic pain and relieving breakthrough pain. At the end of life, there is no reason to doubt the patient’s report of pain. Pain medications are the cornerstone of management. If these are failing and nonpharmacologic interventions—including radiotherapy, anesthetic or neurosurgical procedures, such as peripheral nerve blocks or epidural morphine—are required, a pain consultation is appropriate.

Pharmacologic interventions follow the World Health Organization...
three-step approach involving nonopioid analgesics, mild opioids, and strong opioids, with or without adjuvants (Chap. 11). Nonopioid analgesics, especially nonsteroidal anti-inflammatory drugs, are the initial treatments for mild pain. They work primarily by inhibiting peripheral prostaglandins, reducing inflammation, but may also have central nervous system (CNS) effects. They have a ceiling effect. Weak opioids, such as codeine, should be used initially. However, if the weak opioids are escalated and also fail to relieve pain sufficiently, then strong opioids, such as morphine 5 to 10 mg every 4 h, should be used. Nonopioid analgesics should be combined with opioids because they potentiate the effect of opioids.

For continuous pain, the opioids should be administered on a regular, around-the-clock basis consistent with their duration of analgesia. They should not be provided only when the patient experiences pain; the goal is to prevent patients from experiencing pain. Patients should also be provided rescue medication, such as liquid morphine, for breakthrough pain and should be instructed to take one-half of the standing opioid dose. Patients should be informed that using the rescue medication does not obviate their taking the next standard dose of pain medication. If after 24 h the patient’s pain remains uncontrolled and recurs before the next dose, requiring the patient to utilize the rescue medication, increase the daily opioid dose by the total dose of rescue medications used by the patient, or by 50% for moderate pain and 100% for severe pain of the standing opioid daily dose.

It is inappropriate to start with extended-release preparations. Once pain relief is obtained, then switch to extended-release preparations. Even with a stable extended-release preparation regimen, the patient may have incident pain, such as pain during dressing changes. Short-acting preparations should be used to cover such predictable episodes.

Because of differences in opioid receptors, cross-tolerance among opioids is incomplete and patients may experience different side effects with different opioids. Therefore, if a patient is not experiencing pain relief or is experiencing too many side effects, change to another opioid preparation. When switching, begin with ≥50% of the published equianalgesic dose of the new opioid. (Starting at 25% of the equianalgesic dose is inadequate for terminally ill patients.) Opioids have no ceiling effect; therefore, there is no maximum dose no matter how many milligrams the patient is receiving. The appropriate dose is the dose needed to achieve pain relief. Addiction or excessive respiratory depression is extremely unlikely in the terminally ill; fear of these side effects should neither prevent escalating opioid medications when the patient is experiencing insufficient pain relief nor justify using opioid antagonists, such as naloxone.

Opioid side effects should be anticipated and treated preemptively. Nearly all patients experience constipation that can be quite debilitating (see below). Failure to prevent constipation often results in noncompliance with narcotic therapy. About a third of patients experience nausea and vomiting, but tolerance develops, usually within a week. Therefore, when beginning opioids, an antiemetic, such as metoclopramide or a serotonin antagonist, should be prescribed prophylactically and stopped after 1 week. Drowsiness, a common side effect of opioids, also abates within a week. During this period, drowsiness can be treated with psychostimulants, such as dextroamphetamine or methylphenidate. Anecdotal reports suggest that donepezil may also be helpful for opiate-induced drowsiness. Metabolites of morphine and most opioids are cleared renally; doses may need to be adjusted for renal failure.

Patients and families may withhold the prescribed opioids for fear of addiction or dependence. Physicians and health care providers must reassure patients and families that the patient will not become addicted or dependent upon the opioids if used as prescribed for pain relief; this fear should not prevent the patient from taking the medications around the clock.

Seriously ill patients with chronic pain relief rarely if ever become addicted. Suspicions of addiction should not be a reason to withhold pain medications from terminally ill patients. However, diversion of drugs for use by other family members or illicit sale may occur. If this occurs, it should be managed in a way that does not inflict unnecessary pain on the dying patient. Contract writing with the patient and family can help. If that fails, transfer to a safe facility may be necessary.

Tolerance is the need for increasing medication dosage for the same pain relief without a change in disease. In the case of patients with advanced disease, the need for increasing opioid dosage for pain relief is usually caused by disease progression rather than tolerance. Physical dependence is indicated by symptoms from the abrupt withdrawal of opioids and should not be confused with addiction.

Adjuvant analgesic medications are nonopioids that potentiate the analgesic effects of opioids. In the management of neuropathic pain, tricyclic antidepressants, such as desipramine, which has fewer side effects than other tricyclic antidepressants, can begin to work in a few days at doses of 10 to 25 mg before bedtime. Similarly, anticonvulsants, especially gabapentin (begun at 100 mg tid and titrated up by 100 mg tid until relief, with usual doses between 300 mg and 1200 mg tid) or carbamazepine, have shown effectiveness in relief of neuropathic pain. Glucocorticoids, preferably dexamethasone provided once a day, can be useful in reducing inflammation that causes pain while elevating mood, energy, and appetite. Other drugs, including clonidine and baclofen, can be effective in pain relief. These drugs are adjuvants and should all be used in conjunction with—not instead of—opioids. Methadone, carefully dosed, has activity at the N-methyl D-aspartate (NMDA) receptor and is useful for complex pain syndromes and neuropathic pain.

Radiation therapy can treat bone pain from single metastatic lesions. Bone pain from multiple metastases can be amenable to radiopharmaceuticals, such as strontium 89 and samarium 153. Pamidronate (90 mg every 4 weeks) and calcitonin (200 IU intranasally once or twice a day) can also provide relief from bone pain.

**Constipation**

**FREQUENCY** Constipation is reported in up to 90% of terminally ill patients.

**ETIOLOGY** While hypercalcemia and other factors can cause constipation, it is a predictable consequence of the use of opioids for the relief of pain and dyspnea and of tricyclic antidepressants, from their anticholinergic effects, as well as of the inactivity and poor diet that are common among seriously ill patients. If untreated, constipation can cause substantial pain, vomiting, impaction, and mental confusion. Whenever opioids, tricyclic antidepressants, and other medications known to cause constipation are used, preemptive cathartic treatment should be instituted.

**ASSESSMENT** Establish the patient’s previous bowel habits, including the frequency, consistency, and volume. Abdominal and rectal examinations should be performed to exclude impaction or acute abdomens. Radiographic assessments beyond a simple flat plate of the abdomen are rarely necessary except when obstruction cannot be definitively excluded.

**INTERVENTION** While physical activity, adequate hydration, and dietary treatments with fiber and roughage can be helpful, each is limited in its effectiveness for most seriously ill patients, and roughage may exacerbate problems if impaired motility is the etiology. Fiber is contraindicated in the presence of opioid use. Stimulant and osmotic laxatives, stool softeners, fluids, and enemas are the mainstay of therapy (Table 9-5). When preventing constipation from opioids and other medications, a combination of a laxative and stool softener should be utilized. If after several days of treatment a bowel movement has not occurred, a rectal examination to remove impacted stool and to place
a suppository is necessary. For patients with impending bowel obstruction or gastric stasis, octreotide to reduce secretions can be helpful.

**Dyspnea**  
**FREQUENCY** Dyspnea is a subjective experience of being short of breath. Nearly 75% of dying patients experience dyspnea. Dyspnea is among the most distressing of physical symptoms, even more distressing than pain.

**ASSESSMENT** As with pain, dyspnea is a subjective experience that may not correlate with objective measures of $P_O_2$, $P_CO_2$, or respiratory rate. Consequently, measurements, much less repeated measurements, of oxygen saturation through pulse oximetry or blood gases are rarely helpful. Reversible or treatable causes of dyspnea include infection, pleural effusions, pulmonary emboli, or lung tumor encroachment on the airway. However, the risk-benefit ratio of the diagnostic and therapeutic interventions for patients with little time left to live must be carefully considered before undertaking diagnostic steps. Frequently, secondary etiologies cannot be identified, and dyspnea is the consequence of progression of the underlying disease that cannot be treated. The anxiety caused by dyspnea and the choking sensation can significantly exacerbate the underlying dyspnea in a negative reinforcing cycle.

**INTERVENTIONS** When reversible or treatable etiologies are diagnosed, they should be treated as long as the side effects of treatment, such as repeated drainage of effusions or anticoagulants, are less bothersome than the dyspnea itself. Usually, treatment will be symptomatic (Table 9-6). Low-dose opioids reduce the sensitivity of the central respiratory center and the sensation of dyspnea. If patients are not receiving opioids, weak opioids can be initiated; if patients are already receiving opioids, then morphine should be used. Benzodiazepines are helpful if anxiety is present. If the patient has a history of COPD, bronchodilators may also be helpful, as may glucocorticoids. Secretions can be dried with scopolamine. Oxygen can be used, although it may only be an expensive placebo. Medical staff should sit the patient upright, remove smoke or other irritants such as perfume, ensure a supply of fresh air with sufficient humidity, and minimize other factors that can increase anxiety.

**Fatigue**  
**FREQUENCY** Fatigue and weakness are the most common experience of terminally ill patients. More than 90% of the terminally ill experience fatigue and/or weakness. Fatigue is frequently cited as among the most distressing of symptoms.

**ETIOLOGY** The multiple causes of fatigue in the terminally ill can be categorized as resulting from the underlying disease; from disease-induced factors, such as tumor necrosis factor and other cytokines; and from secondary factors such as cachexia, dehydration, anemia, infection, hypothyroidism, and drug side effects. Apart from low caloric intake, loss of muscle mass and changes in muscle enzymes may play an important role in fatigue of terminal illness. The importance of changes in the CNS, especially the reticular activating system, have been hypothesized based on reports of fatigue in patients receiving cranial radiation, experiencing depression, or with chronic pain in the absence of cachexia or other physiologic changes. Finally, depression and other causes of psychological distress can contribute to fatigue.

**ASSESSMENT** Fatigue is subjective; objective changes, even in body weight, may be absent. Consequently, assessment must rely on patient self-reporting. Scales used to measure fatigue, such as the Edmonton Functional Assessment Tool, the Fatigue Self-Report scales, or the Rhoten Fatigue scale, are usually appropriate for research rather than clinical purposes. In clinical practice, a simple performance assessment such as the Karnofsky Performance Status or the Eastern Cooperative Oncology Group’s question “How much of the day does the patient spend in bed?” is the best measure. In this 0 to 4 performance status assessment, a 0 = normal activity, 1 = symptomatic without being bedridden, 2 = requiring some, but <50%, bed time, 3 = bedbound more than half the day, and 4 = bedbound all the time. Such a scale allows for assessment over time and by third parties.

**INTERVENTION** At the end of life, fatigue will not be “cured.” The goal is the ameliorate it and adjust expectations. Behavioral interventions should be utilized to avoid blaming the patient for inactivity, and to educate both the family and patient that the underlying disease causes physiologic changes producing low energy levels. Understanding that the problem is physiologic not psychological can help to alter expectations regarding the patient’s level of physical activity. Practically, this may mean reducing routine activities, such as housework and cooking, or social events outside the house, and making it acceptable to receive guests lying on a couch. At the same time, institution of exercise regimens that are possible can raise endorphins, reduce muscle wasting, and reduce the risk of depression. In addition, ensuring good hydration without worsening edema may help reduce fatigue. Discontinuing medications that worsen fatigue, such as cardiac medications or even opioids, if pain is well controlled, may help.

</table>
Only a few pharmacologic interventions target fatigue and weakness. Glucocorticoids can increase energy and enhance mood. Dexamethasone is preferred for its once-a-day dosing and minimal mineralocorticoid activity. However, use for >1 month tends to diminish the positive effects. Psychostimulants, such as dextroamphetamine (5 to 10 mg orally) and methylphenidate (2.5 to 5 mg orally), can also enhance energy levels. Dosages should be given in the morning and at noon, otherwise they can cause counterproductive insomnia. Modafinil, developed for narcolepsy, has shown some promise in the treatment of fatigue. Its precise role in the fatigue at the end of life is yet to be determined.

**Mental Symptoms and Their Management**

**Depression**

Depression at the end of life presents an apparently paradoxical situation. Many people believe that depression is normal among seriously ill patients because they are dying. People frequently say “wouldn’t you be depressed?” Depression is not a necessary part of terminal illness and constitutes needless suffering. While sadness, anxiety, anger, and irritability are normal responses to a serious condition, they are typically of modest intensity and transient. Persistent sadness and anxiety are abnormal and suggestive of major depression. While as many as 75% of terminally ill patients experience depressive symptoms, <25% of terminally ill patients have major depression.

**Etiology**

Previous history of depression, family history of depression or manic-depression, and prior suicide attempts are associated with increased risk for depression among terminally ill patients. Other symptoms, such as pain and fatigue, are associated with higher rates of depression; uncontrolled pain can exacerbate depression, and depression can cause patients to be more distressed by pain. Many medications used in the terminal stages, including glucocorticoids, and some anticancer agents, such as tamoxifen, interleukin 2, interferon alfa, and vincristine, are also associated with depression. Some terminal conditions, such as pancreatic cancer and certain strokes, have been reported to be associated with higher rates of depression, although this is controversial. Finally, depression may be attributable to grief over the loss of a role or function, social isolation, or loneliness.

**Assessment**

Diagnosing depression among patients at the end of life is complicated because many of the vegetative symptoms contained in the DSM IV criteria—insomnia, anorexia and weight loss, fatigue, decreased libido, and difficulty concentrating—are associated with the dying process itself. The assessment of depression in seriously ill patients must focus on the dysphoric mood, helplessness, hopelessness, and lack of interest and enjoyment. The single questions “how often do you feel downhearted and blue?” (more than a good bit of the time or similar responses) or “do you feel depressed most of the time?” are appropriate for screening.

Certain conditions may be confused with depression. Endocrinopathies, such as hypothyroidism or Cushing’s syndrome, electrolyte abnormalities such as hypercalcemia, and akathisia, especially from dopamine blocking antiemetics such as metoclopramide and prochlorperazine, can mimic depression and should be excluded.

**Interventions**

Physicians must treat any physical symptom, such as pain, that may be causing or exacerbating depression. Nonpharmacologic interventions, including group or individual psychological counseling, and behavioral therapies, such as relaxation or imagery, can be helpful, especially in combination with drug therapy.

Pharmacologic interventions remain the core of therapy. The same medications are used to treat depression in terminally ill as in non-terminally ill patients. Psychostimulants may be preferred for patients with a poor prognosis or for those with fatigue or opioid-induced somnolence. Psychostimulants are comparatively fast acting, working within a few days. Dextroamphetamine or methylphenidate should be started at 2.5 to 5.0 mg in the morning and at noon, the same starting dosages used for treating fatigue. The dose can be escalated up to 15 mg twice a day; higher doses are only rarely necessary. Pemoline is a nonamphetamine psychostimulant with minimal abuse potential. It is also effective as an antidepressant beginning at 18.75 mg in the morning and at noon. Because it can be absorbed through the buccal mucosa, it is preferred for patients with intestinal obstruction or dysphagia. If used for prolonged periods, liver function must be monitored. The psychostimulants can also be combined with more traditional antidepressants, while waiting for the latter to become effective, and then tapered after a few weeks if necessary. Psychostimulants have side effects, particularly initial anxiety, insomnia, and rarely paranoia, which may necessitate lowering the dose or discontinuing treatment. A newer, promising agent is mirtazapine starting at 7.5 mg before bed. It is sedating and has antiemetic and anxiolytic properties with few drug interactions. Its side effect of weight gain may also be beneficial for seriously ill patients, and it is available in orally disintegrating tablets.

For patients with a prognosis of several months or longer, selective serotonin reuptake inhibitors, including fluoxetine, sertraline, and citalopram, and serotonin-noradrenaline reuptake inhibitors, such as venlafaxine, are the preferred treatment because of their efficacy and comparatively few side effects. Because low doses of these medications may be effective for seriously ill patients, use half the usual starting dose for healthy adults. The starting dose for fluoxetine is 10 mg once a day. In most cases, once-a-day dosing is possible.

Atypical antidepressants are recommended only in selected circumstances, usually with the assistance of a specialty consultation. Trazadone can be an effective antidepressant but is sedating and can cause orthostatic hypotension and priapism. Therefore, it should be used only when a sedating effect is desired. In addition to its antidepressant effects, bupropion is energizing, making it useful for depressed patients suffering from fatigue. However, it can cause seizures, preventing its use for patients with a risk of CNS neoplasms or terminal delirium. Finally, alprazolam, a benzodiazepine, starting at 0.25 to 1.0 mg three times a day, can be effective in seriously ill patients suffering from a combination of anxiety and depression. While it is potent and works quickly, it has many drug interactions and may cause delirium, especially among very ill patients, because of its strong binding to the benzodiazepine-GABA receptor complex.

Unless used as adjuvants for the treatment of pain, tricyclic antidepressants are not recommended. Similarly the monoamine oxidase inhibitors are not recommended because of their side effects and dangerous drug interactions.

**Delirium**

Delirium is a global cerebral dysfunction characterized by alterations in cognition and consciousness. It is frequently preceded by anxiety, changes in sleep patterns (especially reversal of day and night), and decreased attention. In contrast to dementia, delirium has an acute onset and is reversible, although reversibility may be more theoretical than real for patients near death. It is possible to have delirium in a patient with dementia.

Causes of delirium include metabolic encephalopathy arising from liver failure, hypoxemia, or sepsis; electrolyte imbalances such as hypercalcemia; nutritional deficiencies such as vitamin B12 deficiency; paraneoplastic syndromes; and primary brain tumors or brain metastases. Commonly, among dying patients, delirium can be caused by side effects of treatments, including radiation for brain metastases, and medications, including opioids, glucocorticoids, anticholinergic drugs, antihistamines, antiemetics, and many chemotherapeutic agents. In many terminally ill patients, the etiology will be multifactorial; e.g., dehydration may exacerbate opioid-induced delirium.

**Assessment**

Delirium should be recognized in any terminally ill patient with new onset of disorientation, impaired cognition, somnolence, fluctuating levels of consciousness, or delusions, with or without agitation. Delirium must be distinguished from acute anxiety and de-
INTERVENTIONS

One of the most important objectives of terminal care is to provide terminally ill patients the lucidity to say goodbye to the people they love. Delirium, especially with agitation during the final days, is distressing to family and caregivers. A strong determinant of bereavement difficulties is witnessing a difficult death. Thus, terminal delirium should be treated aggressively.

At the first sign of delirium, such as day-night reversal with slight changes in mentation, let the family know that it is time to be sure that everything they want to have said has been said. The family should be informed that delirium is common just before death.

If medications such as opioids are suspected of being a cause of the delirium, then unnecessary agents should be discontinued. Other reversible causes such as constipation, urinary retention, and metabolic abnormalities should be treated. Supportive measures aimed at providing a familiar environment should be instituted, including restricting visits only to individuals with whom the patient is familiar and eliminating new experiences; orienting the patient, if possible, by providing a clock and calendar; and gently correcting the patient’s hallucinations or cognitive mistakes.

Pharmacologic management focuses on the use of neuroleptics and, in the extreme, anesthetics (Table 9-7). Haloperidol remains first-line therapy. Usually, patients can be controlled with a low dose (1 to 3 mg/d), although some may require as much as 20 mg/d. It can be administered orally, subcutaneously, or intravenously. Intramuscular injections should not be used, except when it is the only way to get a patient under control. Chlorpromazine (10 to 25 mg every 4 to 6 h) can be useful if sedation is desired. Dystonic reactions resulting from dopamine blockade are a side effect of neuroleptics, although they are reported to be rare when used to treat terminal delirium. The new atypical neuroleptics—risperidone and olanzapine—have also been used successfully and are especially helpful for patients with longer anticipated life spans since they are less likely to cause dysphoria and have a lower risk of dystonic reactions. If patients develop dystonic reactions, benzotropine should be administered. Neuroleptics may be combined with lorazepam to reduce agitation when the delirium is the result of alcohol or sedative withdrawal.

If no response to first-line therapy is seen, a specialty consultation should be obtained with a change to a different medication. If patients fail to improve after a second neuroleptic, then sedation with an anesthetic such as propofol or continuous-infusion midazolam may be necessary. By some estimates, at the very end of life as many as 25% of patients experiencing delirium, especially restless delirium with myoclonus or convulsions, may require sedation.

Physical restraints should be used with great reluctance only when the patient’s violence is threatening to self or others. If used, their appropriateness should be reevaluated frequently.

SOCIAL NEEDS AND THEIR MANAGEMENT

Dying can impose substantial economic strains on patients and families, causing distress. In the United States, with one of the least comprehensive health insurance systems among the developed countries, about 20% of terminally ill patients and their families spend >10% of family income on health care costs over and above health insurance premiums. Between 10 and 30% of families sell assets, use savings, or take out a mortgage to pay for the patient’s health care costs. Nearly 40% of terminally ill patients in the United States report that the cost of their illness is a moderate or great economic hardship for their family.

The patient is likely to reduce and stop working. In 20% of cases, a family member of the terminally ill patient stops working to provide care. The major underlying causes of economic burden are related to poor physical functioning and care needs, such as the need for housekeeping, nursing, and personal care. More debilitated patients and poor patients experience greater economic burdens.

INTERVENTION

The economic burden should not be ignored as a private matter. It has been associated with a number of adverse health outcomes, including preferring comfort care over life-prolonging care as well as consideration of euthanasia or physician-assisted suicide. Economic burdens tend to increase the psychological distress of families and caregivers of terminally ill patients. Assistance from a social worker, early on if possible, to ensure access to all available benefits may be helpful. Many people and health care providers are unaware of options for long-term care insurance, respite care, the Family Medical Leave Act, and other sources of assistance.

Relationships

Settling personal issues and closing the narrative of lived relationships are universal needs. When asked if sudden death or death after an illness is preferable, respondents often initially select the former but soon change to the latter as they reflect on the importance of saying goodbye. Bereaved family members who have not had the chance to say goodbye often have a more difficult grief process.

INTERVENTION

Care of seriously ill patients requires efforts to facilitate the types of encounters and time spent with family and friends that are necessary to meet these needs. Family and close friends may need to be accommodated with unrestricted visiting hours, which perhaps may include sleeping near the patient even in otherwise regimented institutional settings. Physicians and health care providers may facilitate and resolve strained interactions between the patient and other family members. Assistance for patients and family members who are unsure about how to create or help preserve memories, whether by providing raw materials such as a scrap book or memory box or by offering them suggestions and informational resources, can be deeply appreciated. Taking photographs and creating videos can be especially helpful to terminally ill patients who have younger children or grandchildren.

Family Caregivers

Caring for seriously ill patients places a heavy burden on families. Families are frequently required to provide transportation and homemaking as well as other services. Typically, paid professionals such as home health nurses and hospice workers supplement family care; only about a quarter of all care giving is exclusively paid professional assistance. The trend toward more out-of-hospital deaths will increase reliance on families for end-of-life care.

Three-quarters of the caregivers of terminally ill patients are women—wives, daughters, and even sisters. Since many are widowed, women themselves tend to be able to rely less on family for care-
giving assistance and may need more paid assistance. About 20% of terminally ill patients report substantial unmet needs for nursing and personal care.

**INTERVENTION** It is imperative to inquire about unmet needs and to try to ensure those needs are met either through the family or paid professional services when possible. Community assistance through houses of worship or other community groups can often be mobilized by one or two phone calls from the medical team to someone the patient or family identifies.

**EXISTENTIAL NEEDS AND THEIR MANAGEMENT** Religion and spirituality are often important to dying patients. Nearly 70% of patients report becoming more religious or spiritual when they became terminally ill, and many find comfort in various religious or spiritual practices such as prayer. However, ~20% of terminally ill patients become less religious, frequently feeling somehow cheated or betrayed by becoming terminally ill. For other patients, the need is for existential meaning and purpose that is distinct from and maybe even antithetical to religion or spirituality.

**ASSESSMENT** Health care providers are often hesitant about involving themselves in the religious, spiritual, and existential experiences of their patients, because it may seem private, related to alternative lifestyles, or “soft.” But physicians and other members of the interdisciplinary team should be able to at least detect spiritual and existential needs. Screening questions have been developed for a physician’s spiritual history taking. Spiritual distress can amplify other types of suffering and even masquerade as intractable physical pain, anxiety, or depression, for instance. The screening questions in the whole-person assessment are usually sufficient. Deeper evaluation and intervention are rarely appropriate for the physician unless no other member of an interdisciplinary team is available or suitable. Pastoral care providers may be helpful, whether from the medical institution or the patient’s community.

**INTERVENTION** Precisely how religious practices, spirituality, and existential explorations can be facilitated and improve end-of-life care is not well established. In one study, only 36% of respondents indicated that a clergy member would be comforting. Nevertheless, this increase in religious and spiritual interest among a substantial fraction of dying patients suggests inquiring of individual patients how this need can be addressed.

**MANAGING THE LAST STAGES**

**WITHDRAWING AND WITHHOLDING LIFE-SUSTAINING TREATMENT**

**LEGAL ASPECTS** For centuries, it has been deemed ethical to withhold or withdraw life-sustaining interventions. The current legal consensus is that patients have a constitutional and common law right to refuse medical interventions (Table 9-8). Courts have held that incompetent patients have a right to refuse medical interventions. For patients who are incompetent and terminally ill and who have not completed an advance care directive, next of kin can exercise this right, although this may be restricted in some states depending how clear and convincing the evidence is of the patient’s preferences. Courts are limiting families’ ability to terminate life-sustaining treatments from patients who are conscious, incompetent, but not terminally ill. In theory, patients’ right to refuse medical therapy can be limited by four countervailing interests: (1) preservation of life, (2) prevention of suicide, (3) protection of third parties such as children, and (4) preserving the integrity of the medical profession. In practice, these interests almost never override the right of competent patients and incompetent patients who have left explicit and advance care directives.

Regarding incompetent patients who either appointed a proxy without specific indications of their wishes or who never completed an advance care directive, three criteria have been suggested to guide the decision to terminate medical interventions. Some commentators suggest that ordinary care should be administered but extraordinary care could be terminated. Because the ordinary/extraordinary distinction is too vague, courts and commentators widely agree that it should not be used to justify decisions about stopping treatment. Many courts have advocated use of the substituted-judgment criterion, which holds that the proxy decision-makers should try to imagine what the incompetent patient would do if he or she were competent. However, most proxies, even close family members, cannot accurately predict what the patient would have wanted. Therefore, substituted judgment becomes more of a guessing game than a way of fulfilling the patient’s wishes. Finally, the best-interests criterion holds that proxies should evaluate treatments by balancing their benefits and risks and select those treatments in which the benefits maximally outweigh the burdens of treatment. Yet, as many family conflicts reveal, different individuals can have very different views of what is in the patient’s best interests. Indeed, this criterion has been criticized because no objective way exists of determining the balance between benefits and burdens; it depends on a patient’s personal values. As a matter of practice, physicians rely on family members to make decisions that they feel are best and object only if these decisions seem to demand treatments that the physicians consider not beneficial.

**PRACTICES** Withholding and withdrawing acutely life-sustaining medical interventions from terminally ill patients are now standard practice. More than 90% of American patients die without cardiopulmonary resuscitation (CPR), and just as many forgo other potentially life-sustaining interventions. For instance, during 1987 to 1988 in ICUs, CPR was performed 49% of the time, but only 10% of the time in 1992 to 1993. On average, 3.8 interventions, such as vasopressors and transfusions, were stopped from each dying ICU patient.

Mechanical ventilation may be the most challenging intervention to withdraw. The two approaches are terminal extubation, which is the removal of the endotracheal tube, and terminal wean, which is the gradual reduction of the FIO₂ or ventilator rate. One-third of ICU physicians prefer to use the terminal wean technique, while 13% extubate; the majority of physicians utilize both techniques. Some recommend the terminal wean because patients do not develop upper airway obstruction and the distress caused by secretions or stridor; however, terminal weaning can prolong the dying process. To ensure comfort for conscious or semiconscious patients before withdrawal of the ventilator, neuromuscular blocking agents should be terminated and sedatives and analgesics administered. Removing the neuromuscular blocking agents permits patients to show discomfort, facilitating the titration of sedatives and analgesics; it also permits interactions between patients and their families. A common practice is to inject a bolus of midazolam (2 to 4 mg) before withdrawal followed by 5 to 10 mg of morphine and continuous infusion of morphine (50% of the bolus dose per hour) during weaning. Additional boluses of morphine or increases in the infusion rate should be administered for any distress. Higher doses will be needed for patients already receiving anxiolytics and opioids. Families need to be warned that up to 10% of patients unexpectedly survive for 1 day or more after mechanical ventilation is stopped.

**FUTILE CARE** Beginning in late 1980s, some commentators argued that physicians could terminate futile treatments demanded by families of terminally ill patients. No objective definition or standard of futility exists. Physiologic futility means that an intervention will have no physiologic effect. Some have defined qualitative futile treatments as those that “fail to end a patient’s total dependence on intensive medical care.” Quantitative futility occurs “when physicians conclude (either through personal experience, experiences shared with colleagues, or consideration of reported empiric data) that in the last 100 cases, a medical treatment has been useless.” The term conceals subjective value judgments about when a treatment is “not beneficial.” Deciding whether a treatment that obtains an additional 6 weeks of life or a 1% survival advantage confers benefit depends upon patients’ preferences and goals. Furthermore, physicians’ predictions of when treatments were futile deviated markedly from the quantitative definition. When residents thought CPR was quantitatively futile, more than one in five

</table>
of 15 had inadequate pain control compared to 15 of 43 patients in a control group experiencing inadequate pain relief. Depression, hopelessness, and, more vaguely, worries about loss of dignity or autonomy appear to be the primary factors motivating a desire for euthanasia or physician-assisted suicide.

Euthanasia and physician-assisted suicide are no guarantee of a painless, quick death. Data from the Netherlands indicate that in as many as 20% of cases technical and other problems arose, including patients waking from coma, not becoming comatose, regurgitating medications, and a prolonged time to death. Problems were significantly more common in physician-assisted suicide, sometimes requiring the physician to intervene and provide euthanasia.

After receiving a request for euthanasia and/or physician-assisted suicide, health care providers should carefully clarify the request with empathy, open-ended questions to help elucidate the underlying cause for the request such as: “What makes you want to consider this option?” Endorsing either moral opposition or moral support for the act tends to be counterproductive, either lending an impression of being judgmental or of endorsing the idea that the patient’s life is worthless. Health care providers must reassure the patient of continued care and commitment. The patient should be educated about alternative, less controversial options, such as symptom management and withdrawing any unwanted treatments; the reality of euthanasia and/or physician-assisted suicide, since the patient is likely to have misconceptions about its effectiveness; and also the legal implications of the choice. Depression, hopelessness, and other symptoms of psychological distress as well as physical suffering and economic burdens are likely factors motivating the request, and such factors should be assessed and treated aggressively. After these interventions and clarification of options, most patients proceed with a less controversial approach of declining life-sustaining interventions, possibly including refusal of nutrition and hydration.

### CARE DURING THE LAST HOURS

Most laypersons have limited experiences with the actual dying process and death. They frequently do not know what to expect of the final hours, and afterwards. Therefore, the family and other caregivers must be prepared, especially if the plan is for the patient to die at home.

Patients in the last days of life experience extreme weakness and fatigue and become bedbound; this can lead to bedsores. They stop eating and drinking with drying of mucosal membranes and dysphagia. Careful attention to oral swabbing, lubricants for lips, and use of artificial tears can provide a form of care to substitute for attempts at feeding the patient. With loss of the gag reflex and dysphagia, patients may also experience accumulation of oral secretions, producing noises during respiration sometimes called “the death rattle.” Scopolamine can reduce the secretions. Patients also experience changes in respiration with periods of apnea or Cheyne-Stokes breathing. Decreased intravascular volume and cardiac output causes tachycardia, hypotension, peripheral coolness, and livedo reticularis (skin mottling). Patients can also have urinary and, less frequently, fecal incontinence. Changes in consciousness and neurologic function generally lead to two different paths to death (Fig. 9-2).

Each of these terminal changes can cause patients and families distress, requiring reassurance and targeted interventions (Table 9-10). Informing families that these changes might occur, and even providing them an information sheet, can help to preempt problems and minimize distress. Understanding that patients stop eating because they are dying, not dying because they have stopped eating, can reduce family and caregiver anxiety. Similarly, informing the family and caregivers that the “death rattle” may occur and that it is not indicative of suffocation or choking can reduce their preoccupation with the breathing sounds.

Families and caregivers can also feel guilty about stopping treatments, fearing that they are “killing” the patient. This may lead to demands for interventions that may be ineffective. In such cases, the

<th>Potential Complication</th>
<th>Family’s Possible Reaction and Concern</th>
<th>Advice and Intervention</th>
</tr>
</thead>
<tbody>
<tr>
<td>Profound fatigue</td>
<td>Bedbound with development of pressure ulcers that are prone to infection, malodor, and pain, and joint pain</td>
<td>Patient is lazy and giving up.</td>
<td>Reassure family and caregivers that terminal fatigue will not respond to interventions and should not be resisted. Use an air mattress if necessary.</td>
</tr>
<tr>
<td>Anorexia</td>
<td>None</td>
<td>Patient is giving up; patient will suffer from hunger and will starve to death.</td>
<td>Reassure family and caregivers that the patient is not eating because he or she is dying; not eating at the end of life does not cause suffering or death. Forcibly feeding, whether oral, parenteral, or enteral, does not reduce symptoms or prolong life.</td>
</tr>
<tr>
<td>Dehydration</td>
<td>Dry mucosal membranes (see below)</td>
<td>Patient will suffer from thirst and die of dehydration.</td>
<td>Reassure family and caregivers that terminal dehydration does not cause suffering because patients lose consciousness before any symptom distress. Intravenous hydration can worsen symptoms of dyspnea by pulmonary edema and peripheral edema as well as prolong dying process.</td>
</tr>
<tr>
<td>Dysphagia</td>
<td>Inability to swallow oral medications needed for palliative care</td>
<td>Patient is choking and suffocating.</td>
<td>Do not force oral intake. Discontinue unnecessary medications that may have been continued including antibiotics, diuretics, anti-depressants, and laxatives. If swallowing pills is difficult, convert essential medications (analgesics, antiemetics, anxiolytics, and psychotropics) to oral solutions, buccal, sublingual, or rectal administration.</td>
</tr>
<tr>
<td>“Death rattle”—noisy breathing</td>
<td></td>
<td>Patient is suffocating.</td>
<td>Reassure the family and caregivers that this is caused by secretions in the oropharynx and the patient is not choking. Reduce secretions with scopolamine (0.2–0.4 mg SC q4h or 1–3 patches q3d). Reposition patient to permit drainage of secretions. Do not suction. Suction can cause patient and family discomfort, and is usually ineffective.</td>
</tr>
<tr>
<td>Apnea, Cheyne-Stokes respiration, dyspnea</td>
<td></td>
<td>Patient is suffocating.</td>
<td>Reassure family and caregivers that unconscious patients do not experience suffocation or air hunger. Apneic episodes are frequently a premorbid change. Opioids or anxiolytics may be used for dyspnea. Oxygen is unlikely to relieve dyspneic symptoms and may prolong the dying process.</td>
</tr>
<tr>
<td>Urinary or fecal incontinence</td>
<td>Skin breakdown if days until death Potential transmission of infectious agents to caregivers</td>
<td>Patient is dirty, malodorous, and physically repellent.</td>
<td>Remind family and caregivers to use universal precautions. Frequent changes of bedclothes and bedding. Use diapers, urinary catheter, or rectal tube if diarrhea or high urine flow occur.</td>
</tr>
<tr>
<td>Agitation or delirium</td>
<td>Day/night reversal Hurt self or caregivers</td>
<td>Patient is in horrible pain and going to have a horrible death.</td>
<td>Reassure family and caregivers that agitation and delirium do not necessarily connote physical pain. Depending upon the prognosis and goals of treatment, consider evaluating for causes of delirium and modify medications. Manage symptoms with haloperidol, chlorpromazine, diazepam, or midazolam.</td>
</tr>
<tr>
<td>Dry mucosal membranes</td>
<td>Cracked lips, mouth sores, and candidiasis can also cause pain Malodor</td>
<td>Patient may be malodorous, physically repellent.</td>
<td>Use baking soda mouthwash or saliva preparation q15–30min. Use topical nystatin for candidiasis. Coat lips and nasal mucosa with petroleum jelly q60–90min. Use ophthalmic lubricants q4h or artificial tears q30min.</td>
</tr>
</tbody>
</table>

physician should remind the family and caregivers about the inevitability of events, the palliative goals, and that interventions may prolong the dying process and cause discomfort. Physicians should also emphasize that withholding treatments is both legal and ethical, and that they are not the cause of the patient’s death. This reassurance may need to be provided multiple times.

Hearing and touch are said to be the last senses to stop functioning. Therefore, families and caregivers should be permitted to communicate with the dying patient. Encouraging them to talk directly to the patient, even if he or she is unconscious, and hold the patient’s hand or demonstrate affection in other ways can be an effective way to channel their urge “to do something” for the patient.

When the plan is for the patient to die at home, the physician must inform the family and caregivers how to determine that the patient has died. The cardinal signs are cessation of cardiac function and respiration; the pupils become fixed; the body becomes cool, ashen white, and waxy; muscles relax; and incontinence may occur. Remind the family and caregivers that the eyes may remain open even when the patient has died because the retroorbital fat pad may be depleted permitting the orbit to fall posteriorly, which makes it difficult for the eyelids to cover the eyeball.

The physician should establish a plan of who the family or caregivers will contact when the patient is dying and has died. Without a plan, they may panic and call 911, unleashing a cascade of unwanted events from arrival of emergency personal and resuscitation to hospital admission. The family and caregivers should be instructed to contact the hospice (if one is involved), the covering physician, or the on-call member of the palliative care team. They should also be told that the coroner need not be called, unless the state requires it for all deaths. Unless foul play is suspected, the health care team need not contact the coroner either.

Just after the patient dies, even the best-prepared family may experience shock and loss and be emotionally distraught. They need time to assimilate the event and be comforted. Health care providers should write a bereavement card or letter to the family. The purpose is to communicate about the patient, perhaps emphasizing the patient’s vir-
tues, the honor it was to care for the patient, and express concern for the family’s hardship. Many physicians attend the funerals of their patients. While this is beyond any medical obligation, the presence of the physician can be a source of support to the grieving family, and the funeral provides an opportunity for closure for the physician.

Death is a strong predictor of poor health, and even mortality, for the surviving spouse. It may be important to alert the spouse’s physician about the death to be aware of symptoms that might require professional attention.

**PALLIATIVE CARE SERVICES: HOW AND WHERE**

Determining the best approach to providing palliative care to patients will depend upon patient preferences, the availability of caregivers and specialized services in close proximity, institutional resources, and reimbursement. A hospice is a leading, but not the only, model of palliative care services. In the United States, Medicare pays for hospice services under Part A, the hospital insurance part of reimbursement. Two physicians must certify that the patient has a prognosis of ≤6 months, if the disease runs its usual course. Prognoses are probabilistic by their nature; patients are not required to die within 6 months but rather to have a condition from which half the individuals with it would be dead within 6 months. Patients sign a hospice enrollment form that states their intent to forgo curative services related to their terminal illness, but they can still receive medical services for other comorbid conditions. Patients can also un-enroll and re-enroll later; the hospice Medicare benefit can be revoked later to secure traditional Medicare benefits. Payments to the hospice are per diem, not fee-for-service. Payments are intended to cover physician services for the medical direction of the care team; regular home care visits by registered nurses and licensed practical nurses; home health aid and homemakers; dietary counseling; chaplain services; social work services; bereavement counseling; and medical equipment, supplies, and medications. Additional clinical care, including services of the primary physician, is covered by Medicare Part B even while the hospice Medicare benefit is in place.

By 1996, the mean length of enrollment in a hospice was 65 days, with the median being <24 days. Since then, it appears the length of enrollment is declining. Such short stays create barriers to establishing high-quality palliative services in patients’ homes and also place financial strains on hospice providers since the initial assessments and institution of care plans are resource intensive. Physicians should initiate early referrals to the hospice to allow more time for patients to receive palliative care.

Hospice care has been the main way of securing palliative services for terminally ill patients. However, efforts are now being made to ensure continuity of palliative care across settings and through time. Palliative care services are becoming available as consultative services in hospitals, in day care and other outpatient settings, and in nursing homes. In the United States, while the vast majority of hospice care is provided in residential homes, just over 10% now occurs in nursing homes. Palliative care consultations for non-hospice patients can be billed as for other consultations under Medicare Part B, the physician reimbursement part. Many believe palliative care should be offered to patients regardless of their prognosis. A patient and his or her family should not have to make a “curative vs. palliative care” decision because it is rarely psychologically possible to make such a decisive switch to embracing mortality.

**FUTURE DIRECTIONS**

**OUTCOME MEASURES** Care near the end of life cannot be measured by most of the available validated outcome measures since palliative care does not consider death a bad outcome. Similarly, the family and patients receiving end-of-life care may not desire the elements elicited in current quality-of-life measurements. Symptom control, enhanced family relationships, and quality of bereavement are difficult to measure and are rarely the primary focus of carefully developed or widely used outcome measures. Nevertheless, outcomes are as important in end-of-life care as in any other field of medical care. Specific end-of-life care instruments are being developed both for assessment, such as The Brief Hospice Inventory and NEST (needs near the end of life screening tool), and for outcome measures, such as the Palliative Care Outcomes Scale. The field of end-of-life care is ready to enter an era of evidence-based practice and continuous improvement through clinical trials.

**BACKGROUND Stephen E. Straus**

**COMPLEMENTARY AND ALTERNATIVE MEDICINE**

**DEFINITIONS** In every generation, medical practices exist that are not accepted by the mainstream: they are viewed with suspicion and dismissed as implausible or irrational. For a time, approaches that evoked some appeal, but which had not been thoroughly tested, were deemed unconventional. Over the past decade or so, they have been called complementary or alternative medicine (CAM), to reflect their use as adjuncts to, or as substitutes for, more generally accepted practices,
respectively. CAM does not encompass practices that have yet to be translated fully from the laboratory into the clinic, nor practices that were well studied and disproved, but which manage to persist in some fashion nonetheless. Rather, CAM entails approaches with surprising perservativeness, many of which can claim at least some evidentiary support. Until recently, CAM could also be defined as practices that are not widely taught in medical schools or reimbursed. However, medical students increasingly seek and receive some instruction about CAM, while third-party payers have identified in CAM a marketing tool to attract new, well-heeled clients. In the past few years, another term has been coined—integrated medicine—to suggest encouragingly that some CAM approaches, and the practitioners who deliver them, will be shown worthy of being added to the health care repertoire.

**SCOPE** The myriad practices and products that encompass CAM (Table 10-1) can be organized into five somewhat overlapping domains. Special diets, high doses of vitamins and minerals, and extracts of animal or botanical products are grouped together as biologically based CAM approaches. Massage, osteopathic and chiropractic manipulation, and cranial-sacral therapies are grouped as manipulative and body-based CAM approaches. Diverse forms of meditation, various uses of biofeedback, and hypnosis are considered mind-body approaches. All three of these CAM domains have well-accepted analogues in conventional medicine—low-fat, low-cholesterol diets; physical therapy; psychotherapy; to name but a few.

The fourth domain is known as energy medicine, to reflect its exploitation of veritable or putative energy fields. Today, magnets are increasingly popular health products. Over 2000 years ago, however, while Greek physicians believed that health requires a balance of vital humors, Asian practitioners postulated the flow and balance of vital energies and described tools to restore them. Acupuncture aims to correct energies that flow through special meridians, or channels. Reiki, a Japanese approach, and healing touch, a modern variant, purport to diagnose and correct one’s energy by passing the hands of an adept therapist over the patient.

The fifth domain, termed alternative systems of medicine, combines elements of the four other domains and aims to provide primary approaches to all health needs, rather than just adjunctive solutions to them. Western variants include practices developed by Native Americans, homeopathy, and naturopathic medicine. Eastern variants such as Ayurvedic medicine of India, traditional Chinese medicine, and Tibetan medicine are rich in their use of meditative exercises and herbal products.

**TABLE 10-1** Some Complementary and Alternative Medical Practices

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acupuncture</td>
<td>A Chinese medical practice that involves the insertion of hair-thin needles into nonanatomic energy channels, called meridians</td>
</tr>
<tr>
<td>Alexander technique</td>
<td>A movement therapy that emphasizes efficient use of muscles to relieve pain, decrease skeletal strain, and improve posture</td>
</tr>
<tr>
<td>Anthroposophic medicine</td>
<td>A spiritually based system of medicine that incorporates herbs, homeopathy, diet, and a movement therapy called eurythmy</td>
</tr>
<tr>
<td>Aromatherapy</td>
<td>The use of essential plant oils (distilled concentrates) in massage, baths, or inhalation</td>
</tr>
<tr>
<td>Ayurvedic medicine</td>
<td>The major East Indian traditional medicine system, utilizing pulse and tongue diagnosis; treatment includes diet, exercise, herbs, oil massages, and elimination regimens (utilizing enemetics, diarrhea, etc.)</td>
</tr>
<tr>
<td>Bach flower remedies</td>
<td>Dilute flower infusions used to treat emotional conditions</td>
</tr>
<tr>
<td>Biofeedback</td>
<td>The use of machinery that translates physiologic processes into audio or visual signals</td>
</tr>
<tr>
<td>Chiropractic</td>
<td>Adjustments of spinal vertebrae in an effort to affect neuromuscular function</td>
</tr>
<tr>
<td>Cranial-sacral therapy</td>
<td>Gentle manipulation of the cranium and spine</td>
</tr>
<tr>
<td>Curanderismo</td>
<td>A spiritual healing tradition common in Mexican-American communities that utilizes ritual cleansing, herbs and incantations</td>
</tr>
<tr>
<td>Dance therapy</td>
<td>Therapeutic method that uses movement to facilitate emotional expression and release</td>
</tr>
<tr>
<td>Feldenkrais bodywork</td>
<td>Highly structured movement sequences that emphasize proper head positioning</td>
</tr>
<tr>
<td>Guided imagery</td>
<td>The use of imagination to invoke specific images that are hoped to affect physiologic function</td>
</tr>
<tr>
<td>Hydrotherapy</td>
<td>Treatment utilizing water at various temperatures, sometimes aerated or under pressure, sometimes with added salts or other substances</td>
</tr>
<tr>
<td>Hypnosis</td>
<td>The induction of an altered of mind within which a subject becomes receptive to specific suggestions</td>
</tr>
<tr>
<td>Massage</td>
<td>The use of specific gliding and kneading strokes and friction to achieve muscle relaxation</td>
</tr>
<tr>
<td>Meditation</td>
<td>A process by which one tries to achieve awareness without thought</td>
</tr>
<tr>
<td>Music therapy</td>
<td>Singing, playing instruments, or listening to music</td>
</tr>
<tr>
<td>Naturopathy</td>
<td>A mixture of modalities that may include herbs, homeopathy, acupuncture, hydrotherapy, diet, and exercise</td>
</tr>
<tr>
<td>Native American medicine</td>
<td>Diverse systems, many of which incorporate prayer, chant, music, healing ceremonies, counseling, herbs, laying on of hands, and smudging (ritual cleansing with smoke from sacred plants)</td>
</tr>
<tr>
<td>Osteopathy</td>
<td>A medical field incorporating manipulative techniques for correcting abnormalities of the musculoskeletal system</td>
</tr>
<tr>
<td>Reflexology/zone therapy</td>
<td>Manual stimulation of points on the hands or feet, believed to affect distant organs</td>
</tr>
<tr>
<td>Rolfing/structural integration</td>
<td>A manual therapy that attempts to realign the body by deep tissue manipulation of fasciae</td>
</tr>
<tr>
<td>Shiatsu/acupuncture</td>
<td>Finger pressure at points along nonanatomic meridians</td>
</tr>
<tr>
<td>Siddha medicine</td>
<td>An East Indian medical system (prevalent among Tamil-speaking people) utilizing breathing techniques, incantations, herbs, and muppu (a tri-salt preparation)</td>
</tr>
<tr>
<td>T’ai chi ch’uan</td>
<td>Chinese dancelike exercises described as a “moving meditation”</td>
</tr>
<tr>
<td>Therapeutic touch</td>
<td>Secular version of the laying on hands, described as a “healing meditation” (a tri-salt preparation)</td>
</tr>
<tr>
<td>Tibetan medicine</td>
<td>A medical system that utilizes diagnosis by pulse and urine examination; therapies include herbs, diet, and massage</td>
</tr>
<tr>
<td>Traditional Chinese medicine</td>
<td>A medical system that utilizes examination of the tongue and pulses for diagnosis and acupuncture, herbal mixtures, massage, exercise, and diet</td>
</tr>
<tr>
<td>Trager bodywork</td>
<td>Light massage combined with gentle passive movements to help patients maximize freedom of movement</td>
</tr>
<tr>
<td>Unani medicine</td>
<td>An East Indian medial system, derived from Persian medicine, practiced primarily in the Muslim community</td>
</tr>
<tr>
<td>Yoga</td>
<td>An Indian practice that includes postures (asanas), breathing exercises (pranayama), and cleansing practices (kriyas)</td>
</tr>

</table>
provided in a “holistic” fashion, meaning that the broader medical, social, and emotional contexts of illness are considered in designing the treatment plan.

The very first large survey by Eisenberg in 1993 surprised the medical community by showing that >30% of Americans use CAM approaches. Countless studies since then have extended these conclusions by surveying specific demographic groups and patient populations. The Centers for Disease Control and Prevention (CDC) study of nearly 31,000 American adults revealed that in 1999 29% had used one or more modalities, with spiritual approaches, herbal medicine, chiropractic, and massage being the most prevalent. Over 1% underwent acupuncture treatment that year. Surveys among patients with cancer showed that 30 to 86% used CAM, with highest rates in those with more advanced disease and undergoing aggressive treatments. Similarly, among AIDS patients, 36 to 91% are reported to use CAM. In devastating chronic illnesses like these, CAM is called upon to provide hope of cures when conventional medicine cannot, to extend life, to ameliorate treatment side effects, and to provide emotional and physical comfort. While somewhat subject to vagaries of definition as to what counts as a CAM treatment, surveys have shown that Americans are willing to pay for these services out of pocket, with an estimated $7 billion each year on vitamins and mineral supplements, $4 billion on herbs and other natural products, and nearly $4 billion more on sports supplements. Eisenberg reported that total CAM expenditures in 1997 approached $30 billion, with more visits to practitioners for CAM services than to physicians in general.

**FIELDS OF PRACTICE**  ■ **Osteopathic Medicine**  Founded in 1892 in the American heartland by the physician Andrew Taylor Still, osteopathic medicine was based originally on the belief that manipulation of soft tissue and bone can correct a wide range of diseases of the musculoskeletal and other organ systems. Over the ensuing century, osteopathy evolved progressively towards conventional (allopathic) medicine. Today, the training, practice, credentialing, licensure, and reimbursement of osteopathic physicians is virtually indistinguishable from those of allopathic physicians, with 4 years of osteopathic medical school followed by specialty and subspecialty training and certification by organizations such as the American Board of Internal Medicine. Some osteopathic physicians continue to practice spinal manipulation, primarily as a tool to address specific musculoskeletal complaints.

**Chiropractic Medicine**  In 1895, Daniel David Palmer founded in Missouri the first school of chiropractic medicine to teach manipulation of the spine. Palmer believed that subluxations, or partial dislocations of vertebral columns, cause disease by impinging on key nerve roots. Today, chiropractors undertake 5 years of training in basic and relevant clinical sciences. Increasingly, they complete additional postgraduate training in radiology and outpatient therapeutics, primarily of musculoskeletal conditions, although within the discipline there are factions that continue to perform manipulation for many other pathologic entities. Chiropractors also advise on nutrition, exercise, and other health maintenance approaches. Over 70,000 doctors of chiropractic medicine are licensed to practice in all states and the District of Columbia.

**Acupuncture**  A venerable component of traditional Chinese medicine, acupuncture has emerged in recent decades as a free-standing clinical discipline. Over 3000 American physicians have acquired targeted postgraduate training that permits them to practice acupuncture in over 40 states and the District of Columbia. Over 4000 non-MDs have taken far more extended training, leading to licensure to practice independently or under the supervision of a physician.

**Massage Therapy**  Drawing upon millennia of empirical knowledge, some 80 American schools instruct students in an array of the soft tissue manipulative approaches that constitute massage. Thirty-one states and the District of Columbia license trainees to perform therapeutic massage.

**Naturopathic Medicine**  Eleven states license practitioners of naturopathy, a discipline that emerged in central Europe in the late eighteenth century. That conventional treatments of the day were usually ineffective, if not overtly harmful, stimulated the search for safer and more “natural” approaches—naturopathy is one of them. The concept underlying this discipline is that the body possesses powerful mechanisms for self-healing that a properly instructed practitioner could harness. About 1400 naturopathic physicians have completed 4 years of education in basic and clinical sciences and are licensed to manage a predominantly outpatient population. Conventional and unconventional diagnostic tests and medications are prescribed with an emphasis on relatively low doses of drugs, herbal medicines, special diets, and exercises.

**Homeopathic Medicine**  The late eighteenth century also witnessed the emergence of homeopathy, another discipline that reacted to toxicity of the allopathic approaches of the day. It was developed by Samuel Hahnemann, a German physician, who postulated that substances that cause particular side effects in a well person may be used to treat or prevent such symptoms in an ill person if administered in minuscule amounts—what is known as “the doctrine of similars.” For example, contact with poison ivy (*Rhus toxicodendron*) causes an itchy, blistering rash. Highly diluted extracts of poison ivy are recommended to treat chickenpox. The nascent field of homeopathy used blinded tests on volunteers, presaging to some extent the use of placebo-controlled trials, to prove which materials were the most able to induce or relieve symptoms. By the mid-nineteenth century homeopathy had gained considerable presence in the American medical establishment and may, in fact, have facilitated the development of immunization and allergen desensitization, both of which utilize very small quantities of materials to elicit measurable biologic outcomes. Today, however, homeopathy is accepted less fully in the United States than in some other countries: it is the largest of all CAM practices in the United Kingdom, Germany, and France and is widely used in India. Only three states license the practice of homeopathy. The relative decline of homeopathy relates, at least in part, to the field’s inability to articulate a rational mechanism as to why products that are diluted more than 10^60-fold, vastly greater than Avogadro’s number, could incite biologic effects. Nonetheless, homeopathic remedies are readily available and commonly recommended by naturopathic physicians and other licensed and unlicensed practitioners.

**Other Disciplines**  There are numerous other CAM practices, among which some involve formal training, such as that leading to a Doctorate of Oriental Medicine, or extended apprenticeships, as in learning herbal medicine. Unfortunately, most of the other fields have no agreed upon practice standards, credentialing processes, requirements for continuing education, or accountability.

**REGULATION**  As indicated above, some CAM disciplines are carefully regulated. CAM products, however, are not strongly regulated. Herbal medicines, and dietary supplements more generally, occupy a unique regulatory status that affords the public remarkable freedom of choice but also many undesired challenges, summarized below. Elements of virtually all traditional healing approaches, herbal medicines were presumed safe long before the implementation of stringent drug regulations by the U.S. Food and Drug Administration (FDA). In 1994, the United States Congress passed the Dietary Supplements Health and Education Act (DSHEA) that permits sale of dietary supplements “over-the-counter,” as it were, but without the requirement imposed on manufacturers of prescription or classic over-the-counter drugs to prove their products to be safe and effective before marketing. Supplements can be removed by the FDA from the market only if they are proven to be hazardous. Dietary supplements, however, cannot legally claim to prevent or treat any disease. They can, however, claim to maintain “normal structure and function” of body systems. For example, a product cannot claim to treat arthritis, but it can claim to maintain “normal joint health.”

Homeopathic products predate FDA drug regulations and are sold with no requirement that they be proven effective. It would be reason-
able to assume, however, given the extent to which homeopathic products are diluted, that most of them are safe.

**SAFETY** Despite their lack of apparent toxicities, homeopathic products, like all other CAM products and practices, do convey one type of risk, namely, that people will pursue them in lieu of more conventional modalities that are proven to be beneficial. Members of the public have considerable freedom to determine what is in their own best interest, even if those decisions deny them effective treatment, although the courts have found the rights of parents to withhold treatment of their children to be limited in instances of life-threatening illnesses. Investigators, however, have a broad ethical obligation to not withhold proven treatments for serious illnesses for the sake of testing unproven ones.

Additional risks are imposed by the use of other CAM approaches: injuries inflicted by a practice, inherent toxicities of the modality, and interference by the modality with more conventional treatments.

**Injury** Physical and manipulative interventions can harm patients. In past decades, reused acupuncture needles transmitted hepatitis B virus infection; today, the standard of care requires disposable needles. Aggressive massage can cause soft tissue injuries. Spinal manipulation of patients with unrecognized vertebral lesions has been associated with cord injuries, and cervical manipulation has been associated with stroke. These appear to be rare events.

**Inherent Toxicity** While the public may believe that “natural” equates with “safe,” it is abundantly clear that natural products can be toxic. Misidentification of medicinal mushrooms has led to liver failure. Contamination of tryptophan supplements caused the eosinophilia-myalgia syndrome. Herbal products containing particular species of *Aristolochia* were associated with genitourinary malignancies. In 2001, extracts of kava, long used by Pacific Islanders for its mild anxiolytic and sedative properties, were associated with fulminant liver failure. A number of products, including the popular *Ginkgo biloba*, are known to prolong bleeding times and have been associated with postoperative hemorrhage. Among the most controversial is *Ephedra sinica*, or ma huang, a product used in traditional Chinese medicine for short-term treatment of asthma and bronchial congestion. The scientific basis for these indications was revealed when ephedra was shown to contain the ephedrine alkaloids, especially ephedrine and pseudoephedrine. With the promulgation of the DSHEA regulations, supplements containing ephedra and herbs rich in caffeine flooded the U.S. marketplace, claiming to promote weight loss and to enhance athletic performance. Reports of severe and fatal adverse events in young and, in some cases, well-known Americans led to calls for removal of ephedra-containing supplements.

**Herbal-Drug Interactions** The constituents of natural products may not only be toxic but may also interfere with the metabolism of life-saving drugs. This effect was illustrated most profoundly with the demonstration in 2000 that consumption of St.-John’s-wort interferes with the bioavailability of the HIV protease inhibitor indinavir. Earlier studies had shown that St.-John’s-wort upregulated expression of the pregnane X receptor, a promiscuous nuclear regulatory factor that promotes the expression of many hepatic oxidative, conjugative, and efflux enzymes engaged in drug and food metabolism.

**Acquiring Evidence** CAM evolved through an entirely different epistemologic framework than contemporary biomedicine. Empirical observations of individual patients constitute the primary evidentiary base on which CAM practices are guided and taught. Nonetheless, over the past few decades, thousands of studies have been performed of various CAM approaches, including hundreds of trials involving herbs, acupuncture, or homeopathy. To date, however, no single approach has been proven effective in a convincing way. (If they had, the practice would no longer be considered CAM!) Several factors contribute to this lack of convincing evidence. The vast majority of CAM studies have been seriously flawed by lack of appropriate controls, bias on the part of the investigators, small sample sizes, reliance on highly subjective and nonvalidated measures of benefit, and by inappropriate statistical tests.

There are in addition, a series of methodologic issues that challenge even the better-designed CAM studies. No uniform practice guidelines exist, and the herbal products marketed in the United States are highly variable in quality and composition. Some CAM practices are not amenable to blinding. For example, both the patient and the practitioner would know if spinal manipulation had been performed. These problems are not unique to CAM, however, as they also complicate attempts to study conventional practices such as psychotherapy or surgery. Efforts are now being made to randomize patients to other equally demanding control interventions, and acupuncture at traditional needling points is being compared to needling at what are arguably irrelevant points.

Even with ongoing improvements in study design and conduct, issues of belief stand in the way of comprehending and accepting the results of some CAM studies. Many physicians are reluctant to believe positive outcomes of exotic approaches that have not emerged through the classic experimental paradigm by which drugs and biological agents are now developed, namely, the orderly progression from preclinical testing through three phases of clinical trials. More importantly, it is difficult to accept results that are counterintuitive or whose mechanism cannot be rationally explained. A powerful example of this dilemma involves studies of homeopathy. Some clinical trials of homeopathy for asthma, infantile diarrhea, and other common conditions reported positive results. Two systematic reviews of homeopathy trials gleaned an overall favorable impression of the clinical trials data, concluding that the treatments were more beneficial than placebo. Even the best trials and these reviews have been criticized on methodologic grounds. It remains unclear what evidence could compel a tidal change in belief about the benefits of homeopathy when there remain no cogent explanations for how substances diluted to the point at which only solute remains could exert physiologic effects.

By contrast, while methodologic problems continue to plague acupuncture trials, belief has been growing even in academic centers that acupuncture may be effective. The emerging acceptance of acupuncture may result, in part, from its widespread availability and use in the United States today: the CDC estimated that >1% of adult Americans received acupuncture treatments in 1999. Acupuncturists are now practicing within major medical centers, providing an ancillary approach to pain management. Yet, its acceptance may stem from more than just its communal appeal. Since the mid-1970s, studies have revealed palatable explanations for how substances diluted to the point at which only solute remains could exert physiologic effects.

**Existing Evidence** Numerous CAM approaches lack coherent explanations and any credible body of data regarding their safety and effectiveness. And, while it is difficult to conclude decisively that an approach lacks any merit, it is quite feasible to discern that its effect size, or degree of benefit, is too small to be worth pursuing further. Over the past century, many approaches failed—one need only think back to the exotic electrical devices, procedures, and tonics that fell out of fashion. Two questions are often asked: (1) Whether any of the more contemporary CAM modalities deserve to be rejected? (2) Whether data showing it to be ineffective would change anyone’s mind about using it? The case of laetrile is instructive in this regard. This extract of apricot kernel was in the 1970s a cure for solid tumors. Thousands crossed the Mexican border to be treated. The lack of any positive preclinical data discouraged oncologists from agreeing
to study laetrile, until public pressure required that an answer be obtained. Two studies in the 1980s showed no benefit of laetrile treatment. Today, some continue to seek the product, but the numbers are vastly smaller than before meaningful data were obtained. A similar fate befell a cocktail of drugs used for cancer patients through the 1970s and 1980s by Dr. Luigi DiBella in Italy, once large studies revealed it to have no detectable impact on the course of a variety of advanced cancers.

In contrast, modalities that have been well tested and found ineffective are still in fairly common practice. For example, the renowned biochemist and peace activist Linus Pauling proclaimed vitamin C to be the answer to the common cold. Numerous, high-quality studies failed to demonstrate clinically important effects of vitamin C in preventing or treating viral colds. The early studies were criticized for using too little of the vitamin, yet doses that well exceeded its bioavailability also proved negative. Nonetheless, ingestion of extra vitamin C remains a common habit in individuals who perceive the onset of cold symptoms. For most people, this practice is wasteful but not harmful; however, people with iron overload (either hemochromatosis or chronic transfusion requirement) can be damaged by vitamin C, which generates free radicals in the setting of iron excess.

Despite the failure of some CAM approaches, early studies have yielded positive or at least encouraging data for a number of them. Good sources of information include the Natural Medicines Comprehensive Database (www.NaturalDatabase.com) and National Institutes of Health (NIH) websites such as http://ods.od.nih.gov; http://nccam.nih.gov/health/ and http://www3.cancer.gov/occam/information.html.

**Vitamins/Minerals**

- **Vitamin A**: Massive studies in a number of developing nations proved that vitamin A deficiency is prevalent and associated with increased risks of mortality in young children. Prospective trials showed that 100,000 to 200,000 IU of vitamin A twice a year can reduce the overall death rate significantly.

- **Folic Acid**: Rates of neural tube defects are significantly diminished if the diet is supplemented with folic acid during pregnancy.

- **Folic acid, vitamin B₁₂, and vitamin B₁₉**: Randomized, double-blind, controlled trials suggest that this vitamin combination lowers serum homocysteine levels and the risk of myocardial infarction.

- **Vitamins C and E, β-carotene, and zinc**: A large, randomized controlled trial showed that these supplements combined reduce the progression of age-related macular degeneration.

Even vitamins and minerals, which are presumed safe in moderate doses, can have unexpected adverse effects. Two large controlled trials of β-carotene for prevention of cancer or retinal diseases found increased rates of lung cancer in those randomized to the supplement. Ongoing are large prospective trials seeking benefits from ingestion of supplements on rates of prostate cancer (vitamin E and selenium) and Alzheimer’s disease (vitamin E).

**Herbals and Other Natural Products**

- **Glucosamine and/or chondroitin sulfate**: Systematic surveys of controlled trials concluded that these products of animal joints are superior to placebo in improving performance and slowing the narrowing of the joint space in patients with osteoarthritis of the knee.

- **Ginkgo biloba**: Americans consumed nearly $250 million of this herbal product in 2000. The literature shows no evidence that it improves cognition, but it may decrease the risk of dementia.

- **Saw palmetto (Serenoa repens) and African plum (Pygeum africanum)**: Each of these botanicals is likely effective for the symptomatic treatment of benign prostatic hyperplasia. Sales of saw palmetto are growing, with an estimated $131 million of the product consumed by Americans in 2000.

- **St.-John’s-wort (Hypericum perforatum)**: Among the most popular herbal product worldwide, numerous small studies and systematic reviews suggested it to benefit patients with a wide range of depressive syndromes. High-quality, randomized, placebo-controlled trials, found St.-John’s-wort to not be superior to placebo for treatment of major depression of moderate severity, a spectrum of illness that clearly warrants professional evaluation and treatment.

- **Echinacea species**: Echinacea roots are widely used to treat or prevent respiratory infections, with over $200 million in sales in 2000. Although in vitro studies have shown that Echinacea constituents stimulate humoral and cellular immune responses, systematic reviews of the clinical trials have not concluded that they are beneficial.

**Other Modalities**

- **Acupuncture**: A frequently cited NIH-led consensus development conference in 1997 concluded that evidence exists that acupuncture relieves nausea from chemotherapy and pain following extraction of molars. Some subsequent studies have confirmed these earlier impressions regarding acute nausea and vomiting, but the data regarding pain management have been mixed, with little evidence that it benefits neuropathic pain.

- **Mind-body medicine**: Clinical trials support the use of biofeedback for incontinence, headache, and stroke rehabilitation. Hypnosis may be beneficial in relieving pain due to minor surgical interventions, chemotherapy-associated nausea, and irritable bowel syndrome.

- **Spinal manipulation**: Systematic reviews of fairly well designed trials concluded that chiropractic or osteopathic manipulation provides significant improvement for patients with uncomplicated acute back pain. No proof exists that they are superior to, or more cost-effective than, other conventional approaches, nor do they alter the long-term outcome.

**SUMMARY** An array of unproven modalities will always be used by the patients under our care. Physicians must approach each encounter as an opportunity to better understand patients, their beliefs, and their expectations and as an opportunity to help guide their choices in a constructive way. Many of these choices are entirely innocuous and can be accommodated in the context of the larger diagnostic and therapeutic intervention. Some should be actively discouraged. Along the way, scientific evidence will drive many CAM approaches out of favor. Some modalities will garner sufficient support to become part of mainstream care: the next generation of physicians will never know they were once controversial.

PART II CARDINAL MANIFESTATIONS AND PRESENTATION OF DISEASES

Section 1 Pain

Howard L. Fields, Joseph B. Martin

The task of medicine is to preserve and restore health and to relieve suffering. Understanding pain is essential to both these goals. Because pain is universally understood as a signal of disease, it is the most common symptom that brings a patient to a physician’s attention. The function of the pain sensory system is to protect the body and maintain homeostasis. It does this by detecting, localizing, and identifying tissue-damaging processes. Since different diseases produce characteristic patterns of tissue damage, the quality, time course, and location of a patient’s pain complaint and the location of tenderness provide important diagnostic clues and are used to evaluate the response to treatment. Once this information is obtained, it is the obligation of the physician to provide rapid and effective pain relief.

THE PAIN SENSORY SYSTEM

Pain is an unpleasant sensation localized to a part of the body. It is often described in terms of a penetrating or tissue-destructive process (e.g., stabbing, burning, twisting, tearing, squeezing) and/or of a bodily or emotional reaction (e.g., terrifying, nauseating, sickening). Furthermore, pain may moderate or higher intensity is accompanied by anxiety and the urge to escape or terminate the feeling. These properties illustrate the duality of pain: it is both sensation and emotion. When acute, pain is characteristically associated with behavioral arousal and a stress response consisting of increased blood pressure, heart rate, pupil diameter, and plasma cortisol levels. In addition, local muscle contraction (e.g., limb flexion, abdominal wall rigidity) is often present.

PERIPHERAL MECHANISMS The Primary Afferent Nociceptor

A peripheral nerve consists of the axons of three different types of neurons: primary sensory afferents, motor neurons, and sympathetic postganglionic neurons (Fig. 11-1). The cell bodies of primary afferents are located in the dorsal root ganglia in the vertebral foramina. The primary afferent axon bifurcates to send one process into the spinal cord and the other to innervate tissues. Primary afferents are classified by their diameter, degree of myelination, and conduction velocity. The largest-diameter fibers, A-beta (Aβ), respond maximally to light touch and/or moving stimuli; they are present primarily in nerves that innervate the skin. In normal individuals, the activity of these fibers does not produce pain. There are two other classes of primary afferents: the small-diameter myelinated A-delta (Aδ) and the unmyelinated (C fiber) axons (Fig. 11-1). These fibers are present in nerves to the skin and to deep somatic and visceral structures. Some tissues, such as the cornea, are innervated only by Aδ and C afferents. Most Aδ and C afferents respond maximally only to intense (painful) stimuli and produce the subjective experience of pain when they are electrically stimulated; this defines them as primary afferent nociceptors (pain receptors). The ability to detect painful stimuli is completely abolished when Aδ and C axons are blocked.

Individual primary afferent nociceptors can respond to several different types of noxious stimuli. For example, most nociceptors respond to heating, intense mechanical stimuli such as a pinch, and application of irritating chemicals.

Sensitization When intense, repeated, or prolonged stimuli are applied to damaged or inflamed tissues the threshold for activating primary afferent nociceptors is lowered and the frequency of firing is higher for all stimulus intensities. Inflammatory mediators such as bradykinin, some prostaglandins, and leukotrienes contribute to this process, which is called sensitization. In sensitized tissues normally innocuous stimuli can produce pain. Sensitization is a clinically important process that contributes to tenderness, soreness, and hyperalgesia. A striking example of sensitization is sunburned skin, in which severe pain can be produced by a gentle slap on the back or a warm shower.

Sensitization is of particular importance for pain and tenderness in deep tissues. Viscera are normally relatively insensitive to noxious mechanical and thermal stimuli, although hollow viscera do generate significant discomfort when distended. In contrast, when affected by a disease process with an inflammatory component, deep structures such as joints or hollow viscera characteristically become exquisitely sensitive to mechanical stimulation.

A large proportion of Aδ and C afferents innervating viscera are completely insensitive in normal uninjured, noninflamed tissue. That is, they cannot be activated by known mechanical or thermal stimuli and are not spontaneously active. However, in the presence of inflammatory mediators, these afferents become sensitive to mechanical stimuli. Such afferents have been termed silent nociceptors, and their characteristic properties may explain how under pathologic conditions the relatively insensitive deep structures can become the source of severe and debilitating pain and tenderness. Low pH, prostaglandins, leukotrienes, and other inflammatory mediators such as bradykinin play a significant role in sensitization.

Nociceptor-Induced Inflammation One important concept to emerge in recent years is that afferent nociceptors also have a neuroeffector func-

FIGURE 11-1 Components of a typical cutaneous nerve. There are two distinct functional categories of axons: primary afferents with cell bodies in the dorsal root ganglion, and sympathetic postganglionic fibers with cell bodies in the sympathetic ganglion. Primary afferents include those with large-diameter myelinated (Aβ), small-diameter myelinated (Aδ), and unmyelinated (C) axons. All sympathetic postganglionic fibers are unmyelinated.
tion. Most nociceptors contain polypeptide mediators that are released from their peripheral terminals when they are activated (Fig. 11-2). An example is substance P, an 11-amino-acid peptide. Substance P is released from primary afferent nociceptors and has multiple biologic activities. It is a potent vasodilator, degranulates mast cells, is a chemotactic for leukocytes, and increases the production and release of inflammatory mediators. Interestingly, depletion of substance P from joints reduces the severity of experimental arthritis. Primary afferent nociceptors are not simply passive messengers of threats to tissue injury but also play an active role in tissue protection through these neuroeffector functions.

**CENTRAL MECHANISMS** The Spinal Cord and Referred Pain

The axons of primary afferent nociceptors enter the spinal cord via the dorsal root. They terminate in the dorsal horn of the spinal gray matter (Fig. 11-3). The terminals of primary afferent axons contact spinal neurons that transmit the pain signal to brain sites involved in pain perception. The axon of each primary afferent contacts many spinal neurons, and each spinal neuron receives convergent inputs from many primary afferents.

The convergence of sensory inputs to a single spinal pain-transmission neuron is of great importance because it underlies the phenomenon of referred pain. All spinal neurons that receive input from the viscera and deep musculoskeletal structures also receive input from the skin. The convergence patterns are determined by the spinal segment of the dorsal root ganglion that supplies the afferent innervation of a structure. For example, the afferents that supply the central diaphragm are derived from the third and fourth cervical dorsal root ganglia. Primary afferents with cell bodies in these same ganglia supply the skin of the shoulder and lower neck. Thus sensory inputs from both the shoulder skin and the central diaphragm converge on pain-transmission neurons in the third and fourth cervical spinal segments.

Because of this convergence and the fact that the spinal neurons are most often activated by inputs from the skin, activity evoked in spinal neurons by input from deep structures is mislocalized by the patient to a place that is roughly coextensive with the region of skin innervated by the same spinal segment. Thus inflammation near the central diaphragm is usually reported as discomfort near the shoulder. This spatial displacement of pain sensation from the site of the injury that produces it is known as referred pain.

**Ascending Pathways for Pain**

A majority of spinal neurons contacted by primary afferent nociceptors send their axons to the contralateral thalamus. These axons form the contralateral spinothalamic tract, which lies in the anterolateral white matter of the spinal cord, the lateral edge of the medulla, and the lateral pons and midbrain. The spinothalamic pathway is crucial for pain sensation in humans. Interruption of this pathway produces permanent deficits in pain and temperature discrimination.

Spinothalamic tract axons ascend to several regions of the thalamus. There is tremendous divergence of the pain signal from these thalamic sites to broad areas of the cerebral cortex that subserve different aspects of the pain experience (Fig. 11-4). One of the thalamic projections is to the somatosensory cortex. This projection mediates the purely sensory aspects of pain, i.e., its location, intensity, and quality. Other thalamic neurons project to cortical regions that are linked to emotional responses, such as the cingulate gyrus and other areas of the frontal lobes. These pathways to the frontal cortex subserve the affective or unpleasant emotional dimension of pain. This affective dimension of pain produces suffering and exerts potent control of behavior. Because of this dimension, fear is a constant companion of pain.

**PAIN MODULATION**

The pain produced by similar injuries is remarkably variable in different situations and in different individuals. For example, athletes have been known to sustain serious fractures with only minor pain, and Beecher’s classic World War II survey revealed that many soldiers in battle were unbothered by injuries that would have produced agonizing pain in civilian patients. Furthermore, even the suggestion of relief can have a significant analgesic effect (placebo).

On the other hand, many patients find even minor injuries (such as venipuncture) frightening and unbearable, and the expectation of pain has been demonstrated to induce pain without a noxious stimulus.

The powerful effect of expectation and other psychological varia-
Neuropathic pains typically have an unusual burning, tingling, or electric shock—like quality and may be triggered by very light touch. These features are rare in other types of pain. On examination, a sensory deficit is characteristically present in the area of the patient’s pain. Hyperpathia is also characteristic of neuropathic pain; patients often complain that the very slightest moving stimuli evoke exquisite pain (allodynia). In this regard it is of clinical interest that a topical preparation of 5% lidocaine in patch form is effective for patients with postherpetic neuralgia who have prominent allodynia.

A variety of mechanisms contribute to neuropathic pain. As with sensitized primary afferent nociceptors, damaged primary afferents, including nociceptors, become highly sensitive to mechanical stimulation and begin to generate impulses in the absence of stimulation. There is evidence that this increased sensitivity and spontaneous activity is due to an increased concentration of sodium channels. Damaged primary afferents may also develop sensitivity to noxious stimuli. Interestingly, spinal cord pain-transmission neurons cut off from their normal input may also become spontaneously active. Thus both central and peripheral nervous system hyperactivity contribute to neuropathic pain.

**Sympathetically Maintained Pain**  Patients with peripheral nerve injury can develop a severe burning pain (causalgia) in the region innervated by the nerve. The pain typically begins after a delay of hours to days or even weeks. The pain is accompanied by swelling of the extremity, periarticular osteoporosis, and arthritic changes in the distal joints. The pain is dramatically and immediately relieved by blocking the sympathetic innervation of the affected extremity. Damaged primary afferent nociceptors acquire adrenergic sensitivity and can be activated by stimulation of the sympathetic outflow. A similar syndrome called reflex sympathetic dystrophy can be produced without obvious nerve damage by a variety of injuries, including fractures of bone, soft tissue trauma, myocardial infarction, and stroke (Chap. 354). Although the pathophysiology of this condition is poorly understood, the pain and the signs of inflammation are rapidly relieved by blocking the sympathetic nervous system. This implies that sympathetic activity can activate undamaged nociceptors when inflammation is present. Signs of sympathetic hyperactivity should be sought in patients with posttraumatic pain and inflammation and no other obvious explanation.

**ACUTE PAIN**  The ideal treatment for any pain is to remove the cause; thus diagnosis should always precede treatment planning. Sometimes treating the underlying condition does not immediately relieve pain. Furthermore, some conditions are so painful that rapid and effective analgesia is essential (e.g., the postoperative state, burns, trauma, cancer, sickle cell crisis). Analgesic medications are a first line of treatment in these cases, and all practitioners should be familiar with their use.

**Aspirin, Acetaminophen, and Nonsteroidal Anti-Inflammatory Agents (NSAIDS)**  These drugs are considered together because they are used for similar problems and may have a similar mechanism of action (Table 11-1). All these compounds inhibit cyclooxygenase (COX), and, except for acetaminophen, all have anti-inflammatory actions, especially at higher dosages. They are particularly effective for mild to moderate headache and for pain of musculoskeletal origin.

Since they are effective for these common types of pain and are available without prescription, COX inhibitors are by far the most commonly used analgesics. They are absorbed well from the gastrointestinal tract and, with occasional use, side effects are minimal. With chronic use, gastric irritation is a common side effect of aspirin and NSAIDs and is the problem that most frequently limits the dose that can be given. Gastric irritation is most severe with aspirin, which may cause erosion of the gastric mucosa, and because aspirin irreversibly acetylates platelets and thereby interferes with coagulation of the blood, gastrointestinal bleeding is a risk. The NSAIDs are less prob-

* Antidepressants, anticonvulsants, and antiarrhythmics have not been approved by the U.S. Food and Drug Administration (FDA) for the treatment of pain.
* Gabapentin in doses up to 1800 mg/d is FDA approved for postherpetic neuralgia.

**Note:** S-5 HT: serotonin; NE: norepinephrine.

Opioids are the most potent pain-relieving drugs currently available. Furthermore, of all analgesics, they have the broadest range of efficacy, providing the most reliable and effective method for rapid pain relief. Although side effects are common, they are usually not serious except for respiratory depression and can be reversed rapidly with the narcotic antagonist naloxone. The physician should not hesitate to use opioid analgesics in patients with acute severe pain. Table 11-1 lists the most commonly used opioid analgesics.

Opioids produce analgesia by actions in the central nervous system. They activate pain-inhibitory neurons and directly inhibit pain-transmission neurons. Most of the commercially available opioid analgesics act at the same opioid receptor (mu receptor), differing mainly in potency, speed of onset, duration of action, and optimal route of administration. Although the dose-related side effects (sedation, respiratory depression, pruritus, constipation) are similar among the different opioids, some side effects are due to accumulation of nonopioid metabolites that are unique to individual drugs. One striking example of this is normeperidine, a metabolite of meperidine. Normeperidine produces hyperexcitability and seizures that are not reversible with naloxone. Normeperidine accumulation is increased in patients with renal failure.

The most rapid relief with opioids is obtained by intravenous administration; relief with oral administration is significantly slower. Common acute side effects include nausea, vomiting, and sedation. The most serious side effect is respiratory depression. Patients with any form of respiratory compromise must be kept under close observation following opioid administration; an oxygen saturation monitor may be useful. The opioid antagonist, naloxone, should be readily available for rescue.

Pressing, and COX-2 is induced in the inflammatory state. COX-2-selective drugs have moderate analgesic potency and produce less gastric irritation than the nonselective COX inhibitors. It is not yet clear whether the use of COX-2-selective drugs is associated with a lower risk of nephrotoxicity compared to nonselective NSAIDs. On the other hand, COX-2-selective drugs offer a significant benefit in the management of acute postoperative pain because they do not affect blood coagulation. This is a situation in which the nonselective COX inhibitors would be contraindicated because they impair platelet-mediated blood clotting and are thus associated with increased bleeding at the operative site. A corollary of this is that COX-2 drugs do not provide the same degree of protection from thromboembolic cardiovascular adverse events such as myocardial infarction. In fact, in patients treated for arthritis, those treated with naproxen had significantly fewer adverse thromboembolic events than those treated with rofecoxib, a selective COX-2 inhibitor.
available. Opioid effects are dose-related, and there is great variability among patients in the doses that relieve pain and produce side effects. Because of this, initiation of therapy requires titration to optimal dose and interval. The most important principle is to provide adequate pain relief. This requires determining whether the drug has adequately relieved the pain and the duration of the relief. The most common error made by physicians in managing severe pain with opioids is to prescribe an inadequate dose. Since many patients are reluctant to complain, this practice leads to needless suffering. In the absence of sedation at the expected time of peak effect, a physician should not hesitate to repeat the initial dose to achieve satisfactory pain relief.

An innovative approach to the problem of achieving adequate pain relief is the use of patient-controlled analgesia (PCA). PCA requires a device that delivers a baseline continuous dose of an opioid drug, and programmed additional doses whenever the patient presses a button. The device can be programmed to limit the total hourly dose so that overdosing is impossible. The patient can then titrate the dose to the optimal level. This approach is used most extensively for the management of postoperative pain, but there is no reason why it should not be used for any hospitalized patient with persistent severe pain. PCA is also used for short-term home care of patients with intractable pain, such as is caused by metastatic cancer.

Many physicians, nurses, and patients have a certain trepidation about using opioids that is based on an exaggerated fear of addiction. In fact, there is a vanishingly small chance of patients becoming addicted to narcotics as a result of their appropriate medical use.

The availability of new routes of administration has extended the usefulness of opioid analgesics. Most important is the availability of spinal administration. Opioids can be infused through a spinal catheter placed either intrathecally or epidurally. By applying opioids directly to the spinal cord, regional analgesia can be obtained using a relatively low total dose. In this way, side effects as sedation, nausea, and respiratory depression can be minimized. This approach has been used extensively in obstetric procedures and for lower-body postoperative pain. Opioids can also be given intranasally (butorphanol), rectally, and transdermally (fentanyl), thus avoiding the discomfort of frequent injections in patients who cannot be given oral medication. The fentanyl transdermal patch has the advantage of providing fairly steady plasma levels, which maximizes patient comfort.

**OPIOID AND CYCLOOXYGENASE INHIBITOR COMBINATIONS** When used in combination, opioids and COX inhibitors have additive effects. Because a lower dose of each can be used to achieve the same degree of pain relief and their side effects are nonadditive, some combinations can be used to lower the severity of dose-related side effects. Fixed-ratio combinations of an opioid with acetaminophen carry a special risk. Dose escalation as a result of increased severity of pain or decreased opioid effect as a result of tolerance may lead to levels of acetaminophen that are toxic to the liver.

**CHRONIC PAIN**

Managing patients with chronic pain is intellectually and emotionally challenging. The patient’s problem is often difficult to diagnose; such patients are demanding of the physician’s time and often appear emotionally distraught. The traditional medical approach of seeking an obscure organic pathology is usually unhelpful. On the other hand, psychological evaluation and behaviorially based treatment paradigms are frequently helpful, particularly in the setting of a multidisciplinary pain-management center.

There are several factors that can cause, perpetuate, or exacerbate chronic pain. First, of course, the patient may simply have a disease that is characteristically painful for which there is presently no cure. Arthritis, cancer, migraine headaches, fibromyalgia, and diabetic neuropathy are examples of this. Second, there may be secondary perpetuating factors that are initiated by disease and persist after that disease has resolved. Examples include damaged sensory nerves, sympathetic efferent activity, and painful reflex muscle contraction. Finally, a variety of psychological conditions can exacerbate or even cause pain.

There are certain areas to which special attention should be paid in the medical history. Because depression is the most common emotional disturbance in patients with chronic pain, patients should be questioned about their mood, appetite, sleep patterns, and daily activity. A simple standardized questionnaire, such as the Beck Depression Inventory, can be a useful screening device. It is important to remember that major depression is a common, treatable, and potentially fatal illness.

Other clues that a significant emotional disturbance is contributing to a patient’s chronic pain complaint include: pain that occurs in multiple unrelated sites; a pattern of recurrent, but separate, pain problems beginning in childhood or adolescence; pain beginning at a time of emotional trauma, such as the loss of a parent or spouse; a history of physical or sexual abuse; and past or present substance abuse.

On examination, special attention should be paid to whether the patient guards the painful area and whether certain movements or postures are avoided because of pain. Discovering a mechanical component to the pain can be useful both diagnostically and therapeutically. Painful areas should be examined for deep tenderness, noting whether this is localized to muscle, ligamentous structures, or joints. Chronic myofascial pain is very common, and in these patients deep palpation may reveal highly localized trigger points that are firm bands or knots in muscle. Relief of the pain following injection of local anesthetic into these trigger points supports the diagnosis. A neuropathic component to the pain is indicated by evidence of nerve damage, such as sensory impairment, exquisitely sensitive skin, weakness and muscle atrophy, or loss of deep tendon reflexes. Evidence suggesting sympathetic nervous system involvement includes the presence of diffuse swelling, changes in skin color and temperature, and hypersensitive skin and joint tenderness compared with the normal side. Relief of the pain with a sympathetic block is diagnostic.

A guiding principle in evaluating patients with chronic pain is to assess both emotional and organic factors before initiating therapy. Addressing these issues together, rather than waiting to address emotional issues after organic causes of pain have been ruled out, improves compliance in part because it assures patients that a psychological evaluation does not mean that the physician is questioning the validity of their complaint. Even when an organic cause for a patient’s pain can be found, it is still wise to look for other factors. For example, a cancer patient with painful bony metastases may have additional pain due to nerve damage and may also be depressed. Optimal therapy requires that each of these factors be looked for and treated.

**TREATMENT**

Once the evaluation process has been completed and the likely causative and exacerbating factors identified, an explicit treatment plan should be developed. An important part of this process is to identify specific and realistic functional goals for therapy, such as getting a good night’s sleep, being able to go shopping, or returning to work. A multidisciplinary approach that utilizes medications, counseling, physical therapy, nerve blocks, and even surgery may be required to improve the patient’s quality of life. There are also some newer, relatively invasive procedures that can be helpful for some patients with intractable pain. These procedures include implanting intraspinal canulae to deliver morphine or intraspinal electrodes for spinal stimulation. There are no set criteria for predicting which patients will respond to these procedures. They are generally reserved for patients who have not responded to conventional pharmacologic approaches. Referral to a multidisciplinary pain clinic for a full evaluation should precede any of these procedures. Such referrals are clearly not necessary for all chronic pain patients. For some, pharmacologic management alone can often provide adequate relief.

**ANTIDEPRESSANT MEDICATIONS** The tricyclic antidepressants (TCAs; Table 11-1) are extremely useful for the management of patients with chronic pain. Although developed for the treatment of depression, the
tricyclics have a spectrum of dose-related biologic activities that include the production of analgesia in a variety of clinical conditions. Although the mechanism is unknown, the analgesic effect of TCAs has a more rapid onset and occurs at a lower dose than is typically required for the treatment of depression. Furthermore, patients with chronic pain who are not depressed obtain pain relief with antidepressants. There is evidence that tricyclic drugs potentiate opioid analgesia, so they are useful adjuncts for the treatment of severe persistent pain such as occurs with malignant tumors. Table 11-2 lists some of the painful conditions that respond to tricyclics. TCAs are of particular value in the management of neuropathic pain such as occurs in diabetic neuropathy and postherpetic neuralgia, for which there are few other therapeutic options.

The TCAs that have been shown to relieve pain have significant side effects (Table 11-1; Chap. 371). Some of these side effects, such as orthostatic hypotension, cardiac conduction delay, memory impairment, constipation, and urinary retention, are particularly problematic in elderly patients, and several are additive to the side effects of opioid analgesics. The serotonin-selective reuptake inhibitors such as fluoxetine (Prozac) have fewer and less serious side effects than TCAs, but they are much less effective for relieving pain. It is of interest that venlafaxine (Effexor), a nontricyclic antidepressant that blocks both serotonin and norepinephrine reuptake, appears to retain most of the pain-relieving effect of TCAs with a side-effect profile more like that of the serotonin-selective reuptake inhibitors. The drug may be particularly useful in patients who cannot tolerate the side effects of tricyclics.

**ANTICONVULSANTS AND ANTIARRHYTHMICS** (Table 11-1) These drugs are useful primarily for patients with neuropathic pain. Phenytoin (Dilantin) and carbamazepine (Tegretol) were first shown to relieve the pain of trigeminal neuralgia. This pain has a characteristic brief, shooting, electric shock–like quality. In fact, anticonvulsants seem to be helpful largely for pains that have such a lancing quality. A new-generation anticonvulsant, gabapentin (Neurontin), is effective for a broad range of neuropathic pains. Antiarrhythmic drugs such as low-dose lidocaine and mexiletine (Mexitil) can also be effective for neuropathic pain. These drugs block the spontaneous activity of damaged primary afferent nociceptors.

**CHRONIC OPIOID MEDICATION** The long-term use of opioids is accepted for patients with pain due to malignant disease. Although opioid use for chronic pain of nonmalignant origin is controversial, it is clear that for many such patients opioid analgesics are the best available option. This is understandable since opioids are the most potent and have the broadest range of efficacy of any analgesic medications. Although addiction is rare in patients who first use opioids for pain relief, some degree of tolerance and physical dependence are likely with long-term use. Therefore, before embarking on opioid therapy, other options should be explored, and the limitations and risks of opioids should be explained to the patient. It is also important to point out that some opioid analgesic medications have mixed agonist-antagonist properties (e.g., pentazocine and butorphanol). From a practical standpoint, this means that they may worsen pain by inducing an abstinence syndrome in patients who are physically dependent on other opioid analgesics.

With long-term outpatient use of orally administered opioids, it is desirable to use long-acting compounds such as levorphanol, methadone, or sustained-release morphine (Table 11-1). Transdermal fentanyl is another excellent option. The pharmacokinetic profile of these drug preparations enables prolonged pain relief, minimizes side effects such as sedation that are associated with high peak plasma levels, and reduces the likelihood of rebound pain associated with a rapid fall in plasma opioid concentration. Constipation is a virtually universal side effect of opioid use and should be treated expectantly.

It is worth emphasizing that many patients, especially those with chronic pain, seek medical attention primarily because they are suffering and because only physicians can provide the medications required for their relief. A primary responsibility of all physicians is to minimize the physical and emotional discomfort of their patients. Familiarity with pain mechanisms and analgesic medications is an important step toward accomplishing this aim.

<sup>a</sup> In order of frequency.

to meet metabolic needs. This mismatch can result from a decrease in oxygen supply, a rise in demand, or both. The most common underlying cause of myocardial ischemia is obstruction of coronary arteries by atherosclerosis; in the presence of such obstruction, transient ischemic episodes are usually precipitated by an increase in oxygen demand as a result of physical exertion. However, ischemia can also result from psychological stress, fever, or large meals or from compromised oxygen delivery due to anemia, hypoxia, or hypotension. Ventricular hypertrophy due to valvular heart disease, hypertrophic cardiomyopathy, or hypertension can predispose the myocardium to ischemia because of impaired penetration of blood flow from epicardial coronary arteries to the endocardium.

**Angina Pectoris** The chest discomfort of myocardial ischemia is a visceral discomfort that is usually described as a heaviness, pressure, or squeezing (Table 12-2). Other common adjectives for anginal pain are burning and aching. Some patients deny any “pain” but may admit to dyspnea or a vague sense of anxiety. The word “sharp” is sometimes used by patients to describe intensity rather than quality.

The location of angina pectoris is usually retrosternal; most patients do not localize the pain to any small area. The discomfort may radiate to the neck, jaw, teeth, arms, or shoulders, reflecting the common origin in the posterior horn of the spinal cord of sensory neurons supplying the heart and these areas. Some patients present with aching in sites of radiated pain as their only symptoms of ischemia. Occasional patients report epigastric distress with ischemic episodes. Less common is radiation to below the umbilicus or to the back.

Stable angina pectoris usually develops gradually with exertion, emotional excitement, or after heavy meals. Rest or treatment with sublingual nitroglycerin typically leads to relief within several minutes. In contrast, pain that is fleeting (lasting only a few seconds) is rarely ischemic in origin. Similarly, pain that lasts for several hours is unlikely to represent angina, particularly if the patient’s electrocardiogram does not show evidence of ischemia.

Anginal episodes can be precipitated by any physiologic or psychological stress that induces tachycardia. Most myocardial perfusion occurs during diastole, when there is minimal pressure opposing coronary artery flow from within the left ventricle. Since tachycardia decreases the percentage of the time in which the heart is in diastole, it decreases myocardial perfusion.

TABLE 12-2  Typical Clinical Features of Major Causes of Acute Chest Discomfort

- **Angina**
- **Unstable angina**
- **Acute myocardial infarction**
- **Aortic stenosis**
- **Pericarditis**
- **Aortic dissection**
- **Pulmonary embolism**
- **Pulmonary hypertension**
- **Pneumonia or pleuritis**
- **Spontaneous pneumothorax**
- **Esophageal reflux**
- **Esophageal spasm**
- **Peptic ulcer**
- **Gallbladder disease**
- **Musculoskeletal disease**
- **Herpes zoster**
- **Emotional and psychiatric conditions**
Unstable Angina and Myocardial Infarction (See also Chaps. 227 and 228) Patients with these acute ischemic syndromes usually complain of symptoms similar in quality to angina pectoris, but more prolonged and severe. The onset of these syndromes may occur with the patient at rest, or awakened from sleep, and sublingual nitroglycerin may lead to transient or no relief. Accompanying symptoms may include diaphoresis, dyspnea, nausea, and light-headedness.

The physical examination may be completely normal in patients with chest discomfort due to ischemic heart disease. Careful auscultation during ischemic episodes may reveal a third or fourth heart sound, reflecting myocardial systolic or diastolic dysfunction. A transient murmur or diastolic regurgitation suggests ischemic papillary muscle dysfunction. Severe episodes of ischemia can lead to pulmonary congestion and even pulmonary edema.

Other Cardiac Causes Myocardial ischemia caused by hypertrophic cardiomyopathy, aortic stenosis, or other conditions leads to angina pectoris similar to that caused by coronary atherosclerosis. In such cases, a systolic murmur or other findings usually suggest the abnormalities other than coronary atherosclerosis that may be contributing to the patient’s symptoms. Some patients with chest pain and normal coronary angiograms have functional abnormalities of the coronary circulation, ranging from coronary spasm visible on coronary angiography to abnormal vasodilator responses and heightened vasokonstrictor responses. The term “Syndrome X” is used to describe patients with angina-like chest pain and ischemic-appearing ST segment depression during stress despite normal coronary angiograms. Some data indicate that many such patients have limited changes in coronary flow in response to pacing stress or coronary vasodilators. Despite the possibility that chest pain may be due to myocardial ischemia in such patients, their prognosis is excellent.

Percarditis (See also Chap. 222) The pain in pericarditis is believed to be due to inflammation of the adjacent parietal pleura, since most of the pericardium is believed to be insensitive to pain. Thus, infectious pericarditis, which usually involves adjoining pleura surfaces, tends to be associated with pain, while conditions that cause only local inflammation (e.g., myocardial infarction or uremia) and cardiac tamponade tend to result in mild or no chest pain.

The adjacent parietal pleura receives its sensory supply from several sources, so the pain of pericarditis can be experienced in areas ranging from the shoulder and neck to the abdomen and back. Most typically, the pain is retrosternal and is aggravated by coughing, deep breaths, or changes in position—all of which lead to movements of pleural surfaces. The pain is often worse in the supine position and relieved by sitting upright and leaning forward. Less common is a steady aching discomfort that mimics acute myocardial infarction.

Diseases of the Aorta (See also Chap. 231) Aortic dissection is a potentially catastrophic condition that is due to spread within the wall of the aorta of a subintimal hematoma. The hematoma may begin with a tear in the intima of the aorta or with rupture of the vasa vasorum within the aortic media. This syndrome can occur with trauma to the aorta, including motor vehicle accidents or medical procedures in which catheters or intraaortic balloon pumps damage the intima of the aorta. Nontraumatic aortic dissections are rare in the absence of hypertension and/or conditions associated with deterioration of the elastic or muscular components of the media within the aorta’s wall. Cystic medial degeneration is a feature of several inherited connective tissue diseases, including Marfan and Ehlers-Danlos syndromes. About half of all aortic dissections in women under 40 years of age occur during pregnancy.

Almost all patients with acute dissections present with severe chest pain, although some patients with chronic dissections are identified without associated symptoms. Unlike the pain of ischemic heart disease, symptoms of aortic dissection tend to reach peak severity immediately, often causing the patient to collapse from its intensity. The adjectives used to describe the pain reflect the process occurring within the wall of the aorta—“ripping” and “tearing”—and the location usually correlates with the site and extent of the dissection. Thus, dissections that begin in the ascending aorta and extend to the descending aorta tend to cause pain in the front of the chest that extends into the back, between the shoulder blades.

Physical findings may also reflect extension of the aortic dissection that compromises flow into arteries branching off the aorta. Thus, loss of a pulse in one or both arms, cerebrovascular accident, or paraplegia can all be catastrophic consequences of aortic dissection. Hematomas that extend proximally and undermine the coronary arteries or aortic valve apparatus may lead to acute myocardial infarction or acute aortic insufficiency. Rupture of the hematoma into the pericardial space leads to pericardial tamponade.

Another abnormality of the aorta that can cause chest pain is a thoracic aortic aneurysm. Aortic aneurysms are frequently asymptomatic but can cause chest pain and other symptoms by compressing adjacent structures. This pain tends to be steady, deep, and sometimes severe.

Pulmonary Embolism (See also Chap. 244) Chest pain due to pulmonary embolism is believed to be due to distention of the pulmonary artery or infarction of a segment of the lung adjacent to the pleura. Massive pulmonary emboli may lead to subternal pain that is suggestive of acute myocardial infarction. More commonly, smaller emboli lead to focal pulmonary infarctions that cause pain that is lateral and pleuritic. Associated symptoms include dyspnea and, occasionally, hemoptysis. Tachycardia is usually present. Although not always present, certain characteristic ECG changes can support the diagnosis.

Pneumothorax (See also Chap. 245) Sudden onset of pleuritic chest pain and respiratory distress should lead to consideration of spontaneous pneumothorax, as well as pulmonary embolism. Such events may occur without a precipitating event in people without lung disease, or as a consequence of underlying lung disorders.

Pneumonia or Pleuritis (See also Chaps. 239 and 245) Lung diseases that damage and cause inflammation of the pleura of the lung usually cause a sharp, knife-like pain that is aggravated by inspiration or coughing.

Gastrointestinal Conditions (See also Chap. 273) Esophageal pain from acid reflux from the stomach, spasm, obstruction, or injury can be difficult to discriminate from myocardial syndromes. Acid reflux typically causes a deep burning discomfort that may be exacerbated by alcohol, aspirin, or some foods; this discomfort is often relieved by antacids or other acid-reducing therapies. Acid reflux tends to be exacerbated by lying down and may be worse in early morning when the stomach is empty of food that might otherwise absorb gastric acid. Esophageal spasm may occur in the presence or absence of acid reflux, and leads to a squeezing pain indistinguishable from angina. Prompt relief of esophageal spasm is often provided by antianginal therapies such as sublingual nifedipine, further promoting confusion between these syndromes. Chest pain can also result from injury to the esophagus, such as a Mallory-Weiss tear caused by severe vomiting.

Chest pain can result from diseases of the gastrointestinal tract below the diaphragm, including peptic ulcer disease, biliary disease, and pancreatitis. These conditions usually cause abdominal pain as well as chest discomfort; symptoms are not likely to be associated with exertion. The pain of ulcer disease typically occurs 60 to 90 min after meals, when postprandial acid production is no longer neutralized by food in the stomach. Cholecystitis usually causes a pain that is described as aching, occurring an hour or more after meals.

Neuromusculoskeletal Conditions Cervical disk disease can cause chest pain by compression of nerve roots. Pain in a dermatomal distribution can also be caused by intercostal muscle cramps or by herpes zoster. Chest pain symptoms due to herpes zoster may occur before skin lesions are apparent.

Costochondral and chondrocosternal syndromes are the most common causes of anterior chest musculoskeletal pain. Only occasionally
are physical signs of costochondritis such as swelling, redness, and warmth (Tietze’s syndrome) present. The pain of such syndromes is usually fleeting and sharp, but some patients experience a dull ache that lasts for hours. Direct pressure on the chondrosternal and costochondral junctions may reproduce the pain from these and other musculoskeletal syndromes. Arthritis of the shoulder and spine and bursitis may also cause chest pain. Some patients who have these conditions and myocardial ischemia blur and confuse symptoms of these syndromes.

EMOTIONAL AND PSYCHIATRIC CONDITIONS As many as 10% of patients who present to emergency departments with acute chest pain have panic disorder or other emotional conditions. The symptoms in these populations are highly variable, but frequently the discomfort is described as visceral tightness or aching that lasts more than 30 min. Some patients offer other atypical descriptions, such as pain that is fleeting, sharp, and/or localized to a small region. The electrocardiogram in patients with emotional conditions may be difficult to interpret if hyperventilation causes ST-T-wave abnormalities. A careful history may elicit clues of depression, prior panic attacks, somatization, agoraphobia, or other phobias.

**APPRAOCH TO THE PATIENT**

The evaluation of the patient with chest discomfort must accommodate two goals—determining the diagnosis and assessing the safety of the immediate management plan. The latter issue is often dominant when the patient has acute chest discomfort, such as patients seen in the emergency department. In such settings, the clinician must focus first on identifying patients who require aggressive interventions to diagnose or manage potentially life-threatening conditions, including acute ischemic heart disease, acute aortic dissection, pulmonary embolism, and tension pneumothorax. If such conditions are unlikely, the clinician must address questions such as the safety of discharge to home, admission to a non-coronary care unit facility, or immediate exercise testing. Table 12-3 displays a sequence of questions that can be used in the evaluation of the patient with chest discomfort, with the diagnostic entities that are most important for consideration at each stage of the evaluation.

**ACUTE CHEST DISCOMFORT** In patients with acute chest discomfort, the clinician must first assess the patient’s respiratory and hemodynamic status. If either is compromised, initial management should focus on stabilizing the patient before the diagnostic evaluation is pursued. If, however, the patient does not require emergent interventions, then a focused history, physical examination, and laboratory evaluation should be performed to assess the patient’s risk of life-threatening conditions.

The **history** should include questions about the quality and location of the chest discomfort (Table 12-2). The patient should also be asked about the nature of onset of the pain and its duration. Myocardial ischemia is usually associated with a gradual intensification of symptoms over a period of minutes. Pain that is fleeting or that lasts hours without being associated with electrocardiographic changes is not likely to be ischemic in origin. Although the presence of risk factors for coronary artery disease may heighten concern for this diagnosis, the absence of such risk factors does not lower the risk for myocardial ischemia enough to be used to justify a decision to discharge a patient.

Wide radiation of chest pain increases probability that pain is due to myocardial infarction. Radiation of chest pain to the left arm is common with acute ischemic heart disease, but radiation to the right arm is also consistent with this diagnosis. Right shoulder pain is common with acute cholecystitis, but this syndrome is usually accompanied by pain that is located in the abdomen rather than chest. Chest pain that radiates between the scapulæ raises the question of aortic dissection.

The **physical examination** should include evaluation of blood pressure in both arms and of pulses in both legs. Poor perfusion of a limb may be due to an aortic dissection that has compromised flow to an artery branching from the aorta. Chest auscultation may reveal diminished breath sounds; a pleural rub; or evidence of pneumothorax, pulmonary embolism, pneumonia, or pleurisy. Tension pneumothorax may lead to a shift in the trachea from the midline, away from the side of the pneumothorax. The cardiac examination should seek pericardial rubs, systolic and diastolic murmurs, and third or fourth heart sounds. Pressure on the chest wall may reproduce symptoms in patients with musculoskeletal causes of chest pain; it is important that the clinician ask if the chest pain syndrome is being completely reproduced before drawing too much reassurance that more serious underlying conditions are not present.

An **electrocardiogram** is an essential test for adults with chest discomfort that is not due to an obvious traumatic cause. In such patients, the presence of electrocardiographic changes consistent with ischemia or infarction (Chap. 210) is associated with high risks of acute myocardial infarction or unstable angina (Table 12-4); such patients should be admitted to a unit with electrocardiographic monitoring and the capacity to respond to a cardiac arrest. The absence of such changes does not exclude acute ischemic heart disease, and laboratory evaluation should be performed to assess the patient’s risk of life-threatening conditions.

disease, but the risk of life-threatening complications is low for patients with normal electrocardiograms or only nonspecific ST-T-wave changes. If these patients are not considered appropriate for immediate discharge, they are often candidates for early or immediate exercise testing.

Markers of myocardial injury are often obtained in the emergency department evaluation of acute chest discomfort. The most commonly used markers are creatine kinase (CK), CK-MB, and the cardiac troponins (I and T). Rapid bedside assays of the cardiac troponins have been developed and shown to be sufficiently accurate to predict prognosis and guide management. Some data support the use of other markers, such as serum myoglobin, C-reactive protein (CRP), and B-type natriuretic peptide (BNP); their roles are the subject of ongoing research. Single values of any of these markers do not have high sensitivity for acute myocardial infarction or for prediction of complications. Hence, decisions to discharge patients home should not be made on the basis of single negative values of these tests.

Provocative tests for coronary artery disease are not appropriate for patients with ongoing chest pain. In such patients, rest myocardial perfusion scans can be considered; a normal scan reduces the likelihood of coronary artery disease, and can help avoid admission of low-risk patients to the hospital. Clinicians frequently employ therapeutic trials with sublingual nitroglycerin or antacids or, in the stable patient seen in the office setting, a proton pump inhibitor. A common error is to assume that a response to any of these interventions clarifies the diagnosis. While such information is often helpful, the patient’s response may be due to the placebo effect. Hence, myocardial ischemia should never be considered excluded solely because of a response to antacid therapy. Similarly, failure of nitroglycerin to relieve pain does not exclude the diagnosis of coronary disease.

If the patient’s history or examination is consistent with aortic dissection, imaging studies to evaluate the aorta must be pursued promptly because of the high risk of catastrophic complications with this condition. A chest x-ray is not sufficient to exclude this diagnosis. Appropriate tests include a chest computed tomography scan with contrast or a magnetic resonance imaging scan in patients who are hemodynamically stable, or a transesophageal echocardiogram in patients who are less stable. Aortic angiography is no longer a first test at most institutions.

Acute pulmonary embolism should be considered in patients with respiratory symptoms, pleuritic chest pain, hemoptysis, or a history of venous thromboembolism or coagulation abnormalities. Initial tests usually include a lung scan and/or pulmonary arteriography.

If patients with acute chest discomfort show no evidence of life-threatening conditions, the clinician should then focus on serious chronic conditions with the potential to cause major complications, the most common of which is stable angina. Early use of exercise electrocardiography, stress echocardiography, or stress perfusion imaging for such patients, whether in the office or the emergency department, is now an accepted management strategy for low-risk patients. Exercise testing is not appropriate, however, for patients who (1) report pain that is believed to be ischemic occurring at rest or (2) have electrocardiographic changes not known to be old that are consistent with ischemia.

Patients with sustained chest discomfort who do not have evidence for life-threatening conditions should be evaluated for evidence of conditions likely to benefit from acute treatment (Table 12-3). Pericarditis may be suggested by the history, physical examination, and electrocardiogram (Table 12-2). Clinicians should carefully assess blood pressure patterns and consider echocardiography in such patients to detect evidence of impending pericardial tamponade. Chest x-rays can be used to evaluate the possibility of pulmonary disease.

**GUIDELINES AND CRITICAL PATHWAYS FOR ACUTE CHEST PAIN**

Guidelines for the initial evaluation for patients with acute chest pain have been developed by the American College of Cardiology, American Heart Association, and other organizations. These guidelines recommend performance of an electrocardiogram for virtually all patients with chest pain who do not have an obvious noncardiac cause of their pain, and performance of a chest x-ray for patients with signs or symptoms consistent with congestive heart failure, valvular heart disease, pericardial disease, or aortic dissection or aneurysm.

Other organizations, including the Agency for Health Care Policy and Research (AHCPR) and the National Heart Attack Alert Program, have also issued guidelines for management of patients with a high probability of acute ischemic heart disease. In these and other guidelines, patients with possible or probable acute myocardial infarction as suggested by the description of their pain or ECG findings are expected to be admitted to the hospital. The AHCPR guidelines for unstable angina note that not all patients with that syndrome require admission but recommend that patients with unstable angina be monitored electrocardiographically during their evaluation; that those with ongoing rest pain should be placed at bed rest during the initial phase of stabilization.

The American Heart Association has published guidelines for the use of exercise testing in the emergency department. These recommendations include having two sets of cardiac enzymes or troponins at 4-h intervals that are normal; an ECG at presentation and preexercise ECG that shows no significant change; absence of rest ECG abnormalities that preclude accurate interpretation of an exercise ECG; and absence of ischemic chest pain at the time of exercise testing or during the observation period after admission to the emergency department.

Many medical centers have adopted critical pathways and other forms of guidelines to increase efficiency and to expedite the treatment of patients with high-risk acute ischemic heart disease syndromes. These guidelines emphasize the following strategies:

- Rapid identification and treatment of patients for whom emergent reperfusion therapy, either via percutaneous coronary interventions or thrombolytic agents, is likely to lead to improved outcomes.
- Triage to non-coronary care unit monitored facilities such as intermediate care units or chest pain units of patients with a low risk for complications, such as patients without new ischemic changes on their electrocardiograms and without ongoing chest pain. Such patients can usually be safely observed in non-coronary care unit settings, undergo early exercise testing, or be discharged home.
- Risk stratification can be assisted through use of prospectively validated multivariate algorithms that have been published for acute ischemic heart disease and its complications.
- Shortening lengths of stay in the coronary care unit and hospital.

Recommendations regarding the minimum length of stay in a monitored bed for a patient who has no further symptoms have decreased in recent years to 12 h or less if exercise testing or other risk stratification technologies are available.

**NONACUTE CHEST DISCOMFORT**

The management of patients who do not require admission to the hospital or who no longer require inpatient observation should seek to identify the cause of the symptoms and the likelihood of major complications. Cost-effectiveness analyses support use of noninvasive testing for coronary disease, such as exercise electrocardiography and stress echocardiography. These tests serve both to diagnose coronary disease and to identify patients with high-risk forms of coronary disease who may benefit from revascularization. Gastrointestinal causes of chest pain can be evaluated via endoscopy or radiology studies, or with trials of medical therapy. Emotional and psychiatric conditions warrant appropriate evaluation and treatment; randomized trial data indicate that cognitive therapy and group interventions lead to decreases in symptoms for such patients.
Palpitations are characterized by an awareness of the beating of the heart. Patients commonly describe “pounding” or “fluttering” heart beats or report a sensation that the heart is stopping or skipping beats. These symptoms may be caused by a change in the heart’s rhythm or rate or by an increase in the force of its contractions. In many cases, this awareness reflects lack of competing sensory stimuli, such as when a person is lying in bed, unable to sleep.

Palpitations are often manifestations of psychiatric conditions, the most common of which are depression and panic disorder. For example, in one study of outpatients referred for ambulatory electrocardiographic monitoring to evaluate palpitations, 19% were found to have a psychiatric disorder. Patients with psychiatric disorders were more likely than other patients to report that their palpitations lasted longer than 15 min or were accompanied by ancillary symptoms. In this study, physicians usually recognized the emotional basis of the patients’ symptoms but frequently did not refer the patient for specific therapy.

Palpitations can also be caused by virtually any cardiac arrhythmia as well as by other cardiac and noncardiac conditions. A markedly enlarged left ventricle can cause awareness of the heart beat by contact with the chest wall. Any condition associated with increased catecholamine levels can lead to palpitations both by increasing the forcefulness of cardiac contractions and by increasing the rate of premature beats.

Palpitations can be intermittent or sustained and regular or irregular. Patients with this complaint should be asked to describe their palpitations’ onset, duration, associated symptoms, and the circumstances in which they occur. Abrupt onset and termination after several minutes may reflect a sustained ventricular or supraventricular tachycardia. Gradual onset and termination of a pounding heart beat is more consistent with sinus tachycardia. Patients should try to replicate the rhythm of their palpitations by tapping on a table. This maneuver can help the physician determine the nature of any cardiac arrhythmia. Patients should also be taught to take their pulse so that they can more accurately report their approximate heart rate and whether the rhythm was regular.

**DIFFERENTIAL DIAGNOSIS**

Patients who report “skipped” beats or a “flopping” sensation often have atrial or ventricular extrasystoles (Chap. 214). These premature beats are followed by a compensatory pause, and the first heart beat after the pause may be unusually strong due to increased left ventricular volume and enhanced contractility (a phenomenon called postextrasystolic potentiation). Sustained bursts of rapid heart beats may be due to ventricular or supraventricular tachyarrhythmias. A sustained irregular rhythm suggests atrial fibrillation.

Conditions that cause marked left ventricular enlargement such as aortic regurgitation can cause an awareness of the heart beat that is sometimes positional. Presumably because of associated arrhythmias, hypertrophic cardiomyopathy, mitral valve prolapse, and other cardiac structural abnormalities are also associated with palpitations.

Palpitations can also be a prominent symptom in noncardiac conditions, including thyrotoxicosis, hypoglycemia, pheochromocytoma, and fever. The physiologic basis of palpitations with these conditions is either arrhythmia or increased catecholamine levels leading to greater myocardial contractility. Drugs that can precipitate arrhythmias and palpitations include tobacco, coffee, tea, alcohol, epinephrine, ephedrine, aminophylline, and atropine.

**APPROACH TO THE PATIENT**

The first goal in the evaluation of patients with palpitations is to exclude the possibility of life-threatening arrhythmias. The risk for such arrhythmias is highest in patients with coronary artery disease, congestive heart failure, or other structural cardiac abnormalities. The history, physical examination, and electrocardiogram should therefore be focused on stratifying patients according to the risk of such conditions. Palpitations are also more likely to reflect serious arrhythmias if they are associated with symptoms that suggest hemodynamic compromise, such as syncope, light-headedness, dizziness, or shortness of breath.

The most common first test after the initial evaluation of palpitations is continuous electrocardiographic (Holter) monitoring. This test is especially useful if patients have unexplained palpitations that recur frequently. For patients with more sporadic palpitations, a variety of new technologies have become available to allow capture of ECG tracings at the time of their symptoms. These technologies include loop recorders, that can freeze the last several minutes of data when the patient presses a button, and telephonic monitors, which can be used to “call in” tracings when symptoms occur. For patients who require very long-term monitoring, implantable loop recorders are available. If episodes are associated with physical stress, exercise electrocardiography can be used in an attempt to elicit an arrhythmia.

Most patients with palpitations do not have evidence of major arrhythmias or abnormal physiologic conditions associated with increased catecholamine levels. Patients with emotional or psychological causes of palpitations should be evaluated for possible cognitive and pharmaceutical therapy. Drugs and medications that may precipitate palpitations should be eliminated or reduced. A trial of beta blockers is often successful in reducing premature beats and symptoms. Regardless of the cause and treatment, the clinician should remain aware that palpitations are extremely bothersome symptoms for patients. Reassurance that a comprehensive evaluation has been performed and that the palpitations do not adversely affect the patient’s prognosis is a critical part of the patient’s care.

**FURTHER READING**

The correct interpretation of acute abdominal pain is challenging. Since proper therapy may require urgent action, the unhurried approach suitable for the study of other conditions is sometimes denied. Few other clinical situations demand greater judgment, because the most catastrophic of events may be forecast by the subtlest of symptoms and signs. A meticulously executed, detailed history and physical examination are of great importance. The etiologic classification in Table 13-1, although not complete, forms a useful basis for the evaluation of patients with abdominal pain.

The diagnosis of “acute or surgical abdomen” is not an acceptable one because of its often misleading and erroneous connotation. The most obvious of “acute abdomens” may not require operative intervention, and the mildest of abdominal pains may herald an urgently correctable lesion. Any patient with abdominal pain of recent onset requires early and thorough evaluation and accurate diagnosis.

### SOMETHING MECHANISMS OF PAIN ORIGINATING IN THE ABDOMEN

#### Inflammation of the Parietal Peritoneum

The pain of parietal peritoneal inflammation is steady and aching in character and is located directly over the inflamed area. The intensity of the pain is dependent on the type and amount of material to which the peritoneal surfaces are exposed in a given time period. For example, the sudden release into the peritoneal cavity of a small quantity of sterile acid gastric juice causes much more pain than the same amount of grossly contaminated neutral feces. Enzymatically active pancreatic juice incites more pain and inflammation than does the same amount of sterile bile containing no potent enzymes. Blood and urine are often so bland as to go undetected if their contact with the peritoneum has not been sudden and massive. In the case of bacterial contamination, such as in pelvic inflammatory disease, the pain is frequently of low intensity early in the illness until bacterial multiplication has caused the elaboration of irritating substances.

The rate at which the irritating material is applied to the peritoneum is important. Perforated peptic ulcer may be associated with entirely different clinical pictures dependent only on the rapidity with which the gastric juice enters the parietal cavity.

The pain of peritoneal inflammation is invariably accentuated by pressure or changes in tension of the peritoneum, whether produced by palpation or by movement, as in coughing or sneezing. The patient with peritonitis lies quietly in bed, preferring to avoid motion, in contrast to the patient with colic, who may writhe incessantly.

#### Obstruction of Hollow Viscera

The pain of obstruction of hollow abdominal viscera is classically described as intermittent, or colicky. Yet the lack of a truly cramping character should not be misleading, because distention of a hollow viscus may produce steady pain with only very occasional exacerbations. It is not nearly as well localized as the pain of parietal peritoneal inflammation.

The colicky pain of obstruction of the small intestine is usually periumbilical or supraumbilical and is poorly localized. As the intestine becomes progressively dilated with loss of muscular tone, the colicky nature of the pain may diminish. With superimposed strangulating obstruction, pain may spread to the lower lumbar region if there is traction on the root of the mesentery. The colicky pain of colonic obstruction is of lesser intensity than that of the small intestine and is often located in the infraumbilical area. Lumbar radiation of pain is common in colonic obstruction.

**Sudden** distention of the biliary tree produces a steady rather than colicky type of pain; hence the term *biliary colic* is misleading. Acute distention of the gallbladder usually causes pain in the right upper quadrant with radiation to the right posterior region of the thorax or to the tip of the right scapula, and distention of the common bile duct is often associated with pain in the epigastrium radiating to the upper part of the lumbar region. Considerable variation is common, however, so that differentiation between these may be impossible. The typical subcapsular pain or lumbar radiation is frequently absent. Gradual dilatation of the biliary tree, as in carcinoma of the head of the pancreas, may cause no pain or only a mild aching sensation in the epigastrium or right upper quadrant. The pain of distention of the pancreatic ducts is similar to that described for distention of the common bile duct but, in addition, is very frequently accentuated by recumbency and relieved by the upright position.

Obstruction of the urinary bladder results in dull suprapubic pain, usually low in intensity. Restlessness without specific complaint of pain may be the only sign of a distended bladder in an obtunded patient. In contrast, acute obstruction of the intravesicular portion of the ureter is characterized by severe suprapubic and flank pain that radiates to the penis, scrotum, or inner aspect of the upper thigh. Obstruction of the ureteropelvic junction is felt as pain in the costovertebral angle, whereas obstruction of the remainder of the ureter is as-

associated with flank pain that often extends into the same side of the abdomen.

**Vascular Disturbances** A frequent misconception, despite abundant experience to the contrary, is that pain associated with intraabdominal vascular disturbances is sudden and catastrophic in nature. The pain of embolism or thrombosis of the superior mesenteric artery or that of impeding rupture of an abdominal aortic aneurysm certainly may be severe and diffuse. Yet, just as frequently, the patient with occlusion of the superior mesenteric artery has only mild continuous diffuse pain for 2 or 3 days before vascular collapse or findings of peritoneal inflammation appear. The early, seemingly insignificant discomfort is caused by hyperperistalsis rather than peritoneal inflammation. Indeed, absence of tenderness and rigidity in the presence of continuous, diffuse pain in a patient likely to have vascular disease is quite characteristic of occlusion of the superior mesenteric artery. Abdominal pain with radiation to the sacral region, flank, or genitalia should always signal the possible presence of a rupturing abdominal aortic aneurysm. This pain may persist over a period of several days before rupture and collapse occur.

**Abdominal Wall** Pain arising from the abdominal wall is usually constant and achy. Movement, prolonged standing, and pressure accentuate the discomfort and muscle spasm. In the case of hematoma of the rectus sheath, now most frequently encountered in association with anti-coagulant therapy, a mass may be present in the lower quadrants of the abdomen. Simultaneous involvement of muscles in other parts of the body usually serves to differentiate myositis of the abdominal wall from an intraabdominal process that might cause pain in the same region.

**REFERRED PAIN IN ABDOMINAL DISEASES** Pain referred to the abdomen from the thorax, spine, or genitalia may prove a vexing diagnostic problem, because diseases of the upper part of the abdominal cavity such as acute cholecystitis or perforated ulcer are frequently associated with intrathoracic complications. A most important, yet often forgotten, dictum is that the possibility of intrathoracic disease must be considered in every patient with abdominal pain, especially if the pain is in the upper part of the abdomen. Systematic questioning and examination directed toward detecting myocardial or pulmonary infarction, pneumonia, pericarditis, or esophageal disease (the intrathoracic diseases that most often masquerade as abdominal emergencies) will often provide sufficient clues to establish the proper diagnosis. Diaphragmatic pleuritis resulting from pneumonia or pulmonary infarction may cause pain in the right upper quadrant and pain in the supraclavicular area, the latter radiation to be distinguished from the referred subcostal pain caused by acute distention of the extrapleural biliary tree. The ultimate decision as to the origin of abdominal pain may require deliberate and planned observation over a period of several hours, during which repeated questioning and examination will provide the diagnosis or suggest the appropriate studies.

Referred pain of thoracic origin is often accompanied by splinting of the involved hemithorax with respiratory lag and decrease in excursion more marked than that seen in the presence of intraabdominal disease. In addition, apparent abdominal muscle spasm caused by referred pain will diminish during the inspiratory phase of respiration, whereas it is persistent throughout both respiratory phases if it is of abdominal origin. Palpation over the area of referred pain in the abdomen also does not usually accentuate the pain and in many instances actually seems to relieve it. Thoracic and abdominal disease frequently coexist and may be difficult or impossible to differentiate. For example, the patient with known biliary tract disease often has epigastric pain during myocardial infarction, or biliary colic may be referred to the precordium or left shoulder in a patient who has suffered previously from angina pectoris. —*For an explanation of the radiation of pain to a previously diseased area, see Chap. 11.*

Referred pain from the spine, which usually involves compression or irritation of nerve roots, is characteristically intensified by certain motions such as cough, sneeze, or strain and is associated with hyperesthesia over the involved dermatomes. Pain referred to the abdo-

**METABOLIC ABDOMINAL CRISIS** Pain of metabolic origin may simulate almost any other type of intraabdominal disease. Several mechanisms may be at work. In certain instances, such as hyperlipidemia, the metabolic disease itself may be accompanied by an intraabdominal process such as pancreatitis, which can lead to unnecessary laparotomy unless recognized. C’1 esterase deficiency associated with angioneurotic edema is often associated with episodes of severe abdominal pain. Whenever the cause of abdominal pain is obscure, a metabolic origin always must be considered. Abdominal pain is also the hallmark of familial Mediterranean fever (Chap. 278). The problem of differential diagnosis is often not readily resolved. The pain of porphyria and of lead colic is usually difficult to distinguish from that of intestinal obstruction, because severe hyperperistalsis is a prominent feature of both. The pain of uremia or diabetes is nonspecific, and the pain and tenderness frequently shift in location and intensity. Diabetic acidosis may be precipitated by acute appendicitis or intestinal obstruction, so if prompt resolution of the abdominal pain does not result from correction of the metabolic abnormalities, an underlying organic problem should be suspected. Black widow spider bites produce intense pain and rigidity of the abdominal muscles and back, an area infrequently involved in intraabdominal disease.

**NEUROGENIC CAUSES** Causalgic pain may occur in diseases that injure sensory nerves. It has a burning character and is usually limited to the distribution of a given peripheral nerve. Normal stimuli such as touch or change in temperature may be transformed into this type of pain, which is frequently present in a patient at rest. The demonstration of irregularly spaced cutaneous pain spots may be the only indication of an old nerve lesion underlying causalgic pain. Even though the pain may be precipitated by gentle palpation, rigidity of the abdominal muscles is absent, and the respirations are not disturbed. Distention of the abdomen is uncommon, and the pain has no relationship to the intake of food.

Pain arising from spinal nerves or roots comes and goes suddenly and is of a lancinating type (Chap. 15). It may be caused by herpes zoster, impingement by arthritis, tumors, herniated nucleus pulposus, diabetes, or syphilis. It is not associated with food intake, abdominal distention, or changes in respiration. Severe muscle spasm, as in the gastric crises of tabes dorsalis, is common but is either relieved or is not accentuated by abdominal palpation. The pain is made worse by movement of the spine and is usually confined to a few dermatomes. Hyperesthesia is very common.

Pain due to functional causes conforms to none of the aforementioned patterns. Mechanism is hard to define. Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterized by abdominal pain and altered bowel habits. The diagnosis is made on the basis of clinical criteria (Chap. 277) and after exclusion of demonstrable structural abnormalities. The episodes of abdominal pain are often brought on by stress, and the pain varies considerably in type and location. Nausea and vomiting are rare. Localized tenderness and muscle spasm are inconsistent or absent. The causes of IBS or related functional disorders are not known.

**APPROACH TO THE PATIENT**

Few abdominal conditions require such urgent operative intervention that an orderly approach need be abandoned, no matter how ill the patient. Only those patients with exsanguinating intraabdominal hemorrhage (e.g., rupture hemorrhage) must be rushed to the operating room immediately, but in such instances, only a few minutes are required to assess the critical nature of the problem. Under these circumstances, all obstacles must be swept aside, adequate venous access for fluid replacement obtained, and the operation begun. Many patients of this type have died in the radiology de-
portional to the facies, position in bed, and respiratory activity, may provide valuable information. A female patient is essential. Narcotics or analgesics should not be responsible for abdominal pain. An accurate menstrual history in the patient is essential. Careful attention should be paid to the extraabdominal regions that may be implicated on involuntary muscular rigidity. Sometimes, even under the best circumstances with all available aids and with the greatest of clinical skill, a definitive diagnosis cannot be established at the time of the initial examination. Nevertheless, despite lack of a clear anatomic diagnosis, it may be abundantly clear to an experienced and thoughtful physician and surgeon that on clinical grounds alone operation is indicated. Should that decision be questionable, watchful waiting with repeated questioning and examination will often elucidate the true nature of the illness and indicate the proper course of action.

**FURTHER READING**

Few of us are spared the experience of head pain. As many as 90% of individuals have at least one headache per year. Severe, disabling headache is reported to occur at least annually by 40% of individuals worldwide. A useful classification of the many causes of headache is shown in Table 14-1. Headache is usually a benign symptom, but occasionally it is the manifestation of a serious illness such as brain tumor, subarachnoid hemorrhage, meningitis, or giant cell arteritis. In emergency settings, approximately 5% of patients with headache are found to have a serious underlying neurologic disorder. Therefore, it is imperative that the serious causes of headache be diagnosed rapidly and accurately.

**PAIN-SENSITIVE STRUCTURES OF THE HEAD**

Pain usually occurs when peripheral nociceptors are stimulated in response to tissue injury, visceral distension, or other factors (Chap. 11). In such situations, pain perception is a normal physiologic response mediated by a healthy nervous system. Pain can also result when pain-sensitive pathways of the peripheral or central nervous system are damaged or activated inappropriately. Headache may originate from either or both mechanisms. Relatively few cranial structures are pain-sensitive: the scalp, middle meningeal artery, dural sinuses, falx cerebri, and the proximal segments of the large pial arteries. Therefore, it is imperative that the serious causes of headache be diagnosed rapidly and accurately.

| 13. | Headache not classifiable |

Note: CSF, cerebrospinal fluid.
Although meningitis, subarachnoid hemorrhage, and cluster headache produce intense cranial pain, most patients entering emergency departments with the most severe headache of their lives usually have migraine. Contrary to common belief, the headache produced by a brain tumor is not usually distinctive or severe.

Data regarding location of headache may be informative. If the source is an extracranial structure, as in giant cell arteritis, the correspondence with the site of pain is fairly precise. Inflammation of an extracranial artery causes pain and exquisite tenderness localized to the site of the vessel. Lesions of paranasal sinuses, teeth, eyes, and upper cervical vertebrae induce less sharply localized pain, but pain that is still referred in a regional distribution. Intracranial lesions in the posterior fossa cause pain that is usually occipitomastoidal, and supratentorial lesions most often induce frontotemporal pain.

Duration and time-intensity curves of headaches are diagnostically useful. A ruptured aneurysm results in head pain that peaks in an instant, thunderclap-like; much less often, unruptured aneurysms may signal their presence in the same way. Cluster headache attacks reach their peak over 3 to 5 min, remain at maximal levels for about 45 min, and then taper off. Migraine attacks build up over hours, are maintained for several hours to days, and are characteristically relieved by sleep. Sleep disruption and early morning headaches that improve during the day are characteristics of headaches produced by brain tumors or other disorders that produce increased intracranial pressure.

Facial pain must be distinguished from headache. Trigeminal and, less commonly, glossopharyngeal neuralgia are frequent causes of facial pain (Chap. 355). Neuralgias are painful disorders characterized by paroxysmal, fleeting, often electric shock–like episodes that are frequently caused by demyelinating lesions of nerves (the trigeminal or glossopharyngeal nerves in cranial neuralgias). Certain maneuvers characteristically trigger paroxysms of pain. However, the most common cause of facial pain is by far is dental; provocation by hot, cold, or sweet foods is typical. The application of a cold stimulus will repeatedly induce dental pain, whereas in neuralgic disorders, a refractory period usually occurs after the initial response so that pain cannot be repeatedly induced.

The effect of eating on facial pain may provide insight into its cause. Is it the chewing, swallowing, or taste of the food that elicits pain? Chewing suggests trigeminal neuralgia, temporomandibular joint dysfunction, or giant cell arteritis (“jaw claudication”), whereas swallowing and taste provocation suggest glossopharyngeal neuralgia. Pain with swallowing is common in patients with carotidynia (see below) because the inflamed, tender carotid artery abuts the esophagus during deglutition.

Many patients with facial pain do not experience stereotypic neuralgias; the term atypical facial pain has been used in this setting. Vague, poorly localized, continuous facial pain is characteristic of nasopharyngeal carcinoma; a burning pain often develops as deafferentation occurs and evidence of cranial neuropathy appears. Burning facial pain may also occur with tumors of the fifth cranial nerve (meningioma or schwannoma) or with lesions of the pons that interrupt the dorsal root entry zone of the nerve (multiple sclerosis). In patients with facial pain, the finding of objective sensory loss is an important clue to a serious underlying disorder. Occasionally, the cause of a pain problem cannot be resolved promptly, necessitating periodic follow-up until further signs appear.

### CLINICAL EVALUATION OF ACUTE, NEW-ONSET HEADACHE

Patients who present with their first severe headache raise entirely different diagnostic possibilities than those with recurrent headaches over many years. In new-onset and severe headaches, the probability of finding a potentially serious cause is considerably greater than in recurrent headache. When a patient complains of an acute, new-onset headache, a number of causes should be considered including meningitis, subarachnoid hemorrhage, epidural or subdural hematoma, glaucoma, and purulent sinusitis. Clinical features of acute, new-onset headache caused by serious underlying conditions are summarized in Table 14-2.

A complete neurologic examination is an essential first step in the evaluation. In most cases, an abnormal examination should be followed by a computed tomography (CT) or a magnetic resonance imaging (MRI) study. As a screening procedure for intracranial pathology in this setting, CT and MRI methods appear to be equally sensitive. A general evaluation of acute headache might include the investigation of cardiovascular and renal status by blood pressure monitoring and urine examination; eyes by fundoscopy, intraocular pressure measurement, and refraction; cranial arteries by palpation; and cervical spine by the effect of passive movement of the head and imaging.

The psychological state of the patient should also be evaluated since a relationship exists between head pain and depression. Many patients in chronic daily pain cycles become depressed; moreover, there is a greater-than-chance coincidence of migraine with both bipolar (manic-depressive) and unipolar major depressive disorders. Drugs with antidepressant actions are also effective in the prophylactic treatment of both tension-type headache and migraine.

Underlying recurrent headache disorders may be activated by pain that follows otologic or endodontic surgical procedures. Thus, pain about the head as the result of diseased tissue or trauma may reawaken an otherwise quiescent migrainous syndrome. Treatment of the headache is largely ineffective until the cause of the primary problem is addressed.

Serious underlying conditions that are associated with headache are described below and in Table 14-3.

### MENINGITIS

In general, acute, severe headache with stiff neck and fever suggests meningitis. Lumbar puncture is mandatory. Often there is striking accentuation of pain with eye movement. Meningitis is par-

</tbody>
</table>

**Note:** CT, computed tomography.
particularly easy to mistake for migraine in that the cardinal symptoms of 
pounding headache, photophobia, nausea, and vomiting are present. →A detailed discussion of meningitis can be found in Chaps. 360 and 361.

**INTRACRANIAL HEMORRHAGE**  In general, acute, severe headache with stiff neck but without fever suggests subarachnoid hemorrhage. A ruptured aneurysm, arteriovenous malformation, or intraparenchymal hemorrhage may also present with headache alone. Rarely, if the hemorrhage is small or below the foramen magnum, the head CT scan can be normal. Therefore, a lumbar puncture may be required to make the definitive diagnosis of a subarachnoid hemorrhage. →A detailed discussion of intracranial hemorrhage can be found in Chap. 349.

**BRAIN TUMOR**  Approximately 30% of patients with brain tumors consider headache to be their chief complaint. The head pain is usually nonoperative—an intermittent deep, dull aching of moderate intensity, which may worsen with exertion or change in position and may be associated with nausea and vomiting. This pattern of symptoms results from migraine far more often than from brain tumor. Headache of brain tumor disturbs sleep in about 10% of patients. Vomiting that precedes the appearance of headache by weeks is highly characteristic of posterior fossa brain tumors. A history of amenorrhea or galactorrhea should lead one to question whether a prolactin-secreting pituitary adenoma (or the polycystic ovary syndrome) is the source of the headache. Headache arising de novo in a patient with known malignancy suggests either cerebral metastases and/or carcinomatous meningitis. Head pain appearing abruptly after bending, lifting, or coughing can be due to a posterior fossa mass (or a Chiari malformation). →A detailed discussion of brain tumors can be found in Chap. 358.

**TEMPORAL ARTERITIS**  (See also Chaps. 25 and 306) Temporal (giant cell) arteritis is an inflammatory disorder of arteries that frequently involves the extracranial carotid circulation. This is a common disorder of the elderly; its annual incidence is 77:100,000 in individuals aged 50 and older. The average age of onset is 70 years, and women account for 65% of cases. About half of patients with untreated temporal arteritis develop blindness due to involvement of the ophthalmic artery and its branches; indeed, the ischemic optic neuropathy induced by giant cell arteritis is the major cause of rapidly developing bilateral blindness in patients >60 years. Because treatment with glucocorticoids is effective in preventing this complication, prompt recognition of this disorder is important. Typical presenting symptoms include headache, polymyalgia rheumatica (Chap. 306), jaw claudication, fever, and weight loss. Headache is the dominant symptom and often appears in association with malaise and muscle aches. Head pain may be unilateral or bilateral and is located temporarily in 50% of patients but may involve any and all aspects of the cranium. Pain usually appears gradually over a few hours before peak intensity is reached; occasionally, it is explosive in onset. The quality of pain is only seldom throbbing; it is almost invariably described as dull and boring with superimposed episodic ice pick–like lancinating pains similar to the sharp pains that appear in migraine. Most patients can recognize that the origin of their head pain is superficial, external to the skull, rather than originating deep within the cranium (the pain site for migraineurs). Scalp tenderness is present, often to a marked degree; brushing the hair or resting the head on a pillow may be impossible because of pain. Headache is usually worse at night and is often aggravated by exposure to cold. Reddened, tender nodules or red streaking of the skin overlying the temporal arteries may be found in patients with headache, as is tenderness of the temporal or, less commonly, the occipital arteries.

The erythrocyte sedimentation rate (ESR) is often, though not always, elevated; a normal ESR does not exclude giant cell arteritis. A temporal artery biopsy and treatment with prednisone at 80 mg daily for the first 4 to 6 weeks should be initiated when clinical suspicion is high. The prevalence of migraine among the elderly is substantial, considerably higher than that of giant cell arteritis. Migraineurs often report amelioration of their headaches with prednisone, so that one must be cautious about interpreting the therapeutic response.

**GLAUCOMA**  Glaucoma may present with a prostrating headache associated with nausea and vomiting. The history will usually reveal that the headache started with severe eye pain. On physical examination, the eye is often red with a fixed, moderately dilated pupil. →A discussion of glaucoma can be found in Chap. 25.

**OTHER CAUSES OF HEADACHE**  (Systemic Illness)  There is hardly any illness that is never manifested by headache; however, some illnesses are frequently associated with headache. These include infectious mononucleosis, systemic lupus erythematosus, chronic pulmonary failure with hypercapnia (early morning headaches), Hashimoto’s thyroiditis, inflammatory bowel disease, many of the illnesses associated with HIV, and the acute blood pressure elevations that occur in pheochromocytoma and in malignant hypertension. The last two examples are the exceptions to the generalization that hypertension per se is a very uncommon cause of headache; diastolic pressures of at least 120 mmHg are requisite for hypertension to cause headache. Persistent headache and fever are often the manifestations of an acute systemic viral infection; if the neck is supple in such a patient, lumbar puncture may be deferred. Some drugs and drug-withdrawal states, e.g., oral contraceptives, ovulation-promoting medications, and glucocorticoid withdrawal, are also associated with headache in some individuals.

**Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)**  Headache, clinically resembling that of brain tumor, is a common presenting symptom of pseudotumor cerebri, a disorder of raised intracranial pressure probably resulting from impaired cerebrospinal fluid (CSF) absorption by the arachnoid villi. Morning headaches that are worsened by coughing and straining are typical. The pain is sometimes retroocular and worsened by eye movements. Transient visual obscurations and papilledema with enlarged blind spots and loss of peripheral visual fields are additional manifestations. Most patients are young, female, and obese. They often have a history of exposure to provoking agents such as vitamin A and glucocorticoids. →Treatment of idiopathic intracranial hypertension is discussed in Chap. 25.

**Cough**  A male-dominated (4:1) syndrome, cough headache is characterized by transient, severe headache with photophobia, nausea, and vomiting are present. Typically, cough headache is characterized by transient, severe headache with photophobia, nausea, and vomiting are present. Particularly easy to mistake for migraine in that the cardinal symptoms of pounding headache, photophobia, nausea, and vomiting are present. →A detailed discussion of meningitis can be found in Chaps. 360 and 361.

**OTHER CAUSES OF HEADACHE**  (Systemic Illness)  There is hardly any illness that is never manifested by headache; however, some illnesses are frequently associated with headache. These include infectious mononucleosis, systemic lupus erythematosus, chronic pulmonary failure with hypercapnia (early morning headaches), Hashimoto’s thyroiditis, inflammatory bowel disease, many of the illnesses associated with HIV, and the acute blood pressure elevations that occur in pheochromocytoma and in malignant hypertension. The last two examples are the exceptions to the generalization that hypertension per se is a very uncommon cause of headache; diastolic pressures of at least 120 mmHg are requisite for hypertension to cause headache. Persistent headache and fever are often the manifestations of an acute systemic viral infection; if the neck is supple in such a patient, lumbar puncture may be deferred. Some drugs and drug-withdrawal states, e.g., oral contraceptives, ovulation-promoting medications, and glucocorticoid withdrawal, are also associated with headache in some individuals.

**Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)**  Headache, clinically resembling that of brain tumor, is a common presenting symptom of pseudotumor cerebri, a disorder of raised intracranial pressure probably resulting from impaired cerebrospinal fluid (CSF) absorption by the arachnoid villi. Morning headaches that are worsened by coughing and straining are typical. The pain is sometimes retroocular and worsened by eye movements. Transient visual obscurations and papilledema with enlarged blind spots and loss of peripheral visual fields are additional manifestations. Most patients are young, female, and obese. They often have a history of exposure to provoking agents such as vitamin A and glucocorticoids. →Treatment of idiopathic intracranial hypertension is discussed in Chap. 25.

**Cough**  A male-dominated (4:1) syndrome, cough headache is characterized by transient, severe headache with photophobia, nausea, and vomiting are present. Typically, cough headache is characterized by transient, severe headache with photophobia, nausea, and vomiting are present. Particularly easy to mistake for migraine in that the cardinal symptoms of pounding headache, photophobia, nausea, and vomiting are present. →A detailed discussion of meningitis can be found in Chaps. 360 and 361.

**GRAFT INJURY**  The term graft injury implies either cerebral metastases and/or carcinomatous meningitis. Head pain appearing abruptly after bending, lifting, or coughing can be due to a posterior fossa mass (or a Chiari malformation). →A detailed discussion of brain tumors can be found in Chap. 358.

**TEMPORAL ARTERITIS**  (See also Chaps. 25 and 306) Temporal (giant cell) arteritis is an inflammatory disorder of arteries that frequently involves the extracranial carotid circulation. This is a common disorder of the elderly; its annual incidence is 77:100,000 in individuals aged 50 and older. The average age of onset is 70 years, and women account for 65% of cases. About half of patients with untreated temporal arteritis develop blindness due to involvement of the ophthalmic artery and its branches; indeed, the ischemic optic neuropathy induced by giant cell arteritis is the major cause of rapidly developing bilateral blindness in patients >60 years. Because treatment with glucocorticoids is effective in preventing this complication, prompt recognition of this disorder is important. Typical presenting symptoms include headache, polymyalgia rheumatica (Chap. 306), jaw claudication, fever, and weight loss. Headache is the dominant symptom and often appears in association with malaise and muscle aches. Head pain may be unilateral or bilateral and is located temporarily in 50% of patients but may involve any and all aspects of the cranium. Pain usually appears gradually over a few hours before peak intensity is reached; occasionally, it is explosive in onset. The quality of pain is only seldom throbbing; it is almost invariably described as dull and boring with superimposed episodic ice pick–like lancinating pains similar to the sharp pains that appear in migraine. Most patients can recognize that the origin of their head pain is superficial, external to the skull, rather than originating deep within the cranium (the pain site for migraineurs). Scalp tenderness is present, often to a marked degree; brushing the hair or resting the head on a pillow may be impossible because of pain. Headache is usually worse at night and is often aggravated by exposure to cold. Reddened, tender nodules or red streaking of the skin overlying the temporal arteries may be found in patients with headache, as is tenderness of the temporal or, less commonly, the occipital arteries.

The erythrocyte sedimentation rate (ESR) is often, though not always, elevated; a normal ESR does not exclude giant cell arteritis. A temporal artery biopsy and treatment with prednisone at 80 mg daily for the first 4 to 6 weeks should be initiated when clinical suspicion is high. The prevalence of migraine among the elderly is substantial, considerably higher than that of giant cell arteritis. Migraineurs often report amelioration of their headaches with prednisone, so that one must be cautious about interpreting the therapeutic response.
that when a patient is upright there is probably dilution and tension placed on the brain’s anchoring structures, the pain-sensitive dural sinuses, resulting in pain. Intracranial hypotension often occurs, but severe lumbar puncture headache may be present even in patients who have normal CSF pressure.

Treatment with intravenous caffeine sodium benzoate given over a few minutes as a 500-mg dose will promptly terminate headache in 75% of patients; a second dose given in 1 h brings the total success rate to 85%. An epidural blood patch accomplished by injection of 15 mL of autologous whole blood rarely fails for those who do not respond to caffeine. The mechanism for these treatment effects is not elucidated (Chap. 349).

**TENSION-TYPE HEADACHE**

The term tension-type headache is still commonly used to describe a chronic headache syndrome characterized by bilateral, tight, bandlike discomfort. Patients may report that the head feels as if it is in a vise or that the posterior neck muscles are tight. The pain typically builds slowly, fluctuates in severity, and may persist more or less continuously for many days. Exertion does not usually worsen the headache. The headache may be episodic or chronic (i.e., present >15 days per month). Tension-type headache is common in all age groups, and females tend to predominate. In some patients, anxiety or depression coexist with tension headache.

The pathophysiologic basis of tension-type headache remains unknown. Many investigators believe that periodic tension headache is biologically indistinguishable from migraine, whereas others believe that tension-type headache and migraine are two distinct clinical entities. Abnormalities of cervical and temporal muscle contraction are likely to exist, but the exact nature of the dysfunction has not yet been elucidated.

Relaxation almost always relieves tension-type headaches. Patients should be encouraged to find a means of relaxation, which, for a given individual, could include bed rest, massage, and/or formal biofeedback training. Pharmacologic treatment consists of either simple analgesics and/or muscle relaxants. Ibuprofen and naproxen sodium are useful treatments for most individuals. When simple over-the-counter analgesics such as acetaminophen, aspirin, and/or other nonsteroidal anti-inflammatory drugs (NSAIDs) alone fail, the addition of butalbital and caffeine (in a combination product such as Fiorinal, Fioricet) to these analgesics may be effective. A list of commonly used analgesics for tension-type headaches is presented in Table 14-4. For chronic tension-type headache, prophylactic therapy is recommended. Low doses of amitriptyline (10 to 50 mg at bedtime) can provide effective prophylaxis.

**MIGRAINE**

Migraine, the most common cause of headache, affects approximately 15% of women and 6% of men. A useful definition of migraine is a benign and recurring syndrome of headache, nausea, vomiting, and/or other symptoms of neurologic dysfunction in varying admixtures (Table 14-5). Migraine can often be recognized by its activators (red wine, menses, hunger, lack of sleep, glare, estrogen, worry, perfumes, let-down periods) and its deactivators (sleep, pregnancy, exhilaration, trips). A classification of the many subtypes of migraine, as defined by the International Headache Society, is shown in Table 14-1.

Severe headache attacks, regardless of cause, are more likely to be described as throbbing and associated with vomiting and scalp tenderness. Milder headaches tend to be nondescript—tight, bandlike discomfort often involving the entire head—the profile of tension-type headache.

**Pathogenesis**

**Genetic Basis of Migraine**

Migraine has a definite genetic predisposition. Specific mutations leading to rare causes of vascular headache have been identified (Table 14-6). For example, the MELAS syndrome consists of a mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes and is caused by an A → G point mutation in the mitochondrial gene encoding for tRNA^Leu(UUR) at nucleotide position 3243. Episodic migraine-like headaches are another
Familial hemiplegic migraine (FHM) is characterized by episodes of recurrent hemiparesis or hemiplegia during the aura phase of a migraine headache. Other associated symptoms may include hemianesthesia or paresthesias; hemianopic visual field disturbances; dysphasia; and variable degrees of drowsiness, confusion, and/or coma. In severe attacks, these symptoms can be quite prolonged and persist for days or weeks, but characteristically they last for only 30 to 60 min and are followed by a unilateral throbbing headache.

Approximately 50% of cases of FHM appear to be caused by mutations within the CACNL1A4 gene on chromosome 19, which encodes a P/Q type calcium channel subunit expressed only in the central nervous system. The gene is very large (>300 kb in length) and consists of 47 exons. Four distinct point mutations have been identified within the gene (in five different families) that cosegregate with the clinical diagnosis of FHM. Analysis of haplotypes in the two families with the same mutation suggest that each mutation arose independently rather than representing a founder effect. CACNL1A4 is likely to play a role in calcium-induced neurotransmitter release and/or contraction of smooth muscle. Different mutations within this gene are the cause of two other neurogenic disorders, spinocerebellar ataxia type 6 and episodic ataxia type 2 (Chap. 352).

In a genetic association study, a NcoI polymorphism in the gene encoding the D2 dopamine receptor (DRD2) was overrepresented in a population of patients with migraine with aura compared to a control group of nonmigraineurs, suggesting that susceptibility to migraine with aura is modified by certain DRD2 alleles. In a Sardinian population, an association between different DRD2 alleles and migraine has also been demonstrated. These initial studies suggest that variations in dopamine receptor regulation and/or function may alter susceptibility to migraine since molecular variations within the DRD2 gene have been associated with variations in dopaminergic function.

However, since not all individuals with the implicated DRD2 genotypes suffer from migraine with aura, additional genes or factors must also be involved. Migraine is likely to be a complex disorder with polygenic inheritance and a strong environmental component.

**The Vascular Theory of Migraine** It was widely held for many years that the headache phase of migrainous attacks was caused by extracranial vasodilatation and that the neurologic symptoms were produced by intracranial vasoconstriction (i.e., the “vascular” hypothesis of migraine). Regional cerebral blood flow studies have shown that in patients with classic migraine there is, during attacks, a modest cortical hyperperfusion that begins in the visual cortex and spreads forward at a rate of 2 to 3 mm/min. The decrease in blood flow averages 25 to 30% (insufficient to explain symptoms on the basis of ischemia) and progresses anteriorly in a wavelike fashion independent of the topography of cerebral arteries. The wave of hyperperfusion persists for 4 to 6 h, appears to follow the convolutions of the cortex, and does not cross the central or lateral sulcus, progressing to the frontal lobe via the insula. Perfusion of subcortical structures is normal. Contralateral neurologic symptoms appear during temporoparietal hyperperfusion; at times, hyperperfusion persists in these regions after symptoms cease. More often, frontal spread continues as the headache phase begins. A few patients with classic migraine show no flow abnormalities; an occasional patient has developed focal ischemia sufficient to cause symptoms. However, focal ischemia does not appear to be necessary for focal symptoms to occur.

The ability of these changes to induce the symptoms of migraine has been questioned. Specifically, the decrease in blood flow that is observed does not appear to be significant enough to cause focal neurologic symptoms. Second, the increase in blood flow per se is not painful, and vasodilatation alone cannot account for the local edema and focal tenderness often observed in migraineurs. Moreover, in migraine without aura, no flow abnormalities are usually seen. Thus, it is unlikely that simple vasodistraction and vasodilatation are the fundamental pathophysiologic abnormalities in migraine. However, it is clear that cerebral blood flow is altered during certain migraine attacks, and these changes may explain some, but clearly not all, of the clinical syndrome of migraine.

**The Neuronal Theory of Migraine** Fortification spectrum is a migraine aura characterized by a slowly enlarging visual scotoma with luminous edges (see below). It is believed to result from spreading depression, a slowly moving (2 to 3 mm/min), potassium-liberating depression of cortical activity, preceded by a wavefront of increased metabolic activity. Spreading depression can be produced by a variety of experimental stimuli, including hypoxia, mechanical trauma, and the topical application of potassium. These observations suggest that neuronal abnormalities could be the cause of a migraine attack.

Physiologically, electrical stimulation near dorsal raphe neurons in the upper brainstem can result in migraine-like headaches. Blood flow in the pons and midbrain increases focally during migraine headache episodes; this alteration probably results from increased activity of cells in the dorsal raphe and locus coeruleus. There are projections from the dorsal raphe that terminate on cerebral arteries and alter cerebral blood flow. There are also major projections from the dorsal raphe to important visual centers, including the lateral geniculate body, superior colliculus, retina, and visual cortex. These various serotonergic projections may represent the neural substrate for the circulatory and visual characteristics of migraine. The dorsal raphe cells stop firing during deep sleep, and sleep is known to ameliorate migraine; the antimigraine prophylactic drugs also inhibit activity of the dorsal raphe cells through a direct or indirect agonist effect.

Positron emission tomography (PET) scan studies have demon-
strated that midbrain structures near the dorsal raphe are activated during a migraine attack. In one study of acute migraine, an injection of sumatriptan relieved the headache but did not alter the brainstem changes noted on the PET scan. These data suggest that a “brainstem generator” may be the cause of migraine and that certain antimigraine medications may not interfere with the underlying pathologic process in migraine.

**THE TRIGEMINOVASCULAR SYSTEM IN MIGRAINE**

Activation of cells in the trigeminal nucleus caudalis in the medulla (a pain-processing center for the head and face region) results in the release of vasoactive neuropeptides, including substance P and calcitonin gene–related peptide, at vascular terminations of the trigeminal nerve. These peptide neurotransmitters have been proposed to induce a sterile inflammation that activates trigeminal nociceptive afferents originating on the vessel wall, further contributing to the production of pain. This provides a potential mechanism for the soft tissue swelling and tenderness of blood vessels that accompany migraine attacks. However, numerous pharmacologic agents that are effective in preventing or reducing inflammation in this animal model (e.g., selective 5-HT\(_{1D}\) agonists, NK-1 antagonists, endothelin antagonists) have failed to demonstrate any clinical efficacy in migraine trials.

**5-HYDROXYTRYPTAMINE IN MIGRAINE**

Pharmacologic and other data point to the involvement of the neurotransmitter 5-hydroxytryptamine (5-HT; also known as serotonin) in migraine. Approximately 40 years ago, methysergide was found to antagonize certain peripheral actions of 5-HT and was introduced as the first drug capable of preventing migraine attacks. Subsequently, it was found that platelet levels of 5-HT fall consistently at the onset of headache and that drugs that cause 5-HT to be released may trigger migrainous episodes. Such changes in circulating 5-HT levels proved to be pharmacologically trivial, however, and interest in the humoral role of 5-HT in migraine declined.

More recently, interest in the role of 5-HT in migraine has been renewed due to the introduction of the triptan class of antimigraine drugs. The triptans are designed to stimulate selectively a particular subpopulation of 5-HT receptors. At least 14 specific 5-HT receptors exist in humans. The triptans (e.g., naratriptan, rizatriptan, sumatriptan, and zolmitriptan) are potent agonists of 5-HT\(_{1B}\), 5-HT\(_{1D}\), and 5-HT\(_{1F}\) receptors and are less potent at 5-HT\(_{1A}\) and 5-HT\(_{1E}\) receptors. A growing body of data indicates that the antimigraine efficacy of the triptans relates to their ability to stimulate 5-HT\(_{1B}\) receptors, which are located on both blood vessels and nerve terminals. Selective 5-HT\(_{1B}\) receptor agonists have, thus far, failed to demonstrate clinical efficacy in migraine. Triptans that are weak 5-HT\(_{1A}\) agonists are also effective in migraine; however, only 5-HT\(_{1B}\) efficacy is currently thought to be essential for antimigraine efficacy.

**DOPAMINE IN MIGRAINE**

A growing body of biologic, pharmacologic, and genetic data supports a role for dopamine in the pathophysiology of certain subtypes of migraine. Most migraine symptoms can be induced by dopaminergic stimulation. Moreover, there is dopamine receptor hypersensitivity in migraineurs, as demonstrated by the induction of yawning, nausea, vomiting, hyponatremia, and other symptoms of a migraine attack by dopaminergic agonists at doses that do not affect nonmigraineurs. Conversely, dopamine receptor antagonists are effective therapeutic agents in migraine, especially when given parenterally or concurrently with other antimigraine agents. As noted above, genetic data also suggest that molecular variations within dopamine receptor genes play a modifying role in the pathophysiology of migraine with aura. Therefore, modulation of dopaminergic neurotransmission should be considered in the therapeutic management of migraine.

**THE SYMPATHETIC NERVOUS SYSTEM IN MIGRAINE**

Alterations occur within the sympathetic nervous system (SNS) of migraineurs before, during, and between migraine attacks. Factors that activate the SNS are also triggers for migraine. Specific examples include environmental changes (e.g., stress, sleep patterns, hormonal shifts, hypoglycemia) and agents that cause release and a secondary depletion of peripheral catecholamines (e.g., tyramine, phenylethylamine, fenfluramine, m-chlorophenylpiperazine, and reserpine). By contrast, effective therapeutic approaches to migraine share an ability to mimic and/or enhance the effects of norepinephrine in the peripheral SNS. For example, norepinephrine itself, sympathomimetics (e.g., isometheptene), monoamine oxidase inhibitors (MAOIs), and reuptake blockers alleviate migraine. Dopamine antagonists, prostaglandin synthesis inhibitors, and adenosine antagonists are pharmacologic agents effective in the acute treatment of migraine. These drugs block the negative feedback inhibition or norepinephrine release induced by endogenous dopamine, prostaglandins, and adenosine. Therefore, migraine susceptibility may relate to genetically based variations in the ability to maintain adequate concentrations of certain neurotransmitters within postganglionic sympathetic nerve terminals. This hypothesis has been called the *empty neuron theory* of migraine.

**Clinical Features ■ MIGRAINE WITHOUT AURA (COMMON MIGRAINE)**

In this syndrome no focal neurologic disturbance precedes the recurrent headaches. Migraine without aura is by far the more frequent type of vascular headache. The International Headache Society criteria for migraine include moderate to severe head pain, pulsating quality, unilateral location, aggravation by walking stairs or similar routine activity, attendant nausea and/or vomiting, photophobia and phonophobia, and multiple attacks, each lasting 4 to 72 h.

**MIGRAINE WITH AURA (CLASSIC MIGRAINE)**

In this syndrome headache is associated with characteristic premonitory sensory, motor, or visual symptoms. Focal neurologic disturbances are more common during headache attacks than as prodromal symptoms. Focal neurologic disturbances without headache or vomiting have come to be known as *migraine equivalents* or *migraine accompaniments* and appear to occur more commonly in patients between the ages of 40 and 70 years. The term *complicated migraine* has generally been used to describe migraine with dramatic transient focal neurologic features or a migraine attack that leaves a persisting residual neurologic deficit.

The most common premonitory symptoms reported by migraineurs are visual, arising from dysfunction of occipital lobe neurons. Scotomas and/or hallucinations occur in about one-third of migraineurs and usually appear in the central portions of the visual fields. A highly characteristic syndrome occurs in about 10% of patients; it usually begins as a small paracentral scotoma, which slowly expands into a “C” shape. Luminous angles appear at the enlarging outer edge, becoming colored as the scintillating scotoma expands and moves toward the periphery of the involved half of the visual field, eventually disappearing over the horizon of peripheral vision. The entire process lasts 20 to 25 min. This phenomenon is pathognomonic for migraine and has never been described in association with a cerebral structural anomaly. It is commonly referred to as a *fortification spectrum* because the serrated edges of the hallucinated “C” seemed to resemble a fortified town with bastions around it; spectrum is used in the sense of an apparition or specter.

**BASILAR MIGRAINE**

Symptoms referable to a disturbance in brainstem function, such as vertigo, dysarthria, or diplopia, occur as the only neurologic symptoms of the attack in about 25% of patients. A dramatic form of basilar migraine (Bickerstaff’s migraine) occurs primarily in adolescent females. Episodes begin with total blindness accompanied or followed by admixtures of vertigo, ataxia, dysarthria, tinnitus, and distal and perioral paresthesias. In about one-quarter of patients, a confusional state supervenes. The neurologic symptoms usually persist for 20 to 30 min and are generally followed by a throbbing occipital headache. This basilar migraine syndrome is now known also to occur in children and in adults over age 50. An altered sensorium may persist for as long as 5 days and may take the form of confusional states superficially resembling psychotic reactions. Full recovery after the episode is the rule.

**CAROTIDYNYA**

The carotidynia syndrome, sometimes called *lower-half headache* or *facial migraine*, is most common among older patients,
with the incidence peaking in the fourth through sixth decades. Pain is usually located at the jaw or neck, although sometimes periorbital or maxillary pain occurs; it may be continuous, deep, dull, and aching, and it becomes pounding or throbbing episodically. There are often superimposed sharp, ice pick–like jabs. Attacks occur one to several times per week, each lasting several minutes to hours. Tenderness and prominent pulsations of the cervical carotid artery and soft tissue swelling overlying the carotid are usually present ipsilateral to the pain; many patients also report throbbing ipsilateral headache concurrent with carotidynia attacks as well as between attacks. Dental trauma is a common precipitant of this syndrome. Carotid artery involvement is often noted with carotidynia attacks as well as between attacks. Dental trauma can often be associated with carotid tenderness at several points on the side most often involved during hemicranial migraine attacks.

### Nonpharmacologic Approaches for All Migraineurs

Migraine can often be managed to some degree by a variety of nonpharmacologic approaches (Table 14-7). The measures that apply to a given individual should be used routinely since they provide a simple, cost-effective approach to migraine management. Patients with migraine do not encounter more stress than headache-free individuals; overresponsiveness to stress appears to be the issue. Since the stresses of everyday living cannot be eliminated, lessening one’s response to stress by various techniques is helpful for many patients. These include yoga, transcendental meditation, hypnosis, and conditioning techniques such as biofeedback. For most patients, this approach is, at best, an adjunct to pharmacotherapy. Avoidance of migraine trigger factors may also provide significant prophylactic benefits. Unfortunately, these measures are unlikely to prevent all migraine attacks. When these measures fail to prevent an attack, pharmacologic approaches are then needed to abort an attack.

### Pharmacologic Treatment of Acute Migraine

The mainstay of pharmacologic therapy is the judicious use of one or more of the many drugs that are effective in migraine. The selection of the optimal regimen for a given patient depends on a number of factors, the most important of which is the severity of the attack (Table 14-8). Mild migraine attacks can usually be managed by oral agents; the average efficacy rate is 50 to 70%. Severe migraine attacks may require parenteral therapy. Most drugs effective in the treatment of migraine are members of one of three major pharmacologic classes: anti-inflammatory agents, 5-HT1 agonists, and dopamine antagonists.

Table 14-9 lists specific drugs effective in migraine. In general, an adequate dose of whichever agent is chosen should be used as soon as possible after the onset of an attack. If additional medication is required within 60 min because symptoms return or have not abated, the initial dose should be increased for subsequent attacks. Migraine therapy must be individualized for each patient; a standard approach for all patients is not possible. A therapeutic regimen may need to be constantly refined and personalized until one is identified that provides the patient with rapid, complete, and consistent relief with minimal side effects.

### Nonsteroidal Anti-Inflammatory Agents

Both the severity and duration of a migraine attack can be reduced significantly by anti-inflammatory agents. Indeed, many undiagnosed migraineurs are self-treated with nonprescription anti-inflammatory agents. Indeed, many undiagnosed migraineurs are self-treated with nonprescription anti-inflammatory agents (Table 14-4). A general consensus is that NSAIDs are most effective when taken early in the migraine attack. However, the effectiveness of anti-inflammatory agents in migraine is usually less than optimal in moderate or severe migraine attacks. The combination of acetaminophen, aspirin, and caffeine (Excedrin Migraine) has been approved for use by the U.S. Food and Drug Administration (FDA) for the treatment of mild to moderate migraine. The combination of aspirin and metoclopramide has been shown to be equivalent to a single dose of sumatriptan. Major side effects of NSAIDs include dyspepsia and gastrointestinal irritation.

### 5-HT1 Agonists

Stimulation of 5-HT1 receptors can stop an acute migraine attack. Ergotamine and dihydroergotamine are nonselective receptor agonists, while the series of drugs known as triptans are selective 5-HT1 receptor agonists. A variety of triptans (e.g., naratriptan, rizatriptan, sumatriptan, zolmitriptan, almotriptan, frovatriptan) are now available for the treatment of migraine (Table 14-9).

Each of the triptan class of drugs has similar pharmacologic properties but varies slightly in terms of clinical efficacy. Rizatriptan and almotriptan are the fastest acting and most efficacious of the triptans currently available in the United States. Sumatriptan and zolmitriptan have similar rates of efficacy as well as time to onset, whereas naratriptan and frovatriptan are the slowest acting and the least efficacious. Clinical efficacy appears to be related more to the T_{max} (time to peak plasma level) than to the potency, half-life, or bioavailability (Table 14-10). This observation is in keeping with a significant body of data indicating that faster-acting analogues are more efficacious than slower-acting agents.

Unfortunately, monotherapy with a selective oral 5-HT1 agonist does not result in rapid, consistent, and complete relief of migraine in all patients. Triptans are not effective in migraine with aura unless given after the aura is completed and the headache initiated. Side effects, although often mild and transient, occur in up to 89% of patients. Moreover, 5-HT1 agonists are contraindicated in individuals with a history of cardiovascular disease. Recurrence of headache is a major limitation of triptan use, and occurs at least occasionally in 40 to 78% of patients.

Ergotamine preparations offer a nonselective means of stimulating 5-HT1 receptors. A nauseating dose of ergotamine should be sought since a dose that provokes nausea is too high and may intensify head pain. Except for a sublingual formulation of ergotamine (Ergo-

the triptans, it is difficult to assess the clinical efficacy of this symp-
thomimetic compound in comparison to other agents.

**Nasal**  A nasal preparation of butorphanol is available for the treatment of acute pain. As with all narcotics, the use of nasal butorphanol should be limited to a select group of migraineurs, as described below.

**Parenteral**  Narcotics are effective in the acute treatment of migraine. For example, intravenous meperidine (Demerol), 50 to 100 mg, is given frequently in the emergency room. This regimen “works” in the sense that the pain of migraine is eliminated. However, this regimen is clearly suboptimal in patients with recurrent headache for two major reasons. First, narcotics do not treat the underlying headache mechanism; rather, they act at the thalamic level to alter pain sensation. Second, the recurrent use of narcotics can lead to significant problems. In patients taking oral narcotics such as oxycodeone (Percodan) or hydrocodone (Vicodin), narcotic addiction can greatly confuse the treat-
ment of migraine. The headache that results from narcotic craving and/or withdrawal can be difficult to distinguish from chronic migraine. Therefore, it is recommended that narcotic use in migraine be limited to patients with severe, but infrequent, headaches that are unresponsive to other pharmacologic approaches.

**Prophylactic Treatment of Migraine**  A substantial number of drugs are now available that have the capacity to stabilize migraine (Table 14-11). The decision of whether to use this approach depends on the frequency of attacks and on how well acute treatment is working. The occurrence of at least three attacks per month could be an indication for this approach. Drugs must be taken daily, and there is usually a lag of at least 2 to 6 weeks before an effect is seen. The drugs that have been approved by the FDA for the prophylactic treatment of migraine include propranolol, timolol, sodium valproate, and methysergide. In addition, a number of other drugs appear to display pro-
phylactic efficacy. This group of drugs includes amitriptyline, nortriptyline, verapamil, phenelzine, gabapentin, and cyproheptadine. Phenelzine and methysergide are usually reserved for recalcitrant cases because of their serious potential side effects. Phenelzine is an MAOI; therefore, tyramine-containing foods, decongestants, and meperidine are contraindicated. Methysergide may cause retroperitoneal or cardiac valvular fibrosis when it is used for >8 months, thus monitoring is required for patients using this drug; the risk of the fibrotic com-
plication is required for patients using this drug; the risk of the fibrotic com-
plication is 1:1500 and is likely to reverse after the drug is stopped.

The probability of success with any one of the antimigraine drugs is 50 to 75%; thus, if one drug is assessed each month, there is a good chance that effective stabilization will be achieved within a few months. Many patients are managed adequately with low-dose ami-
triptyline, propranolol, or valproate. If these agents fail or lead to un-
acceptable side effects, then methysergide or phenelzine can be used. Once effective stabilization is achieved, the drug is continued for 5 to 6 months and then slowly tapered to assess the continued need. Many patients are able to discontinue medication and experience fewer and milder attacks for long periods, suggesting that these drugs may alter the natural history of migraine.

**CLUSTER HEADACHE**  A variety of names have been used for this condition, including *Raeder’s syndrome*, histamine cephalalgia, and *sphenopalatine neuralgia*. Cluster headache is a distinctive and treat-
able vascular headache syndrome. The episodic type is most common and is characterized by one to three short-lived attacks of periocular pain per day over a 4- to 8-week period, followed by a pain-free in-
terval that averages 1 year. The chronic form, which may begin de
 novo or several years after an episodic pattern has become established, is characterized by the absence of sustained periods of remission. Each type may transform into the other. Men are affected seven to eight times more often than women; hereditary factors are usually absent. Although the onset is generally between ages 20 and 50, it may occur as early as the first decade of life. Propranolol and amitriptyline are largely ineffective. Lithium is beneficial for cluster headache and ineffective in migraine. The cluster syndrome is thus clinically, geneti-
cally, and therapeutically different from migraine. Nevertheless, mixed features of the two disorders are occasionally present, suggesting some common elements to their pathogenesis.

**Clinical Features**  Periorbital or, less commonly, temporal pain begins without warning and reaches a crescendo within 5 min. It is often excruciating in intensity and is deep, nonfluctuating, and explosive in quality; only rarely is it pulsatile. Pain is strictly unilateral and usually affects the same side in subsequent months. Attacks last from 30 min to 2 h; there are often associated symptoms of homolateral lacrimation, reddening of the eye, nasal stuffiness, lid ptosis, and nausea. Alcohol provokes attacks in about 70% of patients but ceases to be provocative when the bout remits; this on-off vulnerability to alcohol is pathog-
nomonic of cluster headache. Only rarely do foods or emotional factors precipitate pain, in contrast to migraine.

There is a striking periodicity of attacks in at least 85% of patients. At least one of the daily attacks of pain recurrs at the same hour each day for the duration of a cluster bout. Onset is nocturnal in about 50% of the cases, and then the pain usually awakens the patient within 2 h of falling asleep.

**Pathogenesis**  No consistent cerebral blood flow changes accompany attacks of pain. Perhaps the strongest evidence for a central mechanism is the periodicity of attacks; the existence of a central mechanism is also suggested by the observation that autonomic symptoms that accom-
pany the pain are bilateral and are more severe on the painful side. The hypothalamus is probably the site of activation in this disorder. The posterior hypothalamus contains cells that regulate autonomic functions, and the anterior hypothalamus contains cells (in the supra-
chiasmatic nuclei) that constitute the principal circadian pacemaker in mammals. Activation of both is necessary to explain the symptoms of cluster headache. The pacemaker is modulated via serotoninergic dorsal raphe projections. It can be concluded tentatively that both migraine and cluster headache result from abnormal serotoninergic neurotrans-
mis, albeit at different loci.

* Not specifically indicated for migraine by the U.S. Food and Drug Administration.

**TREATMENT**  The most satisfactory treatment is the administration of drugs to pre-
vent cluster attacks until the bout is over. Effective prophylactic drugs are prednisone, lithium, methysergide, ergotamine, sodium valproate, and verapamil. Lithium (600 to 900 mg daily) appears to be particu-
larly useful for the chronic form of the disorder. A 10-day course of prednisone, beginning at 60 mg daily for 7 days followed by a rapid taper, may interrupt the pain bout for many patients. When ergotamine is used, it is most effective when given 1 to 2 h before an expected...
The importance of back and neck pain in our society is underscored by the following: (1) the cost of back pain in the United States is between $20 and $50 billion annually, (2) back symptoms are the most common cause of disability in patients under 45 years of age, (3) low back pain is the second most common reason for visiting a physician in the United States, and (4) approximately 1% of the U.S. population is chronically disabled because of back pain.

ANATOMY OF THE SPINE

The anterior portion of the spine consists of cylindrical vertebral bodies separated by intervertebral disks and held together by the anterior and posterior longitudinal ligaments. The intervertebral disks are composed of a central gelatinous nucleus pulposus surrounded by a tough cartilagenous ring, the annulus fibrosis; disks are responsible for 25% of spinal column length (Figs. 15-1 and 15-2). The disks are largest in the cervical and lumbar regions where movements of the spine are greatest. The disks are elastic in youth and allow the bony vertebrae to move easily upon each other. Elasticity is lost with age. The function of the anterior spine is to absorb the shock of body movements such as walking and running.

The posterior portion of the spine consists of the vertebral arches and seven processes. Each arch consists of paired cylindrical pedicles anteriorly and paired laminae posteriorly. The vertebral arch gives rise to two transverse processes laterally, one spinous process posteriorly, plus two superior and two inferior articular facets. The functions of the posterior spine are to protect the spinal cord and nerves within the spinal canal and to stabilize the spine by providing sites for the attachment of muscles and ligaments. The contraction of muscles attached to the spinous and transverse processes produces a system of pulleys and levers that results in flexion, extension, and lateral bending movements of the spine.

Nerve root injury (radiculopathy) is a common cause of neck, arm, low back, and leg pain. The nerve roots exit at a level above their respective vertebral bodies in the cervical region (the C7 nerve root exits at the C6-C7 level) and below their respective vertebral bodies in the thoracic and lumbar regions (the T1 nerve root exits at the T1-T2 level). The cervical nerve roots follow a relatively short intraspinal course before exiting. By contrast, because the spinal cord ends at the vertebral L1 or L2 level, the lumbar nerve roots follow a long intraspinal course and can be injured anywhere from the upper lumbar spine to their exit at the intervertebral foramen. For example, it is common for disk herniation at the L4-L5 level to produce compression of the S1 nerve root (Fig. 15-3).

Pain-sensitive structures in the spine include the periosteum of the vertebrae, dura, facet joints, annulus fibrosus of the intervertebral disk, epidural veins, and the posterior longitudinal ligament. The nucleus pulposus of the intervertebral disk is not pain-sensitive under normal circumstances. Pain sensation is conveyed by the sinuvertebral nerve that arises from the spinal nerve at each spine segment and reenters the spinal canal through the intervertebral foramen at the same level. Disease of these diverse pain-sensitive spine structures may explain many cases of back pain without nerve root compression. The lumbar and cervical spine possess the greatest potential for movement and injury.

APPROACH TO THE PATIENT

Types of Back Pain

Understanding the type of pain experienced by the patient is the essential first step. Attention is also focused on identification of risk factors for serious underlying diseases.

Local pain is caused by stretching of pain-sensitive structures that compress or irritate sensory nerve endings. The site of the pain is near the affected part of the back.

Pain referred to the back may arise from abdominal or pelvic viscera. The pain is usually described as primarily abdominal or pelvic but is accompanied by back pain and usually unaffected by posture. The patient may occasionally complain of back pain only.

Pain of spine origin may be located in the back or referred to the buttocks or legs. Diseases affecting the upper lumbar spine tend to refer pain to the lumbar region, groin, or anterior thighs. Diseases affecting the lower lumbar spine tend to produce pain referred to the buttocks, posterior thighs, or rarely the calves or feet. Provocative injections into the pain-sensitive structures of the spine may produce leg pain that does not follow a dermatomal distribution. This “sclerotomal” pain may explain instances in which back and leg pain is unaccompanied by evidence of nerve root compression.

Radicular back pain is typically sharp and radiates from the spine to the leg within the territory of a nerve root (see “Lumbar Disk Disease,” below). Coughing, sneezing, or voluntary contraction of abdominal muscles (lifting heavy objects or...
Back pain at rest or unassociated with specific postures should raise the index of suspicion for an underlying serious cause (e.g., spine tumor, fracture, infection, or referred pain from visceral structures). Knowledge of the circumstances associated with the onset of back pain is important when weighing possible serious underlying causes for the pain. Some patients involved in accidents or work-related injuries may exaggerate their pain for the purpose of compensation or for psychological reasons.

Examination of the Back A physical examination that includes the abdomen and rectum is advisable. Back pain referred from visceral organs may be reproduced during palpation of the abdomen [pancreatitis, abdominal aortic aneurysm (AAA)] or percussion over the costovertebral angles (pyelonephritis, adrenal disease).

The normal spine has a thoracic kyphosis, lumbar lordosis, and cervical lordosis. Exaggeration of these normal alignments may result in hyperkyphosis (lameback) of the thoracic spine or hyperlordosis (swayback) of the lumbar spine. Spasm of lumbar paraspinal muscles results in flattening of the usual lumbar lordosis. Inspection may reveal lateral curvature of the spine (scoliosis) or an asymmetry in the paraspinal muscles, suggesting muscle spasm. Taut paraspinal muscles limit motion of the lumbar spine. Back pain of bony spine origin is often reproduced by palpation or percussion over the spinous process of the affected vertebrae.

Forward bending is frequently limited by paraspinal muscle spasm. Flexion of the hips is normal in patients with lumbar spine disease, but flexion of the lumbar spine is limited and sometimes painful. Lateral bending to the side opposite the injured spinal element may stretch the damaged tissues, worsen pain, and limit motion. Hyperextension of the spine (with the patient prone or standing) is limited when nerve root compression or bony spine disease is present.

Pain from hip disease may resemble the pain of lumbar spine disease. Hip pain can be reproduced by internal and external rotation at the hip with the knee and hip in flexion (Patrick sign) and by tapping the heel with the examiner’s palm while the leg is extended.

With the patient lying flat, passive flexion of the extended leg at the hip stretches the L5 and S1 nerve roots and the sciatic nerve. Passive dorsiflexion of the foot during the maneuver adds to the stretch. While flexion to at least 80° is normally possible without causing pain, tight hamstrings may be a source of pain in some patients. The straight leg–raising (SLR) test is positive if the maneuver reproduces the patient’s usual back or limb pain. Eliciting the SLR sign in the sitting position may help determine if the finding is reproducible. The patient may describe pain in the low back, buttocks, posterior thigh, or lower leg, but the key feature is reproduction of the patient’s usual pain. The crossed SLR sign is positive when flexion of one leg reproduces the pain in the opposite leg or buttocks. The crossed SLR sign is less sensitive but more specific for disk herniation than the SLR sign. The nerve or nerve root lesion is always on the side of the pain. The reverse SLR sign is elicited by standing the patient next to the examination table and passively extending each leg. This maneuver, which stretches the L2-L4 nerve roots and the femoral nerve, is considered positive if the patient’s usual back or limb pain is reproduced.

The neurologic examination includes a search for weakness, muscle atrophy, focal reflex changes, diminished sensation in the legs, and signs of spinal cord injury. The examiner should be alert to the possibility of breakaway weakness, defined as fluctuating levels of strength in one or more muscle groups on examination. The weakness may be due to pain or a combination of pain and underlying true weakness. Breakaway weakness without pain is due to lack of effort. In uncertain cases, electromyography (EMG) can determine whether or not true weakness is present. Findings with specific nerve root lesions are shown in Table 15-1 and are discussed below.

**Laboratory, Imaging, and EMG Studies** Routine laboratory studies such as a complete blood count, erythrocyte sedimentation rate, chem-

<sup>a</sup> Reverse straight leg–raising sign present—see “Examination of the Back.”
<sup>b</sup> These muscles receive the majority of innervation from this root.
<sup>c</sup> Straight leg–raising sign present—see “Examination of the Back.”

EMG can be used to assess the functional integrity of the peripheral nervous system (Chap. 363). Sensory nerve conduction studies are normal when focal sensory loss is due to nerve root damage because the nerve roots are proximal to the nerve cell bodies in the dorsal root ganglia. The diagnostic yield of needle EMG is higher than that of nerve conduction studies for radiculopathy. Denervation changes in a myotomal (segmental) distribution are detected by sampling multiple muscles supplied by different nerve roots and nerves; the pattern of muscle involvement indicates the nerve root(s) responsible for the injury. Needle EMG provides objective information about motor nerve fiber injury when the clinical evaluation of weakness is limited by pain or poor effort. EMG and nerve conduction studies will be normal when only limb pain or sensory nerve root injury or irritation is present. Mixed nerve somatosensory evoked potentials and F-wave studies are of uncertain value in the evaluation of radiculopathy.

CAUSES OF BACK PAIN (Table 15-2)

**Congenital Anomalies of the Lumbar Spine**

*Spinal dysraphism (spondylolysis)* is a bony defect in the pars interarticularis (a segment near the junction of the pedicle with the lamina) of the vertebra; the etiology may be a stress fracture in a congenitally abnormal segment. The defect (usually bilateral) is best visualized on oblique projections in plain x-rays or by CT scan and occurs in the setting of a single injury, repeated minor injuries, or growth. *Spinal dysraphism* is the anterior slippage of the vertebral body, pedicles, and superior articular facets, leaving the posterior elements behind. Spondylolisthesis is associated with spondylolysis and degenerative spine disease and occurs more frequently in women. The slippage may be asymptomatic but may also cause low back pain, nerve root injury (the L5 root most frequently), or symptomatic spinal stenosis. Tenderness may be elicited near the segment that has “slipped” forward (most often L4 on L5 or occasionally L5 on S1). A “step” may be present on deep palpation of the posterior elements of the segment above the spondylolisthetic joint. The trunk may be shortened and the abdomen protuberant as a result of extreme forward displacement of L4 on L5; in severe cases cauda equina syndrome (CES) may occur (see below).

*Spina bifida occulta* is a failure of closure of one or several vertebral arches posteriorly; the meningies and spinal cord are normal. A dimple or small lipoma may overlie the defect. Most cases are asymptomatic and discovered incidentally during evaluation for back pain.

<sup>a</sup> Low back pain only.
<sup>b</sup> Neck pain only.
equinai disorder (see below), although myelopathy may also be the initial manifestation. The patient is often a young adult who complains of perineal or perianal pain, sometimes following minor trauma. Neuroimaging studies reveal a low-lying conus (below L1-L2) and a short and thickened filum terminale.

TR AUM A Patient complaining of back pain and inability to move the legs may have a spinal fracture or dislocation and, with fractures above L1, spinal cord compression. Care must be taken to avoid further damage to the spinal cord or nerve roots by immobilizing the back pending results of x-rays.

Sprains and Strains The terms low back sprain, strain, or mechanically induced muscle spasm refer to minor, self-limited injuries associated with lifting a heavy object, a fall, or a sudden deceleration such as in an automobile accident. These terms are used loosely and do not clearly describe a specific anatomic lesion. The pain is usually confined to the lower back, and there is no radiation to the buttocks or legs. Patients with paraspinal muscle spasm often assume unusual postures.

Traumatic Vertebral Fractures Most traumatic fractures of the lumbar vertebral bodies result from injuries producing anterior wedging or compression. With severe trauma, the patient may sustain a fracture-dislocation or a "burst" fracture involving the vertebral body and posterior elements. Traumatic vertebral fractures are caused by falls from a height (a pars interarticularis fracture of the L5 vertebra is common), sudden deceleration in an automobile accident, or direct injury. Neurologic impairment is common, and early surgical treatment is indicated.

LUMBAR DISK DISEASE This is a common cause of chronic or recurrent low back and leg pain (Fig. 15-4). Disk disease is most likely to occur at the L4-L5 and L5-S1 levels, but upper lumbar levels are involved occasionally. The cause is often unknown; the risk is increased in overweight individuals. Disk herniation is unusual prior to age 20 and is rare in the fibrotic disks of the elderly. Degeneration of the nucleus pulposus and the annulus fibrosus increases with age and may be asymptomatic or painful. The pain may be located in the low back only or referred to the leg, buttock, or hip. A sneeze, cough, or trivial movement may cause the nucleus pulposus to prolapse, pushing the frayed and weakened annulus posteriorly. With severe disk disease, the nucleus may protrude through the annulus (hermiatation) or become extruded to lie as a free fragment in the spinal canal.

The mechanism by which intervertebral disk injury causes back pain is controversial. The inner annulus fibrosus and nucleus pulposus are normally devoid of innervation. Inflammation and production of proinflammatory cytokines within the protruding or ruptured disk may trigger or perpetuate back pain. Ingrowth of nociceptive (pain) nerve fibers into inner portions of a diseased disk may be responsible for chronic "diskogenic" pain. Nerve root injury (radiculopathy) from disk herniation may be due to compression, inflammation, or both: pathologically, demyelination and axonal loss are usually present.

Symptoms of a ruptured disk include back pain, abnormal posture, limitation of spine motion (particularly flexion), or radicular pain. A dermatomal pattern of sensory loss or a reduced or absent deep tendon reflex is more suggestive of a specific root lesion than the pattern of pain. Motor findings (focal weakness, muscle atrophy, or fasciculations) occur less frequently than sensory or reflex changes. Symptoms and signs are usually unilateral, but bilateral involvement does occur with large central disk herniations that compress several nerve roots at the same level. Clinical manifestations of specific nerve root lesions are summarized in Table 15-1. There is evidence to suggest that lumbar disk herniation with a nonprogressive nerve root deficit can be managed nonsurgically. The size of the disk protrusion may naturally decrease over time.

The differential diagnosis includes a variety of serious and treatable conditions, including epidural abscess, hematoia, or tumor. Fever, constant pain uninfluenced by position, sphincter abnormalities, or signs of spinal cord disease suggest an etiology other than lumbar disk disease. Bilateral absence of ankle reflexes can be a normal finding in old age or a sign of bilateral S1 radiculopathy. An absent deep tendon reflex or focal sensory loss may reflect injury to a nerve root, but other sites of injury along the nerve must also be considered. For example, an absent knee reflex may be due to a femoral neuropathy rather than an L4 nerve root injury. A loss of sensation over the foot and distal calf may result from a peroneal or lateral sciatic neuropathy rather than an L5 nerve root injury. Focal muscle atrophy may reflect a nerve root or peripheral nerve injury, an anterior horn cell disease, or disuse.

An MRI scan or CT-myelogram is necessary to establish the location and type of pathology. Simple MRI yields exquisite views of intraspinal and adjacent soft tissue anatomy. Bony lesions of the lateral recess or intervertebral foramens may be seen with optimal clarity on CT-myelographic studies. The correlation of neuroradiologic findings to symptoms, particularly pain, is not simple. Contrast-enhancing tears in the annulus fibrosus or disk protrusions are widely accepted as common sources of back pain; however, one study found that over half of asymptomatic adults have similar findings. Asymptomatic disk protrusions are also common, and these abnormalities may enhance with contrast. Furthermore, in patients with known disk herniation treated either medically or surgically, persistence of the herniation 10 years later had no relationship to the clinical outcome. MRI findings of disk protrusion, tears in the annulus fibrosus, or contrast enhancement are common incidental findings that by themselves should not dictate management decisions for patients with back pain.

There are four indications for intervertebral disk surgery: (1) progressive motor weakness from nerve root injury demonstrated on clinical examination or EMG, (2) bowel or bladder disturbance or other signs of spinal cord compression, (3) incapacitating nerve root pain despite conservative treatment for at least 4 weeks, and (4) recurrent incapacitating pain despite conservative treatment. The latter two criteria are more subjective and less well established than the others. Surgical treatment should also be considered if the pain and/or neurologic findings do not substantially improve over 4 to 12 weeks.

The usual surgical procedure is a partial hemilaminectomy with excision of the prolapsed disk. Fusion of the involved lumbar segments is considered only if significant spinal instability is present (i.e., degenerative spondylolisthesis, isthmic spondylolysis).

CES is an injury of multiple lumbosacral nerve roots within the spinal canal. Low back pain, weakness and areflexia in the lower ex-
tremities, saddle anesthesia, and loss of bladder function may occur. The problem must be distinguished from disorders of the lower spinal cord (conus medullaris syndrome), acute transverse myelitis (Chap. 356), and Guillain-Barré syndrome (Chap. 365). Combined involvement of the conus medullaris and cauda equina can occur. CES is commonly due to a ruptured lumbosacral intervertebral disk, lumbosacral spine fracture, hematoma within the spinal canal (e.g., following lumbar puncture in patients with coagulopathy), compressive tumors, or other mass lesions. Treatment options include surgical decompression, sometimes urgently in an attempt to restore or preserve motor or sphincter function, or palliative radiotherapy or chemotherapy for metastatic tumors.

**DEGENERATIVE CONDITIONS** Lumbar spinal stenosis describes a narrowed lumbar spinal canal. When severe, neurogenic claudication, consisting of back and buttock or leg pain induced by walking or standing and relieved by sitting, can occur. Symptoms in the legs are usually bilateral. Unlike vascular claudication, symptoms are often provoked by standing without walking. Unlike lumbar disk disease, symptoms are usually relieved by sitting. Focal weakness, sensory loss, or reflex changes may occur when spinal stenosis is associated with radiculopathy. Severe neurologic deficits, including paralysis and urinary incontinence, occur rarely. Spinal stenosis can be acquired (75%), congenital, or due to a combination of the two causes. Congenital forms (achondroplasia, idiopathic) are characterized by short, thick pedicles that produce both spinal canal and lateral recess stenosis. Acquired factors that may contribute to spinal stenosis include degenerative diseases (spondylolisthesis, spondylohisthesis, scoliosis), trauma, spine surgery (postlaminectomy, fusion), metabolic or endocrine disorders (epidural lipomatosis, osteoporosis, acromegaly, renal osteodystrophy, hypoparathyroidism), and Paget’s disease. MRI or CT-myelography provide the best definition of the abnormal anatomy (Fig. 15-5).

Conservative treatment of symptomatic spinal stenosis includes nonsteroidal anti-inflammatory drugs (NSAIDs), exercise programs, and symptomatic treatment of acute pain exacerbations. Surgical therapy is considered when medical therapy does not relieve pain sufficiently to allow for activities of daily living or when significant focal neurologic signs are present. Between 65 and 80% of properly selected patients treated surgically experience 75% relief of back and leg pain. Up to 25% develop recurrent stenosis at the same spinal level or an adjacent level 5 years after the initial surgery; recurrent symptoms usually respond to a second surgical decompression.

**Facet joint hypertrophy** can produce unilateral radicular symptoms or signs due to bony compression, that are indistinguishable from disk-related radiculopathy. Patients may exhibit stretch signs, focal motor weakness, hyporeflexia, or dermatomal sensory loss. Hypertrophic superior or inferior facets can often be visualized radiologically. Foraminotomy results in long-term relief of leg and back pain in 80 to 90% of patients.

**ARTHITIS** Spondylitis, or osteoarthritic spine disease, typically occurs in later life and primarily involves the cervical and lumbosacral spine. Patients often complain of back pain that is increased by motion and associated with stiffness or limitation of motion. The relationship between clinical symptoms and radiologic findings is usually not straightforward. Pain may be prominent when x-ray findings are minimal; alternatively, large osteophytes can be seen in asymptomatic patients in middle and later life. Hypertrophied facets and osteophytes may compress nerve roots in the lateral recess or intervertebral foramen. Osteophytes arising from the vertebral body may cause or contribute to central spinal canal stenosis. Loss of intervertebral disk height reduces the vertical dimensions of the intervertebral foramen; the descending pedicle may compress the nerve root exiting at that level. Rarely, osteoarthritic changes in the lumbar spine compress the cauda equina.

Ankylosing Spondylitis (See also Chap. 305) This distinctive arthritic spine disease typically presents with the insidious onset of low back and buttock pain. Patients are often males below age 40. Associated features include morning back stiffness, nocturnal pain, pain unrelied by rest, an elevated sedimentation rate, and the histocompatibility antigen HLA-B27. Onset at a young age and back pain improving with exercise is characteristic. Loss of the normal lumbar lordosis and exaggeration of thoracic kyphosis are seen as the disease progresses. Inflammation and erosion of the outer fibers of the annulus fibrosus at the point of contact with the vertebral body are followed by ossification and bony growth that bridges adjacent vertebral bodies and reduces spine mobility in all planes. Radiologic hallmarks are periarticular destructive changes, sclerosis of the sacroiliac joints, and bridging of vertebral bodies to produce the fused “bambus spine.” Similar restricted movements may accompany Reiter’s syndrome, psoriatic arthritis, and chronic inflammatory bowel disease. Stress fractures through the spontaneously ankylosed posterior bony elements of the rigid, osteoporotic spine may produce focal pain, spinal cord compression, or CES. Atlantoaxial subluxation with spinal cord compression occasionally occurs. Ankylosis of the ribs to the spine and a decrease in the height of the thoracic spine may compromise respiratory function.

**NEOPLASMS** (See also Chap. 358) Back pain is the most common neurologic symptom in patients with systemic cancer and is usually due to vertebral metastases. Metastatic carcinoma (breast, lung, prostate, thyroid, kidney, gastrointestinal tract), multiple myeloma, and non-Hodgkin’s and Hodgkin’s lymphomas frequently involve the spine. Back pain may be the presenting symptom. The pain tends to be constant, dull, unrelied by rest, and worse at night. In contrast, mechanical low back pain usually improves with rest. Plain x-rays usually, but not always, show destructive lesions in one or several vertebral bodies without disk space involvement. MRI or CT-myelography are the studies of choice when spinal metastasis is suspected. MRI is usually preferred, but the procedure of choice is the study most rapidly available because the patient’s condition may worsen quickly.

**INFECIONS/INFLAMMATION** Vertebral osteomyelitis is usually caused by staphylococci, but other bacteria or the tubercle bacillus (Pott’s disease) may be responsible. A primary source of infection, most often the urinary tract, skin, or lungs, can be identified in 40% of patients. Intravenous drug use is a well-recognized risk factor. Back pain exacerbated by motion and unrelied by rest, spine tenderness over the involved spine segment, and an elevated erythrocyte sedimentation rate are the most common findings. Fever or an elevated white blood cell count are found in a minority of patients. Plain radiographs may show narrowed disk space with erosion of adjacent vertebrae; however, these diagnostic changes may take weeks or months to appear. MRI and CT are sensitive and specific for osteomyelitis; CT may be

---

**FIGURE 15-5** Spinal stenosis. Sagittal T2 fast spine echo magnetic resonance imaging of a normal (left) and stenotic (right) lumbar spine, revealing multifocal narrowing (arrows) of the cerebrospinal fluid spaces surrounding the nerve roots within the thecal sac.
Spinal epidural abscess (Chap. 356) presents with back pain (aggravated by movement or palpation) and fever. Signs of nerve root injury or spinal cord compression may be present. The abscess may track over multiple spinal levels and is best delineated by spine MRI. Lumbar adhesive arachnoiditis with radiculopathy is due to fibrosis following inflammation within the subarachnoid space. The fibrosis results in nerve root adhesions, producing back and leg pain associated with motor, sensory, or reflex changes. Myelography-induced arachnoiditis has become rare with the abandonment of oil-based contrast. Other causes of arachnoiditis include multiple lumbar operations, chronic spinal infections, spinal cord injury, intrahepatic hemorrhage, intravenous injection of glucocorticoids or anesthetics, and foreign bodies. The MRI may show nerve roots that clump together centrally and adhere to the dura peripherally, or loculations of cerebrospinal fluid within the thecal sac. Treatment is often unsatisfactory. Microsurgical lysis of adhesions, dorsal rhizotomy, and dorsal root ganglionectomy have resulted in poor outcomes. Dorsal column stimulation for pain relief has produced varying results. Epidural injections of glucocorticoids have been of limited value.

**METABOLIC CAUSES**

**Osteoporosis and Osteosclerosis** Immobilization or underlying systemic disorders such as osteomalacia, hyperparathyroidism, hyperthyroidism, multiple myeloma, metastatic carcinoma, or glucocorticoid use may accelerate osteoporosis and weaken the vertebral body. The most common causes of atraumatic vertebral body fractures are postmenopausal (type 1) or senile (type 2) osteoporosis (Chap. 333). Compression fractures occur in up to half of patients with severe osteoporosis, and those who sustain a fracture have a 4.5-fold increased risk for recurrence. The sole manifestation of a compression fracture may be localized aching (often after a trivial injury) that is exacerbated by movement. Other patients experience radicular pain only. Focal tenderness to palpation is common. The clinical context, neurologic signs, and x-ray appearance of the spine establish the diagnosis. When compression fractures are found, treatable risk factors should be sought. Antiresorptive drugs including bisphosphonates (e.g., alendronate), transdermal estrogen, and tamoxifen have been shown to reduce the risk of osteoporotic fractures. Compression fractures above the midthoracic region suggest malignancy; if tumor is suspected, a bone biopsy or diagnostic search for a primary tumor is indicated.

Interventions [percutaneous vertebroplasty (PVP), kyphoplasty] exist for osteoprotective compression fractures associated with debilitating pain. Candidates for PVP should have midline pain, focal tenderness over the spinous process of the affected vertebral body, <80% loss of vertebral body height, and onset of symptoms within the prior 4 months. The technique consists of injection of polymethylmethacrylate, under fluoroscopic guidance, into the affected vertebral body. Rare major complications include extravasation of cement into the spinal canal or intervertebral foramina. Single dual-beam photon absorptiometry or quantitative CT can be used to detect small changes in bone mineral density. For further discussion of these bone disorders, see Chaps. 332–334.

**REFERRED PAIN FROM VISCERAL DISEASE** Diseases of the thorax, abdomen, or pelvis may refer pain to the lower thoracic or upper lumbar region (eighth thoracic to the first and second lumbar vertebrae), lower abdominal diseases to the lumbar region (second to fourth lumbar vertebrae), and pelvic diseases to the sacral region. Local signs (pain with spine palpation, paraspinal muscle spasm) are absent, and minimal or no pain accompanies normal spine movements.

**Low Thoracic or Lumbar Pain with Abdominal Disease** Peptic ulcers or tumors of the posterior wall of the stomach or duodenum typically produce epigastric pain (Chaps. 77 and 274), but midline back or paraspinal pain may occur if retroperitoneal extension is present. Back pain due to peptic ulcer may be precipitated by ingestion of an orange, alcohol, or coffee and relieved by food or antacids. Fatty foods are more likely to induce back pain associated with biliary disease. Diseases of the pancreas produce back pain to the right of the spine (head of the pancreas involved) or to the left (body or tail involved). Pathology in retroperitoneal structures (hemorrhage, tumors, pyleonephritis) produces paraspinal pain that radiates to the lower abdomen, groin, or anterior thighs. A mass in the iliopsoas region often produces unilateral lumbar pain with radiation toward the groin, labia, or testicles. The sudden appearance of lumbar pain in a patient receiving anticoagulants suggests retroperitoneal hemorrhage.

Isolated low back pain occurs in 15 to 20% of patients with a contained rupture of an abdominal aortic aneurysm (AAA). The classic clinical triad of abdominal pain, shock, and back pain in an elderly man occurs in <20% of patients. Two of these three features are present in two-thirds of patients, and hypotension is present in half. The typical patient is an elderly male smoker with back pain. The diagnosis is initially missed in at least one-third of patients because the symptoms and signs can be nonspecific. Common misdiagnoses include nonspecific back pain, diverticulitis, renal colic, sepsis, and myocardial infarction. A careful abdominal examination revealing a pulsatile mass (present in 50 to 75% of patients) is an important physical finding. Patients with suspected AAA should be evaluated with ultrasound, CT, or MRI (Chap. 231).

Inflammatory bowel disorders (colitis, diverticulitis) or cancers of the colon may produce lower abdominal pain, midlumbar back pain, or both. The pain may have a bell-like distribution around the body. A lesion in the transverse or proximal descending colon may refer pain to the middle or left back at the L2-L3 level. Lesions of the sigmoid colon may refer pain to the upper sacral or midline suprapubic regions or left lower quadrant of the abdomen.

**Sacral Pain with Gynecologic and Urologic Disease** Pelvic organs rarely cause low back pain, except for gynecologic disorders involving the uterosacral ligaments. The pain is referred to the sacral region. Endometriosis or cancers of the uterus may invade the uterosacral ligaments; malposition of the uterus may cause uterosacral ligament traction. Pain associated with endometriosis is typically premenstrual and often continues until it merges with menstrual pain. Malposition of the uterus (retroversion, descensus, and prolapse) may produce sacral pain after prolonged standing.

Menstrual pain may be felt in the sacral region. The poorly localized, cramping pain can radiate down the legs. Pain due to neoplastic infiltration of nerves is typically continuous, progressive in severity, and unrelieved by rest at night. Less commonly, radiation therapy of pelvic tumors may produce sacral pain from late radiation necrosis of tissue or nerves. Low back pain that radiates into one or both thighs is common in the last weeks of pregnancy.

Urologic sources of lumbosacral back pain include chronic prostatitis, prostate cancer with spinal metastasis, and diseases of the kidney and ureter. Lesions of the bladder and testes do not usually produce back pain. The diagnosis of metastatic prostate carcinoma is established by rectal examination, spine imaging studies (MRI or CT), and measurement of prostate-specific antigen (Chap. 81). Infectious, inflammatory, or neoplastic renal diseases may produce ipsilateral lumbosacral pain, as can renal artery or vein thrombosis. Paraspinal lumbar pain may be a symptom of ureteral obstruction due to nephrolithiasis.
OTHER CAUSES OF BACK PAIN ■ Postural Back Pain There is a group of patients with nonspecific CLBP in whom no anatomic or pathologic lesion can be found despite exhaustive investigation. These individuals complain of vague, diffuse back pain with prolonged sitting or standing that is relieved by rest. The physical examination is unrevealing except for “poor posture.” Imaging studies and laboratory evaluations are normal. Exercises to strengthen the paraspinal and abdominal muscles are sometimes therapeutic.

Psychiatric Disease CLBP may be encountered in patients who seek financial compensation, in malingerers, or in those with concurrent substance abuse, chronic anxiety states, or depression. Many patients with CLBP have a history of psychiatric illness (depression, anxiety, substance abuse) or childhood trauma (physical or sexual abuse) that antedates the onset of back pain. Preoperative psychological assessment has been used to exclude patients with marked psychological impairments; these patients are likely to have a poor surgical outcome.

Unidentified The cause of low back pain occasionally remains unclear. Some patients have had multiple operations for disk disease but have persistent pain and disability. The original indications for surgery may have been questionable, with back pain only, no definite neurologic signs, or a minor disk bulge noted on CT or MRI. Scoring systems based upon neurologic signs, psychological factors, physiologic studies, and imaging studies have been devised to minimize the likelihood of unsuccessful surgical explorations.

**TREATMENT**

**Acute Low Back Pain** A practical approach to the management of low back pain is to consider acute and chronic presentations separately. ALBP is defined as pain of <3 months duration. Full recovery can be expected in 85% of adults with ALBP unaccompanied by leg pain. Most have purely “mechanical” symptoms—i.e., pain that is aggravated by motion and relieved by rest.

Observational studies have been used to justify a minimalist approach to this problem. These studies share a number of limitations: (1) a true placebo control group is often lacking; (2) patients who consult different provider groups (generalists, orthopedists, neurologists) are assumed to have similar etiologies for their back pain; (3) no information is provided about the details of treatment; and (4) no attempt to tabulate serious causes of ALBP is made.

The algorithms for the treatment of back pain (Fig. 15-6) draw from published guidelines. However, since CPGs are based on incomplete evidence, guidelines should not substitute for clinical judgment.

The initial assessment excludes serious causes of spine pathology that require urgent intervention, including infection, cancer, and trauma. Risks factors for a possible serious underlying cause of back pain include: age >50 years, prior diagnosis of cancer or other serious medical illness, bed rest without relief, duration of pain >1 month, urinary incontinence or recent nocturia, focal leg weakness or numbness, pain radiating into the leg(s) from the back, intravenous drug use, chronic infection (pulmonary or urinary), pain increasing with standing and relieved by sitting, history of spine trauma, and glucocorticoid use. Worrisome signs include unexplained fever, unexplained weight loss, positive SLR sign or reverse SLR sign, crossed SLR sign, percussion tenderness over the spine or costovertebral angle, an abdominal mass (pulsatile or nonpulsatile), a rectal mass, focal sensory loss (saddle anesthesia or focal limb sensory loss), leg weakness, spasticity, or reflex asymmetry. Laboratory studies are unnecessary unless a serious underlying cause is suspected. Plain spine films are rarely indicated in the first month of symptoms unless a spine fracture is suspected.

Clinical trials have shown no benefit of prolonged (>2 days) bed rest for uncomplicated ALBP. There is evidence that bed rest is also ineffective for patients with sciatica or for acute back pain with findings of nerve root injury. Theoretical advantages of early ambulation for ALBP include maintenance of cardiovascular conditioning, improved disk and cartilage nutrition, improved bone and muscle strength, and increased endorphin levels. A trial examining the effects of a program of early vigorous exercise was negative, but the benefits of less vigorous exercise or other exercise programs are unknown. The early resumption of normal physical activity (without heavy manual labor) is likely to be beneficial. Traction for ALBP is not effective, as shown in well-designed clinical trials that include a “sham” traction control group. Despite this knowledge, in one survey physicians identified strict bed rest for 3 days, trigger point injections (see below), and physical therapy (PT) as beneficial for ALBP. In many instances, the behavior of treating physicians does not reflect the current medical literature.

Proof is lacking to support the treatment of acute back and neck pain with acupuncture, transcutaneous electrical nerve stimulation, massage, ultrasound, diathermy, or electrical stimulation. Cervical collars can be modestly helpful by limiting spontaneous and reflex neck movements that exacerbate pain. Evidence regarding the efficacy of ice or heat is lacking, but these interventions are optional given the lack of negative evidence, low cost, and low risk. Biofeedback has not been studied rigorously. Facet joint, trigger point, and ligament injections are not recommended.

A role for modification of posture has not been validated by rigorous clinical studies. As a practical matter, temporary suspension of activity known to increase mechanical stress on the spine (heavy lifting, prolonged sitting, bending or twisting, straining at stool) may be helpful.

Education is an important part of treatment. Satisfaction and the likelihood of follow-up increase when patients are educated about prognosis, treatment methods, activity modifications, and strategies to prevent future exacerbations. In one study, patients who felt they did not receive an adequate explanation for their symptoms wanted further diagnostic tests. Evidence for the efficacy of structured education programs (“back school”) is inconclusive; in one study, patients attending back school had a shorter duration of sick leave during the initial episode but not during subsequent episodes. Randomized studies of back school for primary prevention of low back injury and pain have failed to demonstrate any benefit.

NSAIDs and acetaminophen are effective over-the-counter agents for ALBP. Muscle relaxants (cyclobenzaprine, methocarbamol) provide short-term (4 to 7 days) benefit, but drowsiness limits daytime use. Opioid analgesics are no more effective than NSAIDs or acetaminophen for initial treatment of ALBP, nor do they increase the likelihood of return to work. Short-term use of opioids in patients unresponsive to or intolerant of acetaminophen or NSAIDs may be helpful. There is no evidence to support the use of oral glucocorticoids or tricyclic antidepressants for ALBP.

Epidural glucocorticoids may occasionally produce short-term pain relief in ALBP and radiculopathy, but proof is lacking for pain relief beyond 1 month. Epidural anesthetics, glucocorticoids, or opioids are not indicated in the initial treatment of ALBP without radiculopathy. Diagnostic nerve root blocks have been advocated to determine if pain originates from a specific nerve root. However, improvement may result even when the nerve root is not responsible for the pain syndrome; this may occur with placebo effects, painful lesions located distally along the peripheral nerve, or anesthesia of the sinuvertebral nerve. Therapeutic nerve root blocks with injection of glucocorticoids and a local anesthetic is an option after conservative measures fail, particularly when temporary relief of pain is necessary.

A short course of spinal manipulation or PT for symptomatic relief of uncomplicated ALBP is an option. A prospective, randomized study comparing PT, chiropractic manipulation, and education interventions for patients with ALBP found modest trends toward benefit with both PT and chiropractic manipulation at 1 year. Costs per year were equivalent in the PT/chiropractic group and ~$280 less for the group treated with the education booklet alone. The value of such treatment beyond 1 year is unknown. Similarly, the specific PT or chiropractic protocols that may provide benefit have not been fully defined.
Chronic Low Back Pain  CLBP, defined as pain lasting >12 weeks, accounts for 50% of total back pain costs. Overweight individuals appear to be at particular risk. Other risk factors include: female gender, older age, prior history of back pain, restricted spinal mobility, pain radiating into a leg, high levels of psychological distress, poor self-rated health, minimal physical activity, smoking, job dissatisfaction, and widespread pain. Combinations of these premorbid factors have been used to predict which individuals with ALBP are likely to develop CLBP. The initial approach to these patients is similar to that for ALBP, and the differential diagnosis is similar. Treatment of this heterogeneous group of patients is directed toward the underlying cause when known; the ultimate goal is to restore function to the greatest extent possible.

Many conditions that produce CLBP can be identified by a combination of neuroimaging and electrophysiologic studies. Spine MRI or CT-myelography are the techniques of choice but are generally not indicated within the first month after initial evaluation in the absence of risk factors for a serious underlying cause. Imaging studies should be performed only in circumstances where the results are likely to influence surgical or medical treatment.

Diskography provides no additional anatomic information beyond what is available by MRI. Reproduction of the patient’s typical pain with the injection is often used as evidence that a specific disk is the pain generator, but it is not known whether this information has any influence surgical or medical treatment. The correlation between CT and EMG for localization of nerve root injury is between 65 and 73%. Up to one-third of asymptomatic adults have a disk protrusion detected by CT or MRI scans. Thus, surgical...
CERVICAL DISK DISEASE Herniation of a lower cervical disk is a common cause of neck, shoulder, arm, or hand pain. Neck pain (worse with movement), stiffness, and a limited range of motion are the usual manifestations. With nerve root compression, pain may radiate into a shoulder or arm. Extension and lateral rotation of the neck narrows the intervertebral foramen and may reproduce radicular symptoms (Spurling’s sign). In young individuals, acute nerve root compression from a ruptured cervical disk is often due to trauma. Subacute radiculopathy is less likely to be related to a specific traumatic incident and is usually due to a combination of disk disease and spondylosis. Cervical disk herniations are usually postero-lateral near the lateral recess and intervertebral foramen. Typical patterns of reflex, sensory, and motor changes that accompany specific cervical nerve root lesions are summarized in Table 15-3; however, (1) overlap in function between adjacent nerve roots is common, (2) symptoms and signs may be evident in only part of the injured nerve root territory, and (3) the location of pain is the most variable of the clinical features.

CERVICAL Spondylosis Osteoarthritis of the cervical spine may produce neck pain that radiates into the back of the head, shoulders, or arms, or may be the source of headaches in the posterior occipital region (supplied by the C2-C4 nerve roots). Osteophyte formation in the lateral recess or hypertrophic facet joints may produce a monoradiculopathy (Fig. 15-7). Narrowing of the spinal canal by osteophytes, ossification of the posterior longitudinal ligament, or a large central disk may compress the cervical spinal cord. Combinations of radiculopathy and myelopathy also occur. An electrical sensation elicited by neck flexion and radiating down the spine from the neck (Lhermitte’s symptom) usually indicates involvement of the cervical or upper thoracic (T1-T2) spine. When little or no neck pain accompanies the cord compression, the diagnosis may be confused with amyotrophic lateral sclerosis (Chap. 353), multiple sclerosis (Chap. 359), spinal cord tumors, or syringomyelia (Chap. 356). The possibility of treatable cervical spondylosis must be considered even when the patient presents with leg complaints only. In other cases, an unrelated lumbar radiculopathy or polyneuropathy may mask signs of an associated cervical myelopathy. MRI or CT-myelography can define the anatomic abnormalities, and EMG and nerve conduction studies can localize and assess the severity of the nerve root injury.

OTHER CAUSES OF NECK PAIN Rheumatoid arthritis (RA) (Chap. 301) of the cervical apophyseal joints produces neck pain, stiffness, and lim-
Ankylosing spondylitis can cause neck pain and on occasion atlantoaxial subluxation; when spinal cord compression is present or threatened, surgical intervention is indicated. *Herpes zoster* produces acute posterior occipital or neck pain prior to the outbreak of vesicles. Neoplasms metastatic to the cervical spine, infections (osteomyelitis and epidural abscess), and metabolic bone diseases may also be the cause of neck pain. Neck pain may also be referred from the heart with coronary artery ischemia (cervical angina syndrome).

**THORACIC OUTLET** The thoracic outlet contains the first rib, the subclavian artery and vein, the brachial plexus, the clavicle, and the lung apex. Injury to these structures may result in postural or movement-induced pain around the shoulder and supraclavicular region. True neurogenic thoracic outlet syndrome (TOS) results from compression of the lower trunk of the brachial plexus or ventral rami of the C8 or T1 nerve roots by an anomalous band of tissue connecting an elongate transverse process at C7 with the first rib. Signs include weakness of intrinsic muscles of the hand and diminished sensation on the palmar aspect of the fourth and fifth digits. EMG and nerve conduction studies confirm the diagnosis. Treatment consists of surgical division of the anomalous band. The weakness and wasting of intrinsic hand muscles typically does not improve, but surgery halts the insidious progression of weakness. Arterial TOS results from compression of the subclavian artery by a cervical rib; the compression results in poststenotic dilatation of the artery and thrombus formation. Blood pressure is reduced in the affected limb, and signs of emboli may be present in the hand; neurologic signs are absent. Ultrasound can confirm the diagnosis non-invasively. Treatment is with thrombolysis or anticoagulation (with or without embolectomy) and surgical excision of the cervical rib comprising the subclavian artery or vein. Disputed TOS includes a large number of patients with chronic arm and shoulder pain of unclear cause. The lack of sensitive and specific findings on physical examination or laboratory markers for this condition frequently results in diagnostic uncertainty. The role of surgery in disputed TOS is controversial. Multidisciplinary pain management is a conservative approach, although treatment is often unsuccessful.

**BRACHIAL Plexus and Nerves** Pain from injury to the brachial plexus or peripheral nerves of the arm can occasionally mimic pain of cervical spine origin. Neoplastic infiltration of the lower trunk of the brachial plexus may produce shoulder pain radiating down the arm, numbness of the fourth and fifth fingers, and weakness of intrinsic hand muscles innervated by the ulnar and median nerves. Postirradiation fibrosis (breast carcinoma is the most common setting) may produce similar findings, although pain is less often present. A Pancoast tumor of the lung (Chap. 75) is another cause and should be considered, especially when a Horner’s syndrome is present. *Suprascapular neuropathy* may produce severe shoulder pain, weakness, and wasting of the suprascapular and infraspinatus muscles. *Acute brachial neuritis* is often confused with radiculopathy. It consists of the acute onset of severe shoulder or scapular pain followed over days to weeks by weakness of the proximal arm and shoulder girdle muscles innervated by the upper brachial plexus. The onset is often preceded by an infection or immunization. Complete recovery occurs in 75% of patients after 2 years and in 89% after 3 years. Occasional cases of carpal tunnel syndrome produce pain and paresthesias extending into the forearm, arm, and shoulder resembling a C5 or C6 root lesion. Lesions of the radial or ulnar nerve can mimic a radiculopathy at C7 or C8, respectively. EMG and nerve conduction studies can accurately localize lesions to the nerve roots, brachial plexus, or peripheral nerves. →For further discussion of peripheral nerve disorders, see Chap. 363.

**SHOULDER** Pain from the shoulder can be difficult to distinguish from neck pain. If symptoms and signs of radiculopathy are absent, then the differential diagnosis includes mechanical shoulder pain (tendonitis, bursitis, rotator cuff tear, dislocation, adhesive capsulitis, and cuff impingement under the acromion) and referred pain (subdiaphragmatic irritation, angina, Pancoast tumor). Mechanical pain is often worse at night, associated with local shoulder tenderness and aggravated by abduction, internal rotation, or extension of the arm. Pain from shoulder disease may on occasion radiate into the arm or hand, but sensory, motor, and reflex changes are absent.

**TREATMENT**

There are few well-designed clinical trials that address optimal treatment of neck pain. Symptomatic treatment can include the use of analgesic medications and/or a soft cervical collar. Current indications for cervical disk surgery are similar to those for lumbar disk surgery; because of the risk of spinal cord injury with cervical spine disease, an aggressive approach is generally indicated whenever spinal cord injury is threatened. Surgical management of cervical herniated disks usually consists of an anterior approach with discectomy followed by anterior interbody fusion. A simple posterior partial laminectomy with discectomy is an acceptable alternative approach. The risk of subsequent radiculopathy or myelopathy at cervical segments adjacent to the fusion is ~3% per year and 26% per decade. Although this risk is
sometimes portrayed as a late complication of surgery, it may also reflect the natural history of degenerative cervical spine disease. Non-progressive cervical radiculopathy (associated with a focal neurologic deficit) due to a herniated cervical disk may be treated conservatively with a high rate of success. Cervical spondylosis with bony, compressive cervical radiculopathy is generally treated with surgical decompression to forstall the progression of neurologic signs. Cervical spondyotic myelopathy is typically managed with either anterior decompression and fusion or laminectomy. Outcomes in both surgical groups vary, but late functional deterioration occurs in 20 to 30% of patients; a prospective, controlled study comparing different surgical interventions is needed.

**FEVER AND HYPERThERMIA**

Charles A. Dinarello, Jeffrey A. Gelfand

Body temperature is controlled by the hypothalamus. Neurons in both the preoptic anterior hypothalamus and the posterior hypothalamus receive two kinds of signals: one from peripheral nerves that reflect warmth/cold receptors and the other from the temperature of the blood bathing the region. These two types of signals are integrated by the thermoregulatory center of the hypothalamus to maintain normal temperature. In a neutral environment, the metabolic rate of humans consistently produces more heat than is necessary to maintain the core body temperature at 37°C.

A normal body temperature is ordinarily maintained, despite environmental variations, because the hypothalamic thermoregulatory center balances the excess heat production derived from metabolic activity in muscle and the liver with heat dissipation from the skin and lungs. According to studies of healthy individuals 18 to 40 years of age, the mean oral temperature is 36.8° ± 0.4°C (98.2° ± 0.7°F), with low levels at 6 A.M. and higher levels at 4 to 6 P.M. The maximum normal oral temperature is 37.2°C (98.9°F) at 6 A.M. and 37.7°C (99.9°F) at 4 P.M.; these values define the 99th percentile for healthy individuals. In light of these studies, an A.M. temperature of >37.2°C (>99.9°F) or a P.M. temperature of >37.7°C (>99.9°F) would define a fever. The normal daily temperature variation is typically 0.5°C (0.9°F). However, in some individuals recovering from a febrile illness, this daily variation can be as great as 1.0°C. During a febrile illness, diurnal variations are usually maintained but at higher levels. Daily temperature swings do not occur in patients with hyperthermia (see below). Rectal temperatures are generally 0.4°C (0.7°F) higher than oral readings. The lower oral readings are probably attributable to mouth breathing, which is a particularly important factor in patients with respiratory infections and rapid breathing. Lower esophageal temperatures closely reflect core temperature. Tympanic membrane (TM) thermometers measure radiant heat energy from the tympanic membrane and nearby ear canal and display that absolute value (unadjusted mode) or a value automatically calculated from the absolute reading on the basis of nomograms relating the radiant temperature measured to actual core temperatures obtained in clinical studies (adjusted mode). These measurements, although convenient, may be more variable than directly determined oral or rectal values. Studies in adults show that readings are lower with unadjusted-mode than with adjusted-mode TM thermometers and that unadjusted-mode TM values are 0.8°C (1.6°F) lower than rectal temperatures.

In women who menstruate, the A.M. temperature is generally lower in the 2 weeks before ovulation; it then rises by about 0.6°C (1°F) with ovulation and remains at that level until menses occur. Seasonal variation in body temperature has been described but may reflect a meta-bolic change and is not common. Body temperature is elevated in the postprandial state. Pregnancy and endocrinologic dysfunction also affect body temperature. The daily temperature variation appears to be fixed in early childhood; in contrast, elderly individuals can exhibit a reduced ability to develop fever, with only a modest fever even in severe infections.

**FEVER VERSUS HYPERThERMIA**

**FEVER** Fever is an elevation of body temperature that exceeds the normal daily variation and occurs in conjunction with an increase in the hypothalamic set point—for example, from 37°C to 39°C. This shift of the set point from “normothermic” to febrile levels very much resembles the resetting of the home thermostat to a higher level in order to raise the ambient temperature in a room. Once the hypothalamic set point is raised, neurons in the vasomotor center are activated and vasoconstriction commences. The individual first notices vasoconstriction in the hands and feet. Shunting of blood away from the periphery to the internal organs essentially decreases heat loss from the skin, and the person feels cold. For most fevers, body temperature increases by 1° to 2°C. Shivering, which increases heat production from the muscles, may begin at this time; however, shivering is not required if heat conservation mechanisms raise blood temperature sufficiently. Heat production from the liver also increases. In humans, behavior (e.g., putting on more clothing or bedding) helps raise body temperature.

The processes of heat conservation (vasoconstriction) and heat production (shivering and increased metabolic activity) continue until the temperature of the blood bathing the hypothalamic neurons matches the new thermostat setting. Once that point is reached, the hypothalamus maintains the temperature at the febrile level by the same mechanisms of heat balance that are operative in the afebrile state. When the hypothalamic set point is again reset downward (due to either a reduction in the concentration of pyrogens or the use of antipyretics), the processes of heat loss through vasodilation and sweating are initiated. Loss of heat by sweating and vasodilation continues until the blood temperature at the hypothalamic level matches the lower setting.

A fever of >41.5°C (>106.7°F) is called *hyperpyrexia*. This extraordinarily high fever can develop in patients with severe infections but most commonly occurs in patients with central nervous system (CNS) hemorrhages. In the preantibiotic era, fever due to a variety of infectious diseases rarely exceeded 106°F, and there has been speculation that this natural “thermal ceiling” is mediated by neuropeptides functioning as central antipyretics.

In some rare cases, the hypothalamic set point is elevated as a result of local trauma, hemorrhage, tumor, or intrinsic hypothalamic malfunction. The term *hypothalamic fever* is sometimes used to describe elevated temperature caused by abnormal hypothalamic function. However, most patients with hypothalamic damage have subnormal, not supranormal, body temperatures.

**FURTHER READING**

**Section 2 Alterations in Body Temperature**
Hyperthermia is characterized by an unchanged (normothermic) setting of the thermoregulatory center in conjunction with an uncontrolled increase in body temperature that exceeds the body’s ability to lose heat. Exogenous heat exposure and endogenous heat production are two mechanisms by which hyperthermia can result in dangerously high internal temperatures. Excessive heat production can easily cause hyperthermia despite physiologic and behavioral control of body temperature. For example, work or exercise in hot environments can produce heat faster than peripheral mechanisms can lose it.

Although most patients with elevated body temperature have fever, there are a few circumstances in which elevated temperature represents not fever but hyperthermia (Table 16-1). Heat stroke, caused by thermoregulatory failure in association with a warm environment, may be categorized as exertional or nonexertional. Exertional heat stroke typically occurs in younger individuals exercising at ambient temperatures and/or humidities that are higher than normal. In a dry environment and at maximal efficiency, sweating can dissipate ~600 kcal/h, requiring the production of >1 L of sweat. Even in normal individuals, dehydration or the use of common medications (e.g., over-the-counter antihistamines with anticholinergic side effects) may help to precipitate exertional heat stroke. Nonexertional or classic heat stroke typically occurs in either very young or elderly individuals, particularly during heat waves. According to the Centers for Disease Control and Prevention (CDC), there were 7000 deaths attributed to heat injury in the United States from 1979 to 1997. The elderly, the bedridden, persons taking anticholinergic or antiparkinsonian drugs or diuretics, and individuals confined to poorly ventilated and non-air-conditioned environments are most susceptible.

Drug-induced hyperthermia has become increasingly common as a result of the increased use of prescription psychotropic drugs and illicit drugs. Drug-induced hyperthermia may be caused by monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants, and amphetamines and by the illicit use of phencyclidine (PCP), hyseric acid diethylamide (LSD), methylenedioxymethamphetamine (MDMA, "ecstasy"), or cocaine.

Malignant hyperthermia occurs in individuals with an inherited abnormality of skeletal-muscle sarcoplasmic reticulum that causes a rapid increase in intracellular calcium levels in response to halothane and other inhalational anesthetics or to succinylcholine. Elevated temperature, increased muscle metabolism, muscle rigidity, rhabdomyolysis, acidosis, and cardiovascular instability develop rapidly. This condition is often fatal. The neuroleptic malignant syndrome (NMS) occurs in the setting of neuroleptic agent use (antipsychotic phenothiazines, haloperidol, prochlorperazine, metoclopramide) or the withdrawal of dopaminergic drugs and is characterized by "lead-pipe" muscle rigidity, extrapyramidal side effects, autonomic dysregulation, and hyperthermia. This disorder appears to be caused by the inhibition of central dopamine receptors in the hypothalamus, which results in increased heat generation and decreased heat dissipation. The serotonin syndrome, seen with selective serotonin uptake inhibitors (SSRIs), MAOIs, and other serotonergic medications, has many overlapping features, including hyperthermia, but may be distinguished by the presence of diarrhea, tremor, and myoclonus rather than the lead-pipe rigidity of NMS. Thyrotoxicosis and pheochromocytoma can also cause increased thermogenesis.

It is important to distinguish between fever and hyperthermia since hyperthermia can be rapidly fatal and characteristically does not respond to antipyretics. However, there is no rapid way to make this distinction. Hyperthermia is often diagnosed on the basis of the events immediately preceding the elevation of core temperature—e.g., heat exposure or treatment with drugs that interfere with thermoregulation. However, in addition to the clinical history of the patient, the physical aspects of some forms of hyperthermia may alert the clinician. For example, in patients with heat stroke syndromes and in those taking drugs that block sweating, the skin is hot but dry. Moreover, antipyretics do not reduce the elevated temperature in hyperthermia, whereas in fever—and even in hyperpyrexia—adequate doses of either aspirin or acetaminophen usually result in some decrease in body temperature.

**PATHOGENESIS OF FEVER**

**PYROGENS**

The term pyrogen is used to describe any substance that causes fever. Exogenous pyrogens are derived from outside the patient; most are microbial products, microbial toxins, or whole microorganisms. The classic example of an exogenous pyrogen is the lipopolysaccharide endotoxin produced by all gram-negative bacteria. Endotoxins are potent not only as pyrogens but also as inducers of various pathologic changes in gram-negative infections. Another group of potent bacterial pyrogens is produced by gram-positive organisms and includes the enterotoxins of *Staphylococcus aureus* and the group A and B streptococcal toxins, also called *superantigens*. One staphylococcal toxin of clinical importance is the toxic shock syndrome toxin associated with isolates of *S. aureus* from patients with toxic shock syndrome. Like the endotoxins of gram-negative bacteria, the toxins produced by staphylococci and streptococci cause fever in experimental animals when injected intravenously at concentrations of <1 µg/kg of body weight. Endotoxin is a highly pyrogenic molecule in humans: a dose of 2 to 3 ng/kg produces fever and generalized symptoms of malaise in volunteers.

**PYROGENIC CYTOKINES**

Cytokines are small proteins (molecular mass, 10,000 to 20,000 Da) that regulate immune, inflammatory, and hematopoietic processes. For example, stimulation of lymphocyte proliferation during an immune response to vaccination is the result of the cytokines interleukin (IL) 2, IL-4, and IL-6. Another cytokine, granulocyte colony-stimulating factor, stimulates granulocytopoiesis in the bone marrow. Some cytokines cause fever and hence are called pyrogenic cytokines. From a historic point of view, the field of cytokine biology began in the 1940s with laboratory investigations into fever induction by products of activated leukocytes. These fever-producing molecules were called *endogenous pyrogens*.

The known pyrogenic cytokines include IL-1, IL-6, tumor necrosis factor (TNF), ciliary neurotrophic factor (CNTF), and interferon (IFN) α. Others probably exist, although IL-18—a member of the IL-1 family—does not appear to be a pyrogenic cytokine. Each cytokine is

---

**TABLE 16-1 Causes of Hyperthermia Syndromes**

| HEAT STROKE | Exertional: Exercise in higher-than-normal heat and/or humidity | Nonexertional: Anticholinergics, including antihistamines; antiparkinsonian drugs; diuretics; phenothiazines |
| DRUG-INDUCED HYPERThERMIA | Amphetamines, cocaine, phencyclidine (PCP), methylenedioxymethamphetamine (MDMA, “ecstasy”), hyseric acid diethylamide (LSD), salicylates, lithium, anticholinergics, sympathomimetics |
| NEUROLOGIC MALIGNANT SYNDROME | Phenothiazines; butyrophenones, including haloperidol and bromperidol; fluoxetine; loxapine; tricyclic dibenzodiazepines; metoclopramide; domperidone; thiothixene; molindone; withdrawal of dopaminergic agents |
| SEROTONIN SYNDROME | Selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants |
| MALIGNANT HYPERThERMIA | Inhalational anesthetics, succinylcholine |
| ENDOCRINEOPATHY | Thyrotoxicosis, pheochromocytoma |
| CENTRAL NERVOUS SYSTEM DAMAGE | Cerebral hemorrhage, status epilepticus, hypothalamic injury |

Systemic effects of these circulating cytokines lead to fever by inducing pyrogenic cytokines. Pyrogenic cytokines such as IL-1, IL-6, and TNF are released into the circulation, raising the set point to febrile levels. As has been mentioned, several cell types can produce pyrogenic cytokines. Monocytes/macrophages, endothelial cells, and pyrogenic cytokines are primarily monocytes, neutrophils, and lymphocytes, although many other types of cells can synthesize these molecules when stimulated.

**Elevation of the Hypothalamic Set Point by Cytokines** During fever, levels of prostaglandin E$_2$ (PGE$_2$) are elevated in hypothalamic tissue and the third cerebral ventricle. The concentrations of PGE$_2$ are highest near the circumventricular vascular organs (organum vasculosum of lamina terminalis)—networks of enlarged capillaries surrounding the hypothalamic regulatory centers. Destruction of these organs reduces the ability of pyrogens to produce fever. Most studies in animals have failed to show, however, that pyrogenic cytokines pass from the circulation into the brain itself. Thus, it appears that both exogenous and endogenous pyrogens interact with the endothelium of these capillaries and that this interaction is the first step in initiating fever—i.e., in raising the set point to febrile levels.

The key events in the production of fever are illustrated in Fig. 16-1. As has been mentioned, several cell types can produce pyrogenic cytokines. Pyrogenic cytokines such as IL-1, IL-6, and TNF are released from the cells and enter the systemic circulation. Although the systemic effects of these circulating cytokines lead to fever by inducing the synthesis of PGE$_2$, they also induce PGE$_2$ in peripheral tissues. The increase in PGE$_2$ in the periphery accounts for the nonspecific fever.

There are four receptors for PGE$_2$, and each signals the cell in different ways. Of the four receptors, the third (EP-3) is essential for fever: when the gene for this receptor is deleted in mice, no fever follows the injection of IL-1 or endotoxin. Deletion of the other PGE$_2$ receptor genes leaves the fever mechanism intact. Although PGE$_2$ is essential for fever, it is not a neurotransmitter. Rather, the release of PGE$_2$ from the brain side of the hypothalamic endothelium triggers the PGE$_2$ receptor on glial cells, and this stimulation results in the rapid release of cyclic adenosine 5’-monophosphate (cyclic AMP), which is a neurotransmitter. As shown in Fig. 16-1, the release of cyclic AMP from the glial cells activates neuronal endings from the thermoregulatory center that extend into the area. The elevation of cyclic AMP is thought to account for changes in the hypothalamic set point either directly or indirectly by inducing the release of neurotransmitters. Distinct receptors for microbial products (such as endotoxins) from gram-negative bacteria and for teichoic acids from gram-positive bacteria are located on the hypothalamic endothelium. These receptors are called Toll-like receptors and are similar in many ways to IL-1 receptors. The direct activation of Toll-like receptors also results in PGE$_2$ production and fever.

**Production of Cytokines in the CNS** Several viral diseases produce active infection in the brain. Glial and possibly neuronal cells synthesize IL-1, TNF, and IL-6. CNTF is also synthesized by neural as well as neuronal cells. What role in the production of fever is played by these cytokines produced in the brain itself? In experimental animals, the concentrations of cytokine required to cause fever are several orders of magnitude lower with direct injection into the brain than with intravenous injection. Therefore, CNS production of these cytokines apparently can raise the hypothalamic set point, bypassing the circumventricular organs involved in fever caused by circulating cytokines. CNS cytokines may account for the hyperpyrexia of CNS hemorrhage, trauma, or infection.

**Approach to the Patient**

**History** It is in the diagnosis of a febrile illness that the science and art of medicine come together (see also Chaps. 1, 18, and 106). In no other clinical situation is a meticulous history more important. Painstaking attention must be paid to the chronology of symptoms in relation to the use of prescription drugs (including drugs, supplements, or herbs taken without a physician’s supervision) or treatments such as surgical or dental procedures. The exact nature of any prosthetic materials and/or implanted devices should be ascertained. A careful occupational history should include exposures to animals; toxic fumes; potential infectious agents; possible antigens; or other febrile or infected individuals in the home, workplace, or school. A history of the geographic areas in which the patient has lived and a travel history should include locations during military service. Information on unusual hobbies, dietary proclivities (such as raw or poorly cooked meat, raw fish, and unpasteurized milk or cheeses), and household pets should be elicited, as should sexual orientation and practices, including precautions taken or omitted. Attention should be directed to the use of tobacco, marijuana, intravenous drugs, or alcohol; trauma; animal bites; tick or other insect bites; and prior transfusions, immunizations, drug allergies, or hypersensitivities. A careful family history should include information on family members with tuberculosis, other febrile or infectious diseases, arthritis or collagen vascular disease, or unusual familial symptomatology such as deafness, urticaria, fevers and polyserositis, bone pain, or anemia. Ethnic origin may be critical. For example, blacks are more likely than persons in other groups to have hemoglobinopathies. Turks, Arabs, Armenians, and Sephardic Jews are especially likely to have familial Mediterranean fever (Chap. 278).

**Physical Examination** A meticulous physical examination should be repeated on a regular basis. All the vital signs are relevant. The temperature may be taken orally or rectally, but the site used should be consistent. Axillary temperatures are notoriously unreliable. Special attention should be paid to the skin, lymph nodes, eyes, nail beds, cardiovascular system, chest, abdomen, musculoskeletal system, and nervous system. Rectal examination is imperative. The penis, prostate, scrotum, and testes should be examined carefully and the foreskin, if present, retracted. Pelvic examination must be part of every complete physical examination of a woman, with a

**FIGURE 16-1** Chronology of events required for the induction of fever. Abbreviations: AMP, adenosine 5’-monophosphate; IFN, interferon; IL, interleukin; PGE$_2$, prostaglandin E$_2$; TNF, tumor necrosis factor.
search for such causes of fever as pelvic inflammatory disease and tubo-ovarian abscesses.

Laboratory Tests Few signs and symptoms in medicine have as many diagnostic possibilities as fever. If the history, epidemiologic situation, or physical examination suggests more than a simple viral illness or streptococcal pharyngitis, then laboratory testing is indicated. The tempo and complexity of the workup will depend on the pace of the illness, diagnostic considerations, and the immune status of the host. If findings are focal or if the history, epidemiologic setting, or physical examination suggests certain diagnoses, the laboratory examination can be focused. If fever is undifferentiated, the diagnostic nets must be cast farther, and certain guidelines are indicated, as follows.

CLINICAL PATHOLOGY The workup should include a complete blood count; a differential count should be performed manually or with an instrument sensitive to the identification of eosinophils, juvenile or band forms, toxic granulations, and Döhle bodies, the last three of which are suggestive of bacterial infection. Neutropenia may be present with some viral infections, particularly parvovirus B19 infection; drug reactions; systemic lupus erythematosus; typhoid; brucellosis; and infiltrative diseases of the bone marrow, including lymphoma, leukemia, tuberculosis, and histoplasmosis. Lymphocytosis may occur with typhoid, brucellosis, tuberculosis, and viral disease. Atypical lymphocytes are documented in many viral diseases, including infection with Epstein-Barr virus, cytomegalovirus, or HIV; dengue; rubella; varicella; measles; and viral hepatitis. This abnormality also occurs in serum sickness and toxoplasmosis. Monocytosis is a feature of typhoid, tuberculosis, brucellosis, and lymphoma. Eosinophilia may be associated with hypersensitivity drug reactions, Hodgkin’s disease, adrenal insufficiency, and certain metazoan infections. If the febrile illness appears to be severe or is prolonged, the smear should be examined carefully for malarial or babesial pathogens (where appropriate) as well as for classic morphologic features, and the erythrocyte sedimentation rate should be determined. Urinalysis, with examination of urinary sediment, is indicated. It is axiomatic that any abnormal fluid accumulation (pleural, peritoneal, joint), even if previously sampled, merits reexamination in the presence of undiagnosed fever. Joint fluids should be examined for bacteria as well as crystals. Bone marrow biopsy (not simple aspiration) for histopathologic studies (as well as culture) is indicated when marrow infiltration by pathogens or tumor cells is possible. Stool should be inspected for occult blood; an inspection for fecal leukocytes, ova, or parasites also may be indicated.

CHEMISTRY Electrolyte, glucose, blood urea nitrogen, and creatinine levels should be measured. Liver function tests are usually indicated if efforts to identify the cause of fever do not point to the involvement of another organ. Additional assessments (e.g., measurement of creatinine phosphokinase or amylase) can be added as the workup progresses.

MICROBIOLOGY Smears and cultures of specimens from the throat, urethra, anus, cervix, and vagina should be assessed when there are no localizing findings or when findings suggest the involvement of the pelvis or the gastrointestinal tract. If respiratory tract infection is suspected, sputum evaluation (Gram’s staining, staining for acid-fast bacilli, culture) is indicated. Cultures of blood, abnormal fluid collections, and urine are indicated when fever is thought to reflect more than uncomplicated viral illness. Cerebrospinal fluid should be examined and cultured if meningismus, severe headache, or a change in mental status is noted.

RADIOLOGY A chest x-ray is usually part of the evaluation for any significant febrile illness.

Outcome of Diagnostic Efforts In most cases of fever, either the patient recovers spontaneously or the history, physical examination, and initial screening laboratory studies lead to a diagnosis. When fever continues for 2 to 3 weeks, during which time repeat physical examinations and laboratory tests are unrevealing, the patient is provisionally diagnosed as having fever of unknown origin (Chap. 18).

### Treatment

#### The Decision to Treat Fever Most fevers are associated with self-limited infections, most commonly of viral origin. In these cases, the general cause of the fever is easily identified. The routine use of antipyretics given automatically as “standing,” “routine,” or “prn” orders to treat low-grade fevers in adult patients on hospital wards is entirely unacceptable. This practice masks not only fever but also other important clinical indicators of a patient’s course. For example, the daily highs and lows of normal temperature are exaggerated in most fevers, but the usual times of peak and trough temperatures may be reversed in typhoid fever and disseminated tuberculosis. Temperature-pulse dissociation (relative bradycardia) occurs in typhoid fever, brucellosis, leptospirosis, some drug-induced fevers, and factitious fever. In newborns, the elderly, patients with chronic renal failure, and patients taking glucocorticoids, fever may not be present despite infection, or core temperature may be hypothermic. Hypothermia is observed in patients with septic shock.

Some febrile diseases have characteristic patterns. With relapsing fevers, febrile episodes are separated by intervals of normal temperature; when paroxysms occur on the first and third days, the fever is called tertian. *Plasmodium vivax* causes tertian fevers. *Quartan* fevers are associated with paroxysms on the first and fourth days and are seen with *P. malariae*. Other relapsing fevers are related to *Borrelia* infections and rat-bite fever, which are both associated with days of fever followed by a several-day afebrile period and then a relapse of days of fever. Pel-Ebstein fever, with fevers lasting 3 to 10 days followed by afebrile periods of 3 to 10 days, is classic for Hodgkin’s disease and other lymphomas. Another characteristic fever is that of cyclic neutropenia, in which fevers occur every 21 days and accompany the neutropenia. There is no periodicity of fever in patients with familial Mediterranean fever (Chap. 278).

#### Mechanisms of Antipyretic Agents The synthesis of PGE₂ depends on the constitutively expressed enzyme cyclooxygenase. The substrate for cyclooxygenase is arachidonic acid released from the cell membrane, and this release is the rate-limiting step in the synthesis of PGE₂. Inhibitors of cyclooxygenase are potent antipyretics. The antipyretic potency of various drugs is directly correlated with the inhibition of brain cyclooxygenase. Acetaminophen is a poor cyclooxygenase inhibitor in peripheral tissue and is without noteworthy anti-inflammatory activity; in the brain, however, acetaminophen is oxidized by the p450 cytochrome system, and the oxidized form inhibits cyclooxygenase activity. Moreover, in the brain, the inhibition of another enzyme, COX-3, by acetaminophen may account for the antipyretic effect of this agent. However, COX-3 is not found outside the CNS.

Oral aspirin and acetaminophen are equally effective in reducing fever in humans. Nonsteroidal anti-inflammatory agents (NSAIDs) such as indomethacin and ibuprofen are also excellent antipyretics. Chronic high-dose therapy with antipyretics such as aspirin or the NSAIDs used in arthritis does not reduce normal core body temperature. Thus, PGE₂ appears to play no role in normal temperature regulation. As effective antipyretics, glucocorticoids act at two levels. First, similar to the cyclooxygenase inhibitors, glucocorticoids reduce PGE₂ synthesis by inhibiting the activity of phospholipase A₂, which is needed to release arachidonic acid from the cell membrane. Second, glucocorticoids block the transcription of the mRNA for the pyrogenic cytokines.

#### Indications and Regimens for the Treatment of Fever The objectives in treating fever are first to reduce the elevated hypothalamic set point and second to facilitate heat loss. There is no evidence that fever itself
facilitates the recovery from infection or acts as an adjuvant to the immune system. In fact, peripheral PGE$_2$ production is a potent immunosuppressant. Hence, treating fever and its symptoms does no harm and does not slow the resolution of common viral and bacterial infections. Reducing fever with antipyretics also reduces systemic symptoms of headache, myalgias, and arthralgias.

Oral aspirin and NSAIDs effectively reduce fever but can adversely affect platelets and the gastrointestinal tract. Therefore, acetaminophen is preferred to all of these agents as an antipyretic. In children, acetaminophen must be used because aspirin increases the risk of Reye's syndrome. If the patient cannot take oral antipyretics, parenteral preparations of NSAIDs and rectal suppository preparations of various antipyretics can be used.

Treatment of fever in some groups of patients is recommended. Fever increases the demand for oxygen (i.e., for every increase of 1°C over 37°C, there is a 13% increase in oxygen consumption) and can aggravate preexisting cardiac, cerebrovascular, or pulmonary insufficiency. Elevated temperature can induce mental changes in patients with organic brain disease. Children with a history of febrile or nonfebrile seizure should be aggressively treated to reduce fever, although it is unclear what triggers the febrile seizure and there is no correlation between absolute temperature elevation and onset of a febrile seizure in susceptible children.

In hyperpyrexia, the use of cooling blankets facilitates the reduction of temperature; however, cooling blankets should not be used without oral antipyretics. In hyperpyretic patients with CNS disease or trauma, reducing core temperature mitigates the ill effects of high temperature on the brain.

**Treating Hyperthermia** A high core temperature in a patient with an appropriate history (e.g., environmental heat exposure or treatment with anticholinergic or neuroleptic drugs, tricyclic antidepressants, succinylcholine, or halothane) along with appropriate clinical findings (dry skin, hallucinations, delirium, pupil dilation, muscle rigidity, and/or elevated levels of creatine phosphokinase) suggests hyperthermia. The attempt to lower the already normal hypothalamic set point is of little use. Physical cooling with sponging, fans, cooling blankets, and even ice baths should be initiated immediately in conjunction with the administration of intravenous fluids and appropriate pharmacologic agents (see below). If insufficient cooling is achieved by external means, internal cooling can be achieved by gastric or peritoneal lavage with iced saline. In extreme circumstances, hemodialysis or even cardiopulmonary bypass with cooling of blood may be performed.

Malignant hyperthermia should be treated immediately with cessation of anesthesia and intravenous administration of dantrolene sodium. The recommended dose of dantrolene is 1 to 2.5 mg/kg of body weight given intravenously every 6 h for at least 24 to 48 h — until oral dantrolene can be administered, if needed. Procainamide should also be administered to patients with malignant hyperthermia because of the likelihood of ventricular fibrillation in this syndrome. Dantrolene at similar doses is indicated in NMS and in drug-induced hyperthermia and may even be useful in the hyperthermia of the serotonin syndrome and thyrotoxicosis. NMS may also be treated with bromocriptine, levodopa, amantadine, or nifedipine or by induction of muscle paralysis with curare and pancuronium. Tricyclic antidepressant overdose may be treated with physostigmine.

**FURTHER READING**

The acutely ill patient with fever and rash often presents a diagnostic challenge for physicians. The distinctive appearance of an eruption in concert with a clinical syndrome may facilitate a prompt diagnosis and the institution of life-saving therapy or critical infection-control interventions.

**APPROACH TO THE PATIENT**

A thorough history of patients with fever and rash includes the following relevant information: immune status, medications taken within the previous month, specific travel history, immunization status, exposure to domestic pets and other animals, history of animal or arthropod bites, existence of cardiac abnormalities, presence of prosthetic material, recent exposure to ill individuals, and exposure to sexually transmitted diseases. The history should also include the site of onset of the rash and its direction and rate of spread.

A thorough physical examination entails close attention to the rash, with an assessment and precise definition of its salient features. First, it is critical to determine the type of lesions that make up the eruption. **Macules** are flat lesions defined by an area of changed color (i.e., a blanchable erythema). **Papules** are raised, solid lesions <5 mm in diameter; **plaques** are lesions >5 mm in diameter with a flat, plateau-like surface; and **nodules** are lesions >5 mm in diameter with a more rounded configuration. **Wheals** (urticaria, hives) are papules or plaques that are pale pink and may appear annular (ringlike) as they enlarge; classic (nonvasculitic) wheals are transient, lasting only 24 to 48 h in any defined area.

**Vesicles** (<5 mm) and **bullae** (>5 mm) are circumscribed, elevated lesions containing fluid. **Pustules** are raised lesions containing purulent exudate; vesicular processes such as varicella or herpes simplex may evolve to pustules. **Nonpalpable purpura** is a flat lesion that is due to bleeding into the skin; if <3 mm in diameter, the purpuric lesions are termed petechiae; if >3 mm, they are termed ecchymoses. **Palpable purpura** is a raised lesion that is due to inflammation of the vessel wall (vasculitis) with subsequent hemorrhage. An **ulcer** is a defect in the skin extending at least into the upper layer of the dermis, and an **eschar** (tache noire) is a necrotic lesion covered with a black crust.

Other pertinent features of rashes include their configuration (i.e., annular or target), the **arrangement** of their lesions, and their distribution (i.e., central or peripheral). — For further discussion, see Chaps. 46 and 48.

**CLASSIFICATION OF RASH**

This chapter reviews rashes that reflect systemic disease, but it does not include localized skin eruptions (i.e., cellulitis, impetigo) that may also be associated with fever (Chap. 110). Rashes are classified herein on the basis of the morphology and distribution of lesions. For practical purposes, this classification system is based on the most typical disease presentations. However, morphology may vary as rashes evolve, and the presentation of diseases with rashes is subject to many variations (Chap. 48). For instance, the classic petechial rash of Rocky Mountain spotted fever (RMSF, Chap. 158) may initially consist of blanchable erythematosus macules distributed peripherally; at times, the rash associated with RMSF may not be predominantly acral, or a rash may not develop at all.
Diseases with fever and rash may be classified by type of eruption: centrally distributed maculopapular, peripheral, confluent desquamative erythematous, vesiculobullous, urticarial, nodular, purpuric, ulcerated, or eschars (Table 17-1). For a more detailed discussion of each disease associated with a rash, the reader is referred to the chapter dealing with that specific disease. (Reference chapters are cited in the text and listed in Table 17-1.)

CENTRALLY DISTRIBUTED MACULOPAPULAR ERUPTIONS

Centrally distributed rashes, in which lesions are primarily truncal, are the most common type of eruption. The rash of measles (rubella) starts at the hairline 2 to 3 days into the illness and moves down the body, sparing the palms and soles (Chap. 176). It begins as discrete erythematous lesions, which become confluent as the rash spreads. Koplik’s spots (1- to 2-mm white or bluish lesions with an erythematous halo on the buccal mucosa) are pathognomonic for measles and are generally seen during the first 2 days of symptoms. They should not be confused with Fordyce’s spots (ectopic sebaceous glands), which have no erythematous halos and are found in the mouth of healthy individuals. Koplik’s spots may briefly overlap with the measles exanthem.

German measles (rubella) also spreads from the hairline downward; unlike that of measles, however, the rash of rubella tends to clear from originally affected areas as it migrates and may be pruritic (Chap. 177). Forchheimer spots (palatal petechiae) may develop but are nonspecific since they also develop in mononucleosis (Chap. 165) and scarlet fever (Chap. 121). Postauricular and suboccipital adenopathy and arthritis are common among adults with German measles. Exposure of pregnant women to ill individuals should be avoided, as rubella causes severe congenital abnormalities. Numerous strains of enteroviruses (Chap. 175), primarily echoviruses and coxsackieviruses, cause nonspecific syndromes of fever and eruptions that may mimic rubella or measles. Patients with infectious mononucleosis caused by Epstein-Barr virus (Chap. 165) or with primary infection caused by HIV (Chap. 173) may exhibit pharyngitis, lymphadenopathy, and a nonspecific maculopapular exanthem.

The rash of erythema infectiosum (fifth disease), which is caused by human parvovirus B19, primarily affects children 3 to 12 years old; it develops after fever has resolved as a bright blanchable erythema on the cheeks (“slapped cheeks”) with perioral pallor (Chap. 168). A more diffuse rash (often pruritic) appears the next day on the trunk and extremities and then rapidly develops into a lacy reticular eruption that may wax and wane (especially with temperature change) over 3 weeks. Adults with fifth disease often have arthritis, and fetal hydrops can develop in association with this condition in pregnant women.

Exanthem subitum (roseola) is caused by human herpesvirus 6 and is most common among children <3 years of age (Chap. 166). As in erythema infectiosum, the rash usually appears after fever has subsided. It consists of 2- to 3-mm rose-pink macules and papules that rarely coalesce, occur initially on the trunk and sometimes on the extremities (sparing the face), and fade within 2 days.

Although drug reactions have many manifestations, including urticaria, exanthematous drug-induced eruptions (Chap. 50) are most common and are often difficult to distinguish from viral exanthems. Eruptions elicited by drugs are usually more intensely erythematous and pruritic than viral exanthems, but this distinction is not reliable. A history of new medications and an absence of prostration may help to distinguish a drug-related rash from an eruption of another etiology. Rashes may persist for up to 2 weeks after administration of the offending agent is discontinued. Certain populations are more prone than others to drug rashes. Of HIV-infected patients, 50 to 60% develop a rash in response to sulfonamides; 50 to 100% of patients with mononucleosis due to Epstein-Barr virus develop a rash when given ampicillin.

Rickettsial illnesses (Chap. 158) should be considered in the evaluation of individuals with centrally distributed maculopapular eruptions. The clinical setting for epidemic typhus is a site of war or natural disaster in which people are exposed to body lice. A diagnosis of typhus should be considered in European immigrants to the United States. However, an indigenous form of typhus, presumably transmitted by flying squirrels, has been reported in the southeastern United States. Endemic typhus or leptospirosis (the latter caused by a spirochete; Chap. 155) may be seen in urban environments where rodents proliferate. Outside the United States, other rickettsial diseases cause a spotted-fever syndrome and should be considered in residents of or travelers to endemic areas. Similarly, typhoid fever, a nonrickettsial disease caused by Salmonella typhi (Chap. 137), is usually acquired during travel outside the United States. Dengue fever, caused by a mosquito-transmitted flavivirus, occurs in tropical and subtropical regions of the world (Chap. 180).

Some centrally distributed maculopapular eruptions have distinctive features. Erythema chronicum migrans (ECM), the rash of Lyme disease (Chap. 157), typically manifests as singular or multiple annular plaques. Untreated ECM lesions usually fade within a month but may persist for more than a year. Erythema marginatum, the rash of acute rheumatic fever (Chap. 302), has a distinctive pattern of enlarging and shifting transient annular lesions.

Collagen vascular diseases may cause fever and rash. Patients with systemic lupus erythematosus (Chap. 300) typically develop a sharply defined, erythematous eruption in a butterfly distribution on the cheeks (malar rash) as well as many other skin manifestations. Still’s disease (Chap. 316) manifests as an evanescent salmon-colored rash on the trunk and proximal extremities that coincides with fever spikes.

PERIPHERAL ERUPTIONS

These rashes are alike in that they are most prominent peripherally or begin in peripheral (acral) areas before spreading centripetally. Early diagnosis and therapy are critical in RMSF (Chap. 158) because of its grave prognosis if untreated. Lesions evolve from macular to petechial, start on the wrists and ankles, spread centripetally, and appear on the palms and soles only later in the disease. The rash of secondary syphilis (Chap. 153), which may be generalized but is prominent on the palms and soles, should be considered in the differential diagnosis of pityriasis rosea, especially in sexually active patients. Arthropalms (Chap. 176) is seen in individuals contracting measles who received the killed measles vaccine between 1963 and 1967 in the United States and who were not subsequently protected with the live vaccine. Hand-foot-and-mouth disease (Chap. 175), most commonly caused by coxsackievirus A16, is distinguished by tender vesicles distributed peripherally and in the mouth; outbreaks commonly occur within families. The classic target lesions of erythema multiforme appear symmetrically on the elbows, knees, palms, and soles. In relatively severe cases, these lesions may spread diffusely and involve mucosal surfaces (Stevens-Johnson syndrome). Lesions may develop on the hands and feet in endocarditis (Chap. 109).

CONFLUENT DESQUAMATIVE ERTHEMAS

These eruptions consist of diffuse erythema frequently followed by desquamation. The eruptions caused by group A Streptococcus or Staphylococcus aureus are toxin mediated. Certain disease features may provide diagnostic clues. Scarlet fever (Chap. 121) usually follows pharyngitis; patients have a facial flush, a “strawberry” tongue, and accentuated petechiae in body folds (Pastia’s lines). Kawasaki disease (Chaps. 48 and 306) presents in the pediatric population as fissuring of the lips, a strawberry tongue, conjunctivitis, adenopathy, and sometimes cardiac abnormalities. Streplococcal toxic shock syndrome (Chap. 121) manifests with hypotension, multiorgan failure, and often a severe group A streptococcal infection (e.g., necrotizing fasciitis). Staphylococcal toxic shock syndrome (Chap. 120) also presents with hypotension and multiorgan failure, but usually only S. aureus colonization—not a severe S. aureus infection—is documented. Staphylococcal scalded-skin syndrome (Chap. 120) is seen primarily in children and in immunocompromised adults. Generalized erythema is often evident during the prodrome of fever and malaise; profound tenderness of the skin is distinctive. In the exfoliative stage, the skin can be induced to form bullae with light lateral pressure (Nikolsky’s sign). In a mild form, a scarlatiniform eruption mimics scarlet fever, but the patient does not exhibit a straw-

6 See “Purpuric eruptions.”
berry tongue or circumoral pallor. In contrast to the staphylococcal scaled-skin syndrome, in which the cleavage plane is superficial in the epidermis, toxic epidermal necrolysis (Chap. 50) involves sloughing of the entire epidermis, resulting in severe disease. Eruptive erythema multiforme (Chaps. 47 and 50) is a serious reaction associated with systemic toxicity that is often due to eczema, psoriasis, mycosis fungoides, or a severe drug reaction.

**VESICULOBULLOUS ERUPTIONS** Varicella (Chap. 164) is highly contagious, often occurring in winter or spring. At a given time within a given region of the body, varicella lesions are in different stages of development. In immunocompromised hosts, varicella vesicles may lack the characteristic erythematous base or may appear hemorrhagic. Lesions of variola (smallpox; Chap. 205) appear similar to those of varicella but are all at the same stage of development in a given region of the body. Variola lesions are most prominent on the face and extremities, while varicella lesions are most prominent on the trunk. Rickettsialpox (Chap. 158) is often documented in urban settings and is characterized by vesicles. It can be distinguished from varicella by an eschar at the site of the mouse-mite bite and the papule/plaque base of each vesicle. Disseminated *Vibrio vulnificus* infection (Chap. 140) or *echyma gangrenosum* due to *Pseudomonas aeruginosa* (Chap. 136) should be considered in immunosuppressed individuals with sepsis and hemorrhagic bullae.

**URTIQARIAL ERUPTIONS** Individuals with classic urticaria (“hives”) usually have a hypersensitivity reaction without associated fever. In the presence of fever, urticarial eruptions are usually due to urticarial vasculitis (Chap. 306). Unlike individual lesions of classic urticaria, which last up to 48 h, these lesions may last up to 5 days. Etiologies include serum sickness (often induced by drugs such as penicillins, sulfas, salicylates, or barbiturates), connective-tissue disease (e.g., systemic lupus erythematosus or Sjögren’s syndrome), and infection (e.g., with hepatitis B virus, enteroviruses, or parasites). Malignancy may be associated with fever and chronic urticaria (Chap. 48).

**NODULAR ERUPTIONS** In immunocompromised hosts, nodular lesions often represent disseminated infection. Patients with disseminated *candidiasis* (often due to *Candida tropicalis*) may have a triad of fever, myalgias, and eruptive nodules (Chap. 187). Disseminated *cryptococcosis* lesions (Chap. 186) may resemble molluscum contagiosum. Necrosis of nodules should raise the suspicion of *aspergillosis* (Chap. 188) or *mucormycosis* (Chap. 189). Erythema nodosum presents with exquisitely tender nodules on the lower extremities. Sweet’s syndrome (Chap. 48) should be considered in individuals with multiple nodules and plaques, often so edematous that they give the appearance of vesicles or bullae. Sweet’s syndrome may affect either healthy individuals or persons with lymphoproliferative disease.

**PURPURIC ERUPTIONS** Acute meningococcemia (Chap. 127) classically presents in children as a petechial eruption, but initial lesions may appear as blanchable macules or urticaria. RMSF should be considered in the differential diagnosis of acute meningococcemia. *Echovirus 9 infection* (Chap. 175) may mimic acute meningococcemia; patients should be treated as if they have bacterial sepsis since prompt differentiation of these conditions may be impossible. Large ecchymotic areas of purpura *fulminans* (Chaps. 127 and 254) reflect severe underlying disseminated intravascular coagulation, which may be due to infectious or noninfectious causes. The lesions of chronic meningococcemia (Chap. 127) may have a variety of morphologies, including petechial. Purpuric nodules may develop on the legs and resemble erythema nodosum but lack its exquisite tenderness. Lesions of disseminated gonococcemia (Chap. 128) are distinctive, sparse, countable hemorrhagic pustules, usually located near joints. The lesions of chronic meningococcemia and those of gonococcemia may be indistinguishable in terms of appearance and distribution. Viral hemorrhagic fever (Chaps. 180 and 181) should be considered in patients with an appropriate travel history and a petechial rash. *Thrombotic thrombocytopenic purpura* (Chaps. 48, 93, and 101) and *hemolytic-uremic syndrome* (Chaps. 101, 134, and 138) are closely related and are noninfectious causes of fever and petechiae. *Cutaneous small- vessel vasculitis* (leukocytoclastic vasculitis) typically manifests as palpable purpura and has a wide variety of causes (Chap. 48).

**ERUPTIONS WITH ULCERS OR ESCHARS** The presence of an ulcer or eschar in the setting of a more widespread eruption can provide an important diagnostic clue. For example, the presence of an eschar may suggest the diagnosis of scrub typhus or rickettsialpox (Chap. 158) in the appropriate setting. In other illnesses (e.g., anthrax; Chap. 205), an ulcer or eschar may be the only skin manifestation.

---

**DEFINITION AND CLASSIFICATION** Fever of unknown origin (FUO) was defined by Petersdorf and Beeson in 1961 as (1) temperatures of ≥38.3°C (≥101°F) on several occasions; (2) a duration of fever of ≥3 weeks; and (3) failure to reach a diagnosis despite 1 week of inpatient investigation. While this classification has stood for more than 30 years, Durack and Street have proposed a new system for classification of FUO: (1) classic FUO; (2) nosocomial FUO; (3) neutropenic FUO; and (4) FUO associated with HIV infection (Table 18-1).

Classic FUO corresponds closely to the earlier definition of FUO, differing only with regard to the prior requirement for 1 week’s study in the hospital. The new definition is broader, stipulating three outpatient visits or 3 days in the hospital without elucidation of a cause or 1 week of “intelligent and invasive” ambulatory investigation. In nosocomial FUO, a temperature of ≥38.3°C (≥101°F) develops on several occasions in a hospitalized patient who is receiving acute care and in whom infection was not manifest or incubating on admission. Three days of investigation, including at least 2 days’ incubation of cultures, is the minimum requirement for this diagnosis. Neutropenic FUO is defined as a temperature of ≥38.3°C (≥101°F) on several occasions in a patient whose neutrophil count is <500/µL or is expected to fall to that level in 1 to 2 days. The diagnosis of neutropenic FUO is invoked if a specific cause is not identified after 3 days of investigation, including at least 2 days’ incubation of cultures. *HIV-associated FUO* is defined by a temperature of ≥38.3°C (≥101°F) on several occasions over a period of >4 weeks for outpatients or ≥3 days for hospitalized patients with HIV infection. This diagnosis is invoked if appropriate investigation over 3 days, including 2 days’ incubation of cultures, reveals no source.

Adoption of these categories of FUO on a wide scale in the literature would allow a more rational compilation of data regarding these
disparate groups. In the remainder of this chapter, the discussion will focus on classic FUO unless otherwise specified.

**CAUSES OF CLASSIC FUO** Table 18-2 summarizes the findings of several large studies of FUO carried out since the advent of the antibiotic era, including a prospective study of 167 adult patients with FUO encompassing all 8 university hospitals in the Netherlands and using a standardized protocol in which the first author reviewed every patient. Coincident with the widespread use of antibiotics, increasingly useful diagnostic technologies—both noninvasive and invasive—have been developed. Newer studies reflect not only changing patterns of disease but also the impact of diagnostic techniques that make it possible to eliminate many patients with specific illness from the FUO category. The ubiquitous use of potent broad-spectrum antibiotics may have decreased the number of infections causing FUO. The wide availability of ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scanning, and positron emission tomography (PET) scanning has enhanced the detection of occult neoplasms and lymphomas in patients previously thought to have FUO. Likewise, the widespread availability of highly specific and sensitive immunologic testing has reduced the number of undetected cases of systemic lupus erythematosus and other autoimmune diseases.

Infections, especially extrapulmonary tuberculosis, remain the leading diagnosable cause of FUO. Prolonged mononucleosis syndromes caused by Epstein-Barr virus, cytomegalovirus (CMV), or HIV are conditions whose consideration as a cause of FUO is sometimes confounded by delayed antibody responses. Intraabdominal abscesses (sometimes poorly localized) and renal, retroperitoneal, and paraspinal abscesses continue to be difficult to diagnose. Renal malacoplakia, with submucosal plaques or nodules involving the urinary tract, may cause FUO and is often fatal if untreated. It is associated with coliform infection, is seen most often in patients with defects of intracellular bacterial killing, and is treated with fluoroquinolones or trimethoprim-sulfamethoxazole. Occasionally, other organs may be involved. Obstemyelitis, especially where prosthetic devices have been implanted, and infective endocarditis must be considered. Although true culture-negative infective endocarditis is rare, one may be misled by slow-growing organisms of the HACEK group (Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Ei-

kenella corrodens, and Kingella kingae; Chap. 131), Bartonella spp. (previously Rochalimaea), Legionella spp., Coxiella burnetii, Chlamydia psittaci, and fungi. Prostatitis, dental abscesses, sinusitis, and cholangitis continue to be sources of occult fever.

Fungal disease, most notably histoplasmosis involving the reticuloendothelial system, may cause FUO. FUO with headache should prompt examination of spinal fluid for Cryptococcus neoformans. Malaria (which may result from transfusion, the failure to take a prescribed prophylactic agent, or infection with a drug-resistant strain) continues to be a cause, particularly of asynchronous FUO. A related protozoan species, Babesia, may cause FUO and is increasing in geographic distribution and in incidence, especially among the elderly and immunosuppressed.

In most earlier series, neoplasms were the next most common cause of FUO after infections (Table 18-2). In the most recent series, a decrease in the percentage of FUO cases due to malignancy was attributed to improvement in diagnostic technologies—in particular, high-resolution tomography and tumor antigen assays. This observation does not diminish the importance of considering neoplasia in the initial diagnostic evaluation of a patient with fever. A number of patients in these series had temporal arteritis, adult Still’s disease, drug-related fever, and factitious fever. In recent series, ~25 to 30% of cases of FUO have remained undiagnosed. The general term noninfectious inflammatory diseases applies to systemic rheumatologic or vasculitic diseases such as polymyalgia rheumatica, lupus, and adult Still’s disease as well as to granulomatous diseases such as sarcoidosis and Crohn’s and granulomatous hepatitis. Table 18-3 shows the 10 leading causes of FUO identified in an investigation at several U.S. community hospitals; the method of classification—i.e., “lumping or splitting” of specific entities—can skew rank.

In the elderly, multisystem disease is the most frequent cause of FUO, giant cell arteritis being the leading etiologic entity in this category. Tuberculosis is the most common infection causing FUO in the elderly, and colon cancer is an important cause of FUO with malignancy in this age group.

Many diseases have been grouped in the various studies as “miscellaneous.” On this list are drug fever, pulmonary embolism, factitious fever, the hereditary periodic fever syndromes (familial

Mediterranean fever, hyper-IgD syndrome, tumor necrosis factor receptor–associated periodic syndrome, familial cold urticaria, the Muckle-Wells syndrome, and Fabry’s disease.

A drug-related etiology must be considered in any case of prolonged fever. Any febrile pattern may be elicited by a drug, and both relative bradycardia and hypotension are uncommon. Eosinophilia and/or rash is found in only one-fifth of patients with drug fever, which usually begins 1 to 3 weeks after the start of therapy and remits 2 to 3 days after therapy is stopped. Virtually all classes of drugs cause fever, but antimicrobial agents (especially β-lactam antibiotics), cardiovascular drugs (e.g., quinidine), antineoplastic drugs, and drugs acting on the central nervous system (e.g., phenytoin) are particularly common causes.

It is axiomatic that, as the duration of fever increases, the likelihood of an infectious cause decreases, even for the more indolent infectious etiologies (e.g., brucellosis, paracoccidioidomycosis, Plasmodium malariae) (Table 18-4). In a series of 347 patients referred to the National Institutes of Health from 1961 to 1977, only 6% had an infection. A significant proportion (9%) had factitious fevers—i.e., fevers due either to false elevations of temperature or to self-induced disease. A substantial number of these factitious cases were in young women in the health professions. It is worth noting that 8% of the patients with prolonged fevers (some of whom had completely normal liver function studies) had granulomatous hepatitis, and 6% had adult Still’s disease. After prolonged investigation, 19% of cases still had no specific diagnosis. A total of 27% of patients had no actual fever during inpatient observation or had an exaggerated circadian temperature rhythm without chills, elevated pulse, or other abnormalities.

The conditions that may be considered in a differential diagnosis of classic FUO in adults are listed in Table 18-5. This list applies strictly to the United States; the frequency of global travel underscores the need for a detailed travel history, and the continuing emergence of new infectious diseases makes this listing potentially incomplete. Increased international and domestic terrorist activity involving the intentional release of infectious agents, many of which cause illnesses presenting with prolonged fever, further underscores the need for obtaining an insightful environmental, occupational, and professional history, with early notification of public health authorities in cases of suspicious etiology (Chap. 205).

**SPECIALIZED DIAGNOSTIC STUDIES ■ Classic FUO** A stepwise flow chart depicting the diagnostic workup and therapeutic management of FUO is provided in Fig. 18-1. In this flow chart, reference is made to “potentially diagnostic clues,” as outlined by DeKleijn and colleagues; these clues may be key findings in the history (e.g., travel), localizing signs, or key symptoms. Certain specific diagnostic maneuvers become critical in dealing with prolonged fevers. If factitious fever is suspected, electronic thermometers should be used, temperature-taking should be supervised, and simultaneous urine and body temperatures should be measured. Thick blood smears should be examined for Plasmodium; thin blood smears, prepared with proper technique and quality stains and subjected to expert microscopy, should be used to speciate Plasmodium and to identify Babesia, Trypanosoma, Leishmania, Rickettsia, and Borrelia. Any tissue removed during prior relevant surgery should be reexamined; slides should be requested and, if need be, paraffin blocks of fixed pathologic material should be reexamined and additional special studies performed. Relevant x-rays should be reexamined; reviewing of prior radiologic reports may be insufficient. Serum should be set aside in the laboratory as soon as possible and retained for future examination for rising antibody titers. Febrile agglutinins is a vague term that in most laboratories refers to serologic studies for salmonellosis, brucellosis, and rickettsial diseases. These studies are seldom useful, having low sensitivity and variable specificity. Multiple blood samples (no fewer than three and rarely more than six, including samples for anaerobic culture) should be cultured in the laboratory for at least 2 weeks to ensure that any HACEK group organisms that may be present have ample time to grow (Chap. 131). Lysis-centrifugation blood culture techniques should be employed in cases where prior antimicrobial therapy or fungal or atypical mycobacterial infection is suspected. Blood culture media should be supplemented with L-cysteine or pyridoxal to assist in the isolation of nutritionally variant streptococci. It should be noted that sequential cultures positive for multiple organisms may reflect self-injection of contaminated substances. Urine cultures, including cultures for mycobacteria, fungi, and CMV, are indicated. In the setting of recurrent fevers with lymphocytic meningitis (Mollaret’s meningitis), cerebrospinal fluid can be tested for herpesvirus, with use of polymerase chain reaction (PCR) to amplify and detect viral nucleic acid (Chap. 163).

In any FUO workup, the erythrocyte sedimentation rate (ESR) should be determined. Striking elevation of the ESR and anemia of chronic disease are frequently seen in association with giant cell arteritis or polymyalgia rheumatica, common causes of FUO in patients >50 years of age. Still’s disease is also suggested by elevations of ESR, leukocytosis, and anemia and is often accompanied by arthralgias, polyserositis (pleuritis, pericarditis), lymphadenopathy, splenomegaly, and rash. C-reactive protein may be a useful cross-reference for the ESR and is a more sensitive and specific indicator of an “acute-phase” inflammatory metabolic response. Antinuclear antibody, anti-neutrophil cytoplasmic antibody, rheumatoid factor, and serum cryoglobulins should be measured to rule out other collagen vascular diseases and vasculitis. Elevated levels of angiotensin-converting enzyme in serum may point to sarcoidosis. With rare exceptions, the intermediate-strength purified protein derivative (PPD) skin test should be used to screen for tuberculosis in patients with classic FUO. Concurrent control tests, such as the mumps skin test antigen (Aventis-Pasteur, Swiftwater, PA), should be employed. It should be kept in mind that both the PPD skin test and control tests may yield negative results in miliary tuberculosis, sarcoidosis, Hodgkin’s disease, malnutrition, or AIDS. Noninvasive procedures should include an upper abdominal imaging study and endoscopy with biopsies and deep skin punch biopsies. A transjugular liver biopsy may be considered if the diagnosis is unclear.

therapy started if bacteremia is a threat. In many hospital settings, empirical antibiotic coverage for nosocomial FUO now includes vancomycin for coverage of methicillin-resistant *Staphylococcus aureus* as well as broad-spectrum gram-negative coverage with piperacillin/tazobactam, ticarcillin/clavulanate, imipenem, or meropenem. Practice guidelines covering many of these issues have been published jointly by the Infectious Diseases Society of America (IDSA) and the Society for Critical Care Medicine and can be accessed on the IDSA website (www.journals.uchicago.edu/IDSA/guidelines).

**Neutropenic FUO** (See also Chap. 72) Neutropenic patients are susceptible to focal bacterial and fungal infections, to bacteremic infections, to infections involving catheters (including septic thrombophlebitis), and to perianal infections. *Candida* and *Aspergillus* infections are common. Infections due to herpes simplex virus or CMV are sometimes causes of FUO in this group. While the duration of illness may be short in these patients, the consequences of untreated infection may be catastrophic; 50 to 60% of febrile neutropenic patients are infected, and 20% are bacteremic. The IDSA has published extensive practice guidelines covering these critically ill neutropenic patients; these guidelines appear on the website cited in the previous section. In these patients, severe mucositis, quinolone prophylaxis, colonization with methicillin-resistant *S. aureus*, obvious catheter-related infection, or hypotension dictates the use of vancomycin plus cefazidime, cefepime, or a carbapenem with or without an aminoglycoside to provide empirical coverage for bacterial sepis.

**HIV-Associated FUO** HIV infection alone may be a cause of fever. Infection due to *Mycobacterium avium* or *Mycobacterium intracellulare*, tuberculosis, toxoplasmosis, CMV infection, *Pneumocystis* infection, salmonellosis, cryptococcosis, histoplasmosis, non-Hodgkin’s lymphoma, and (of particular importance) drug fever are all possible causes of FUO. Mycobacterial infection can be diagnosed by blood cultures and by liver, bone marrow, and lymph node biopsies. Chest CT should be performed to identify enlarged mediastinal nodes. Serologic studies may reveal cryptococcal antigen, and ⁶⁷Ga scan may help identify *Pneumocystis* pulmonary infection. More than 80% of HIV patients with FUO are infected, but drug fever and lymphoma remain important considerations. → Treatment of HIV-associated FUO depends on many factors and is discussed in Chap. 173.

### TREATMENT

The focus here is on classic FUO. Other modifiers of FUO—neutropenia, HIV infection, a nosocomial setting—all vastly modify the risk equation and dictate therapy based on the probability of various causes of fever and on the calculated risks and benefits of a guided empirical approach. The age and physical state of the patient are factors as well: the frail elderly patient may merit a trial of empirical therapy earlier than the robust young adult.

The emphasis in patients with classic FUO is on continued observation and examination, with the avoidance of “shotgun” empirical therapy. Antibiotic therapy (even that for tuberculosis) may irrevocably alter the ability to culture fastidious bacteria or mycobacteria and delineate ultimate cause. However, vital-sign instability or neutropenia is an indication for empirical therapy with a fluoroquinolone plus piperacillin or the regimen mentioned above, for example. Cirrhosis, asplenia, intercurrent immunosuppressive drug use, or recent exotic travel may all tip the balance toward earlier empirical anti-infective therapy. If the PPD skin test is positive or if granulomatous hepatitis or other granulomatous disease is present with anergy (and sarcoid seems unlikely), then a therapeutic trial withisoniazid and rifampin (and possibly a third drug) should be undertaken, with treatment usually continued for up to 6 weeks. A failure of the fever to respond over this period suggests an alternative diagnosis.

The response of rheumatic fever and Still’s disease to aspirin and nonsteroidal anti-inflammatory agents (NSAIDs) may be dramatic. The effects of glucocorticoids on temporal arteritis, polymyalgia rheumatica, and granulomatous hepatitis are equally dramatic. Colchicine is highly effective in preventing attacks of familial Mediterranean fever but is of little use once an attack is well under way. The ability of glucocorticoids and NSAIDs to mask fever while permitting the spread of infection dictates that their use be avoided unless infection has been largely ruled out and unless inflammatory disease is both probable and debilitating or threatening.

When no underlying source of FUO is identified after prolonged observation (>6 months), the prognosis is generally good, however vexing the fever may be to the patient. Under such circumstances, debilitating symptoms are treated with NSAIDs, and glucocorticoids are the last resort. The initiation of empirical therapy does not mark the end of the diagnostic workup; rather, it commits the physician to continued thoughtful reexamination and evaluation. Patience, compassion, equanimity, and intellectual flexibility are indispensable attributes for the clinician in dealing successfully with FUO.

### ACKNOWLEDGMENT

Sheldon M. Wolff, MD, now deceased, was an author of a previous version of this chapter. It is to his memory that the chapter is dedicated.

### FURTHER READING

elderly have diminished thermal perception and are more susceptible to immobility, malnutrition, and systemic illnesses that interfere with heat generation or conservation. Dementia, psychiatric illness, and socioeconomic factors often compound these problems by impeding adequate measures to prevent hypothermia. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and their lack of effective shivering and adaptive behavioral responses. In addition, malnutrition can contribute to heat loss because of diminished subcutaneous fat and because of its association with depleted energy stores used for thermogenesis.

Individuals whose occupations or hobbies entail extensive exposure to cold weather are clearly at increased risk for hypothermia. Military history is replete with hypothermic tragedies. Hunters, sailors, skiers, and climbers also are at great risk of exposure, whether it involves injury, changes in weather, or lack of preparedness.

Ethanol causes vasodilatation (which increases heat loss), reduces thermogenesis and gluconeogenesis, and may impair judgment or lead to obtundation. Phenothiazines, barbiturates, benzodiazepines, cyclic antidepressants, and many other medications reduce centrally mediated vasoconstriction. Up to one-quarter of patients admitted to an intensive care unit because of drug overdose are hypothermic. Anesthetics can block the shivering responses; their effects may be compounded when patients are not covered adequately in the operating or recovery rooms.

Several types of endocrine dysfunction can lead to hypothermia. Hypothyroidism—particularly when extreme, as in myxedema coma—reduces the metabolic rate and impairs thermogenesis and behavioral responses. Adrenal insufficiency and hypopituitarism can also increase susceptibility to hypothermia. Hypoglycemia, most commonly caused by insulin or oral hypoglycemic drugs, is associated with hypothermia, in part the result of neuroglycopenic effects on hypothalamic function. Increased osmolality and metabolic derangements associated with uremia, diabetic ketoacidosis, and lactic acidosis can lead to altered hypothalamic thermoregulation.

Neurologic injury from trauma, cerebrovascular accident, subarachnoid hemorrhage, or hypothalamic lesions increases susceptibility to hypothermia. Agenesia of the corpus callosum, or Shapiro syndrome, is one cause of episodic hypothermia, characterized by profuse perspiration followed by a rapid fall in temperature. Acute spinal cord injury disrupts the autonomic pathways that lead to shivering and prevents cold-induced reflex vasoconstrictive responses.

Hypothermia associated with sepsis is a poor prognostic sign. Hepatic failure causes decreased glycogen stores and gluconeogenesis, as well as a diminished shivering response. In acute myocardial infarction associated with low cardiac output, hypothermia may be reversed after adequate resuscitation. With extensive burns, psoriasis, erythroderma, and other skin diseases, increased peripheral blood flow leads to excessive heat loss.

**THERMOREGULATION**

Heat loss occurs through five mechanisms: radiation (55 to 65% of heat loss), conduction (10 to 15% of heat loss, but much greater in cold water), convection (increased in the wind), respiration, and evaporation (which are affected by the ambient temperature and the relative humidity).

The preoptic anterior hypothalamus normally orchestrates thermoregulation (Chap. 16). The immediate defense of thermoneutrality is via the autonomic nervous system, whereas delayed control is mediated by the endocrine system. Autonomic nervous system responses include the release of norepinephrine, increased muscle tone, and shivering, leading to thermogenesis and an increase in the basal metabolic rate. Cutaneous cold thermoreception causes direct reflex vasoconstriction to conserve heat. Prolonged exposure to cold also stimulates the thyroid axis, leading to an increased metabolic rate.

**CLINICAL PRESENTATION**

In most cases of hypothermia, the history of exposure to environmental factors, such as prolonged exposure to the outdoors without adequate clothing, makes the diagnosis straightforward. In urban settings, however, the presentation is often more subtle and other disease processes, toxin exposures, or psychiatric diagnoses should be considered.

After initial stimulation by hypothermia, there is progressive depression of all organ systems. The timing of the appearance of these clinical manifestations varies widely (Table 19-2). Without knowing the core temperature, it can be difficult to interpret other vital signs. For example, a tachycardia disproportionate to the core temperature suggests secondary hypothermia resulting from hypoglycemia, hypovolemia, or a toxin overdose. Because carbon dioxide production declines progressively, the respiratory rate should be low; persistent hyperventilation suggests a central nervous system (CNS) lesion or one of the organic acids. A markedly depressed level of consciousness in a patient with mild hypothermia should raise suspicion of an overdose or CNS dysfunction due to infection or trauma.

Physical examination findings can also be altered by hypothermia. For instance, the assumption that a reflex is solely attributable to hypothermia can obscure and delay the diagnosis of a spinal cord lesion. Patients with hypothermia may be confused or combative; these symptoms abate more rapidly with rewarming than with the use of restraints. A classic example of maladaptive behavior in patients with hypothermia is paradoxical undressing, which involves the inappropriate removal of clothing in response to a cold stress. The cold-induced ileus and abdominal rectus spasm can mimic, or mask, the presentation of an acute abdomen (Chap. 13).

When a patient in hypothermic cardiac arrest is first discovered, cardiopulmonary resuscitation is indicated, unless (1) a do-not-resuscitate status is verified, (2) obviously lethal injuries are identified, or (3) the depression of a frozen chest wall is not possible. As the resuscitation proceeds, the prognosis is grave if there is evidence of widespread cell lysis, as reflected by potassium levels exceeding 10 meq/L. Other findings that may preclude continuing resuscitation include a core temperature <12°C, a pH <6.5, or evidence of intravascular thrombosis with a fibrinogen value <50 mg/dL. The decision to terminate resuscitation before rewarming the patient past 33°C is extremely difficult. There are no validated prognostic indicators for recovery from hypothermia. A history of asphyxia with secondary cooling is the most important negative predictor of survival.

**DIAGNOSIS AND STABILIZATION**

Hypothermia is confirmed by measuring the core temperature, preferably at two sites. Rectal probes should be placed to a depth of 15 cm and not adjacent to cold feces. A simultaneous esophageal probe should be placed 24 cm below the larynx; it may read falsely high during heated inhalation therapy. Relying solely on infrared tympanic thermography is not advisable.

</table>

After a diagnosis of hypothermia is established, cardiac monitoring should be instituted, along with attempts to limit further heat loss. If the patient is in ventricular fibrillation, one sequence of 3 defibrillation attempts (2 J/kg) should be administered. Supplemental oxygenation is always warranted, since tissue oxygenation is adversely affected by the leftward shift of the oxyhemoglobin dissociation curve. Pulse oximetry may be unreliable in patients with vasoconstriction. If protective airway reflexes are absent, gentle endotracheal intubation should be performed. Adequate pre-oxygenation will prevent ventricular arrhythmias. Although cardiac pacing for hypothermic bradydysrhythmias is rarely indicated, the transthoracic technique appears preferable to the transvenous.

Insertion of a gastric tube prevents dilatation secondary to decreased bowel motility. Indwelling bladder catheters facilitate monitoring of cold-induced diuresis. Dehydration is commonly encountered with chronic hypothermia, and most patients benefit from a bolus of crystalloid. Normal saline is preferable to lactated Ringer’s solution, as the liver in hypothermic patients inefficiently metabolizes lactate. The placement of a pulmonary artery catheter, although of potential value, risks perforation of the less compliant pulmonary artery. Insertion of a central venous catheter into the cold right atrium should be avoided, since this can precipitate arrhythmias.

Arterial blood gases should not be corrected for temperature (Chap. 42). An uncorrected pH of 7.42 and a $P_{CO_2}$ of 40 mmHg reflects appropriate alveolar ventilation and acid-base balance at any core temperature. Acid-base imbalances should be corrected gradually, since the bicarbonate buffering system is inefficient. A common error is overzealous hyperventilation in the setting of depressed $CO_2$ production. When the $P_{CO_2}$ decreases 10 mmHg at 28°C, it doubles the pH increase of 0.08 that occurs at 37°C.

The severity of anemia may be underestimated because the hematocrit increases 2% for each 1°C drop in temperature. White blood cell sequestration and bone marrow suppression are common, poten-tially masking an infection. Although hypokalemia is more common in chronic hypothermia, hyperkalemia also occurs; the expected electrocardiographic changes can be obscured by hypothermia. Patients with renal insufficiency, metabolic acidoses, or rhabdomyolysis are at greatest risk for electrolyte disturbances.

Coagulopathies are common because cold inhibits the enzymatic reactions required for activation of the intrinsic cascade. In addition, the production of thromboxane $B_2$ by platelets is temperature-dependent, and platelet function is impaired. The administration of platelets and fresh frozen plasma is, therefore, not effective. The prothrombin or partial thromboplastin times reported by the laboratory appear deceptively normal and contrast with the observed in vivo coagulopathy. This contradiction appears because all coagulation tests are routinely performed at 37°C, and the enzymes are thus warmed.

**REWARMING STRATEGIES**

The key initial decision is whether to warm the patient passively or actively. *Passive external rewarming* simply involves covering and insulating the patient in a warm environment. With the head also covered, the rate of rewarming is usually 0.5° to 2.0°C per hour. This technique is ideal for previously healthy patients who develop acute, mild primary accidental hypothermia. The patient must have sufficient glycogen to support endogenous thermogenesis.

There are reservations about the application of heat directly to the extremities of patients with chronic severe hypothermia. Extinguishing peripheral vasoconstriction in the dehydrated patient may precipitate core temperature “afterdrop”—the continual decline in the core temperature after removal of the patient from the cold. Truncal heat application may minimize the risk of afterdrop.

Active rewarming is necessary under the following circumstances: core temperature <32°C (poikilosthermia), cardiovascular instability, age extremes, CNS dysfunction, endocrine insufficiency, or any suspicion of secondary hypothermia. *Active external rewarming* is best...
accomplished with forced-air heating blankets. Other options include radiant heat sources and hot packs. Monitoring a patient with hypothermia in a heated tub is extremely difficult. Electric blankets should be avoided because vasoconstricted skin is easily burned.

There are numerous widely available active core rewarming options. Airway rewarming with heated humidified oxygen (40° to 45°C) is a convenient option via mask or endotracheal tube. Although airway rewarming provides less heat than some other forms of active core rewarming, it eliminates respiratory heat loss and adds 1° to 2°C to the overall rewarming rate. Crystalloids should be heated to 40° to 42°C. The quantity of heat provided is significant only during massive volume resuscitation. The most efficient method for heating and delivering fluid or blood is with a countercurrent in-line heat exchanger. Heated irrigation of the gastrointestinal tract or bladder transfers minimal heat because of the limited available surface area. These methods should be reserved for patients in cardiac arrest and then used in combination with all available active rewarming techniques. Closed thoracic lavage is far more efficient in severely hypothermic patients with cardiac arrest. The hemithoraces are irrigated through two large-bore thoracostomy tubes that are inserted into the left or both of the hemithoraces. Thoracostomy tubes should not be placed in the left chest of a spontaneously perfusing patient for purposes of rewarming. Percutaneous lavage with the dialysate at 40° to 45°C efficiently transfers heat when delivered through two catheters with outflow suction. Like peritoneal dialysis, standard hemodialysis is especially useful for patients with electrolyte abnormalities, rhabdomyolysis, or toxin ingestions. Stabilizes electrolyte or toxicologic abnormalities exchange cycle volumes 200–500 mL/min ROR 2°–3°C/h Continuous arteriovenous rewarming (CAVR) Circuit—percutaneous 8.5 Fr femoral catheters Requires BP 60 mmHg systolic No perfusionist/pump/anticoagulation Flow rates 225–375 mL/min ROR 3°–4°C/h Cardiopulmonary bypass (CBP) Circuit—full circulatory support with pump and oxygenator Perfusate-temperature gradient (5°–10°C) Flow rates 2–7 L/min (ave. 3–4) ROR up to 9.5°C/h

**DRUG THERAPY**

When a patient is hypothermic, target organs and the cardiovascular system respond minimally to most medications. Moreover, cumulative doses can cause toxicity during rewarming because of increased binding of drugs to proteins, and impaired metabolism and excretion. As an example, the administration of repeated doses of digoxin or insulin would be ineffective while the patient is hypothermic, and the residual drugs are potentially toxic during rewarming.

Achieving a mean arterial pressure of at least 60 mmHg should be an early objective. If the hypotension does not respond to crystalloid/colloid infusion and rewarming, low-dose dopamine (2 to 5 μg/kg per min) support should be considered. Perfusion of the vasoconstricted cardiovascular system may also be improved with low-dose IV nitroglycerin.

Atrial arrhythmias should initially be monitored without intervention, as the ventricular response will be slow, and most will convert spontaneously during rewarming. The role of prophylaxis and treatment of ventricular arrhythmias is problematic. Preexisting ventricular ectopy may be suppressed by hypothermia, and reappear during rewarming. None of the class I agents has proved to be safe and efficacious. When available, bretylium tosylate was the class III ventricular antiarrhythmic of choice. Although class III agents such as bretylium possess electrophysiological and antifibrillatory action, there is no evidence that amiodarone is safe.

Initiating empirical therapy for adrenal insufficiency is usually not warranted unless there is a history suggesting steroid dependence, hypoadrenalism, or a failure to rewarw with standard therapy. However, the administration of parenteral levothyroxine to euthyroid patients with hypothermia is potentially hazardous. Because laboratory results can be delayed and confounded by the presence of the sick euthyroid syndrome (Chap. 320), historic clues or physical findings suggestive of hypothyroidism should be sought. When myxedema is the cause of hypothermia, the relaxation phase of the Achilles reflex is prolonged more than the contraction phase.

Hypothermia obscures most of the symptoms and signs of infection, notably fever and leukocytosis. Shaking rigors from infection may be mistaken for shivering. Except in mild cases, extensive cultures and repeated physical examinations are essential. Unless an infectious source is identified, empirical antibiotic prophylaxis is most warranted in the elderly, neonates, and immunocompromised patients.

Preventive measures should be discussed with high-risk individuals, such as the elderly or people whose work frequently exposes them to extreme cold. The importance of layered clothing and headgear, adequate shelter, increased caloric intake, and the avoidance of ethanol should be emphasized, along with access to rescue services.

**FROSTBITE**

Peripheral cold injuries include both freezing and nonfreezing injuries to tissue. Tissue freezes quickly when in contact with thermal conductors such as metal or volatile solutions. Other predisposing factors include constrictive clothing or boots, immobility, or vasoconstrictive medications. Frostbite occurs when the tissue temperature drops below 0°C. Ice crystal formation subsequently distorts and destroys the cellular architecture. Once the vascular endothelium is damaged, stasis progresses rapidly to microvascular thrombosis. After the tissue thaws, there is progressive dermal ischemia. The microvasculature begins to collapse, arteriovenous shunting increases tissue pressures, and edema forms. Finally, thrombosis, ischemia, and superficial necrosis appear. The development of mummification and demarcation may take weeks to months.

**CLINICAL PRESENTATION**

The initial presentation of frostbite can be deceptively benign. The symptoms always include a sensory deficiency affecting light touch, pain, and temperature perception. The acral areas and distal extremities
are the most common insensate areas. Some patients complain of a clumsy or “chunk of wood” sensation in the extremity.

Deep frostbitten tissue can appear waxy, mottled, yellow, or violaceous-white. Favorable presenting signs include some warmth or sensation with normal color. The injury is often superficial if the subcutaneous tissue is pliable or if the dermis can be rolled over boney prominences.

Clinically, it is most practical to classify frostbite as superficial or deep. Superficial does not entail tissue loss. Classically, frostbite is retrospectively graded like a burn once the resultant pathology is demarcated over time. First-degree frostbite causes only anesthesia and erythema. The appearance of superficial vesiculation surrounded by edema and erythema is considered second degree (Fig. 19-1). Hemorrhagic vesicles reflect a serious injury to the microvasculature, and indicate third-degree frostbite. Fourth-degree frostbite causes only anesthesia and cyanosis. The feet initially appear cyanotic, cold, and edematous. The subsequent development of bullae is often indistinguishable from frostbite. This vesication rapidly progresses to ulceration and liquefaction gangrene. Patients with milder cases complain of hyperhidrosis, cold sensitivity, and painful ambulation for many years. Vasculitis can cause erythema, mild edema, and pruritus. Eventually plaques, blue nodules, and ulcerations develop. These lesions typically involve the dorsa of the hands and feet. In contrast, immersion (trench) foot results from repetitive exposure to wet cold above the freezing point. The feet initially appear cyanotic, cold, and edematous. The subsequent development of bullae is often indistinguishable from frostbite. This vesication rapidly progresses to ulceration and liquefaction gangrene. Patients with milder cases complain of hyperhidrosis, cold sensitivity, and painful ambulation for many years.

</tr>
</tbody>
</table>

Frozen tissue should be rapidly and completely thawed by immersion in circulating water at 37° to 40°C. Rapid rewarming often produces an initial hyperemia. The early formation of clear distal large blebs is more favorable than smaller proximal dark hemorrhagic blebs. A common error is the premature termination of thawing, since the reestablishment of perfusion is intensely painful. Parenteral narcotics will be necessary with deep frostbite. If cyanosis persists after rewarming, the tissue compartment pressures should be monitored carefully.

Numerous experimental antithrombotic and vasodilatory treatment regimens have been evaluated. There is no conclusive evidence that dextran, heparin, steroids, calcium channel blockers, or hyperbaric oxygen salvage tissue. A treatment protocol for frostbite is summarized in Table 19-4.

Unless infection develops, any decision regarding debridement or amputation should be deferred until there is clear evidence of demarcation, mummification, and sloughing. The most common symptomatic sequelae reflect neuronal injury and the persistently abnormal sympathetic tone, including paresthesias, thermal misperception, and hyperhidrosis. Delayed findings include nail deformities, cutaneous carcinomas, and epiphyseal damage in children.

Figure 19-1. Frostbite with vesiculation, surrounded by edema and erythema.
SYNCOPE

Syncope is defined as transient loss of consciousness due to reduced cerebral blood flow. Syncope is associated with postural collapse and spontaneous recovery. It may occur suddenly, without warning, or may be preceded by symptoms of faintness (“presyncope”). These include lightheadedness, “dizziness” without true vertigo, a feeling of warmth, diaphoresis, nausea, and visual blurring occasionally proceeding to blindness. Presyncopal symptoms vary in duration and may increase in severity until loss of consciousness occurs or may resolve prior to loss of consciousness if the cerebral ischemia is corrected. The differentiation of syncope from seizure is an important, sometimes difficult, diagnostic problem.

Syncope may be benign when it occurs as a result of normal cardiovascular reflex effects on heart rate and vascular tone, or serious when due to a life-threatening arrhythmia. Syncope may occur as a single event or may be recurrent. Recurrent, unexplained syncope, particularly in an individual with structural heart disease, is associated with a high risk of death (40% mortality within 2 years).

PATHOPHYSIOLOGY Syncope results from a sudden impairment of brain metabolism, usually brought about by hypotension with reduction of cerebral blood flow. Several mechanisms subserve circulatory adjustments to the upright posture. Approximately three-fourths of the systemic blood volume is contained in the venous bed, and any interference in venous return may lead to a reduction in cardiac output. Cerebral blood flow may still be maintained as long as systemic arterial vasoconstriction occurs, but when this adjustment fails, serious hypotension, with resultant cerebral underperfusion to less than half of normal, results in syncope. Normally, the pooling of blood in the lower parts of the body is prevented by (1) pressor reflexes that induce constriction of peripheral arterioles and venules, (2) reflex acceleration of the heart by means of aortic and carotid reflexes, and (3) improvement of venous return to the heart by activity of the muscles of the limbs. Tilting a normal person upright on a tilt table causes some blood to accumulate in the lower limbs and diminishes cardiac output slightly; this may be followed by a slight transitory fall in systolic blood pressure. In a patient with defective vasomotor reflexes, however, tilt table testing may produce an abrupt and sustained fall in blood pressure, precipitating a faint.

CAUSES OF SYNCPE Transiently decreased cerebral blood flow is usually due to one of three general mechanisms: disorders of vascular tone or blood volume, cardiovascular disorders including cardiac arrhythmias, or cerebrovascular disease (Table 20-1). Not infrequently, however, the cause of syncope is multifactorial.

Disorders of Vascular Tone or Blood Volume Disorders of autonomic control of the heart and circulation share common pathophysiologic mechanisms: a cardioinhibitory component (e.g., bradycardia due to increased vagal activity), a vasodepressor component (e.g., inappropriate vasodilation due to sympathetic withdrawal), or both.

NEUROCARDIOGENIC (VASOVAGAL AND VASODEPRESSOR) SYNCPE The term neurocardiogenic is generally used to encompass both vasovagal and vasodepressor syncope. Strictly speaking, vasovagal syncope is associated with both sympathetic withdrawal (vasodilatation) and increased parasympathetic activity (bradycardia), whereas vasodepressor syncope is associated with sympathetic withdrawal alone. These forms of syncope are the common faint that may be experienced by normal persons and account for approximately half of all episodes of syncope. Neurocardiogenic syncope is frequently recurrent and commonly precipitated by a hot or crowded environment, alcohol, extreme fatigue, severe pain, hunger, prolonged standing, and emotional or stressful situations. Episodes are often preceded by a presyncopal prodrome lasting seconds to minutes, and rarely occur in the supine position. The individual is usually sitting or standing and experiences weakness, nausea, diaphoresis, lightheadedness, blurred vision, and often a forceful heart beat with tachycardia followed by cardiac slowing and decreasing blood pressure prior to loss of consciousness. The individual appears pale or ashen; in dark-skinned individuals, the pallor may only be notable in the conjunctivae and lips. Patients with a gradual onset of presyncopal symptoms have time to

POSTURAL (ORTHOSTATIC) HYPOTENSION

This occurs in patients who have a chronic defect in, or variable instability of, vasomotor reflexes. Systemic arterial blood pressure falls on assumption of upright posture due to loss of vasconstrictor reflexes in resistance and capacitance vessels of the lower extremities. Although the syncopal attack differs little from vasodepressor syncope, the effect of posture is critical. Sudden rising from a recumbent position or standing quietly are precipitating circumstances. Orthostatic hypotension may be the cause of syncope in up to 30% of the elderly; polypharmacy with antihypertensive or antidepressant drugs is often a contributor in these patients.

Postural syncope may occur in otherwise normal persons with defective postural reflexes. Patients with idiopathic postural hypotension may be identified by a characteristic response to upright tilt on a table. Initially, the blood pressure diminishes slightly before stabilizing at a lower level. Shortly thereafter, the compensatory reflexes fail and the arterial pressure falls precipitously. The condition is often familial.

Orthostatic hypotension, often accompanied by disturbances in sweating, impotence, and sphincter difficulties, is also a primary feature of autonomic nervous system disorders (Chap. 354). The most common causes of neurogenic orthostatic hypotension are chronic diseases of the peripheral nervous system that involve postganglionic unmyelinated fibers (e.g., diabetic, nutritional, and amyloid polyneuropathy). Much less common are the multiple system atrophies; these are CNS disorders in which orthostatic hypotension is associated with (1) parkinsonism (Shy-Drager syndrome), (2) progressive cerebellar degeneration, or (3) a more variable parkinsonian and cerebellar syndrome (striatoniigral degeneration) (Chap. 351). A rare, acute postganglionic dysautonomia may represent a variant of Guillain-Barré syndrome (Chap. 365).

There are several additional causes of postural syncope: (1) After physical deconditioning (such as after prolonged illness with recumbency, especially in elderly individuals with reduced muscle tone) or after prolonged weightlessness, as in space flight; (2) after sympatho-thectomy that has abolished vasopressor reflexes; and (3) in patients receiving antihypertensive or vasodilator drugs and those who are hypovolemic because of diuretics, excessive sweating, diarrhea, vomiting, hemorrhage, or adrenal insufficiency.

CAROTID SINUS HYPERSENSITIVITY

Syncope due to carotid sinus hypersensitivity is precipitated by pressure on the carotid sinus baroreceptors, which are located just cephalad to the bifurcation of the common carotid artery. This typically occurs in the setting of shaving, a tight collar, or turning the head to one side. Carotid sinus hypersensitivity occurs predominantly in men ≥50 years old. Activation of carotid sinus baroreceptors gives rise to impulses carried via the nerve of Hering, a branch of the glossopharyngeal nerve, to the medulla oblongata. These afferent impulses activate efferent sympathetic nerve fibers to the heart and blood vessels, cardiac vagal efferent nerve fibers, or both. In patients with carotid sinus hypersensitivity, these responses may cause sinus arrest or atrioventricular (AV) block (a cardioinhibitory response), vasodilation (a vasodepressor response), or both (a mixed response). The mechanisms responsible for the syndrome are not clear, and validated diagnostic criteria do not exist; some authorities have questioned its very existence.

SITUATIONAL SYCOPE

A variety of activities, including cough, deglutition, micturition, and defecation, are associated with syncope in susceptible individuals. These syndromes are caused, at least in part, by abnormal autonomic control and may involve a cardioinhibitory response, a vasodepressor response, or both. Cough, micturition, and defecation are associated with maneuvers (such as Valsalva, straining, and coughing) that may contribute to hypotension and syncope by decreasing venous return. Increased intracranial pressure secondary to the increased intrathoracic pressure may also contribute by decreasing cerebral blood flow.

Cough syncope typically occurs in men with chronic bronchitis or chronic obstructive lung disease during or after prolonged coughing fits. Micturition syncope occurs predominantly in middle-aged and older men, particularly those with prostatic hypertrophy and obstruction of the bladder neck; loss of consciousness usually occurs at night during or immediately after voiding. Deglutition syncope and defecation syncope occur in men and women. Deglutition syncope may be associated with esophageal disorders, particularly esophageal spasm. In some individuals, particular foods and carbonated or cold beverages initiate episodes by activating esophageal sensory receptors that trigger reflex sinus bradycardia or AV block. Defecation syncope is probably secondary to a Valsalva maneuver in older individuals with constipation.

GLOSSOPHARYNGEAL NEURALGIA

Syncope due to glossopharyngeal neuralgia (Chap. 355) is preceded by pain in the oropharynx, tonsillar fossa, or tongue. Loss of consciousness is usually associated with asystole rather than vasodilatation. The mechanism is thought to involve activation of afferent impulses in the glossopharyngeal nerve that terminate in the nucleus solitarius of the medulla and, via collaterals, activate the dorsal motor nucleus of the vagus nerve.

CARDIOVASCULAR DISORDERS

Cardiac syncope results from a sudden reduction in cardiac output, caused most commonly by a cardiac arrhythmia. In normal individuals, heart rates between 30 and 180 beats/min do not reduce cerebral blood flow, especially if the person is in...
the supine position. As the heart rate decreases, ventricular filling time and stroke volume increase to maintain normal cardiac output. At rates <30 beats/min, stroke volume can no longer increase to compensate adequately for the decreased heart rate. At rates greater than ~180 beats/min, ventricular filling time is inadequate to maintain adequate stroke volume. In either case, cerebral hyperperfusion and syncpe may occur. Upright posture; cerebrovascular disease; anemia; loss of atrioventricular synchrony; and coronary, myocardial, or valvular dysfunction all reduce the tolerance to alterations in rate.

Bradycardias (Chap. 213) may occur as a result of an abnormality of impulse generation (e.g., sinoatrial arrest) or impulse conduction (e.g., AV block). Either may cause syncpe if the escape pacemaker rate is insufficient to maintain cardiac output. Syncpe due to bradycardias may occur abruptly, without presyncopal symptoms, and recur several times daily. Patients with sick sinus syndrome may have sinus pauses (>3 s), and those with syncpe due to high-degree AV block (Stokes-Adams-Morgagni syndrome) may have evidence of conduction system disease (e.g., prolonged PR interval, bundle branch block). However, the arrhythmia is only transitory, and the surface electrocardiogram or continuous electrocardiographic monitor (Holter monitor) taken later may not reveal the abnormality. The bradycardia-tachycardia syndrome is a common form of sinus node dysfunction in which syncpe generally occurs as a result of marked sinus pauses, some following termination of paroxysms of atrial tachyarrhythmias. Drugs are a common cause for bradycardias, particularly in patients with underlying structural heart disease. Digoxin, β-adrenergic receptor antagonists, calcium channel blockers, and many antiarrhythmic drugs may suppress sinoatrial node impulse generation or slow AV nodal conduction.

Syncpe due to a tachyarrhythmia (Chap. 214) is usually preceded by palpitation or lightheadedness but may occur abruptly with no warning symptoms. Supraventricular tachyarrhythmias are unlikely to cause syncpe in individuals with structurally normal hearts but may if they occur in patients with (1) heart disease that also compromises cardiac output, (2) cerebrovascular disease, (3) a disorder of vascular tone or blood volume, or (4) a rapid ventricular rate. These tachycardias result most commonly from paroxysmal atrial flutter, atrial fibrillation, or reentry involving the AV node or accessory pathways that bypass part or all of the AV conduction system. Patients with the Wolff-Parkinson-White syndrome may experience syncpe when a very rapid ventricular rate occurs due to reentry across an accessory AV connection.

In patients with structural heart disease, ventricular tachycardia is a common cause of syncpe, particularly in patients with a prior myocardial infarction. Patients with aortic valvular stenosis and hypertrophic obstructive cardiomyopathy are also at risk for ventricular tachycardia. Individuals with abnormalities of ventricular repolarization (prolongation of the QT interval) are at risk to develop polymorphic ventricular tachycardia (torsades de pointes). Those with the inherited form of this syndrome often have a family history of sudden death in young individuals. Genetic markers can identify some patients with familial long-QT syndrome, but the clinical utility of these markers remains unproven. Drugs (i.e., certain antiarrhythmics and erythromycin) and electrolyte disorders (i.e., hypokalemia, hypocalcemia, hypomagnesemia) can prolong the QT interval and predispose to torsades de pointes. Antiarrhythmic medications may precipitate ventricular tachycardia, particularly in patients with structural heart disease.

In addition to arrhythmias, syncpe may also occur with a variety of structural cardiovascular disorders. Episodes are usually precipitated when the cardiac output cannot increase to compensate adequately for peripheral vasodilatation. Peripheral vasodilatation may be appropriate, such as following exercise, or may occur due to inappropriate activation of left ventricular mechanoreceptor reflexes, as occurs in aortic stenosis and right ventricular pressure overload (as seen in hypertrophic obstructive cardiomyopathy). Obstruction to forward flow is the most common reason that cardiac output cannot increase. Pericardial tamponade is a rare cause of syncpe. Syncpe occurs in up to 10% of patients with massive pulmonary embolism and may occur with exertion in patients with severe primary pulmonary hypertension. The cause is an inability of the right ventricle to provide appropriate cardiac output in the presence of obstruction or increased pulmonary vascular resistance. Loss of consciousness is usually accompanied by other symptoms such as chest pain and dyspnea. Atrial myxoma, a prosthetic valve thrombus, and, rarely, mitral stenosis may impair left ventricular filling, decrease cardiac output, and cause syncpe.

Cerebrovascular Disease Cerebrovascular disease alone rarely causes syncpe but may lower the threshold for syncpe in patients with other causes. The vertebrobasilar arteries, which supply brainstem structures responsible for maintaining consciousness, are usually involved when cerebrovascular disease causes or contributes to syncpe. An exception is the rare patient with tight bilateral carotid stenosis and recurrent syncpe, often precipitated by standing or walking. Most patients who experience lightheadedness or syncpe due to cerebrovascular disease also have symptoms of focal neurologic ischemia, such as arm or leg weakness, diplopia, ataxia, dysarthria, or sensory disturbances. Basilar artery migraine is a rare disorder that causes syncpe in adolescents.

DIFFERENTIAL DIAGNOSIS ■ Anxiety Attacks and the Hyperventilation Syndrome Anxiety, such as occurs in panic attacks, is frequently interpreted as a feeling of faintness or dizziness resembling presyncope. The symptoms are not accompanied by facial pallor and are not relieved by recumbency. The diagnosis is made on the basis of the associated symptoms such as a feeling of impending doom, air hunger, palpitations, and tingling of the fingers and perioral region. Attacks can often be reproduced by hyperventilation, resulting in hypocapnia, alkalosis, increased cerebrovascular resistance, and decreased cerebral blood flow. The release of epinephrine also contributes to the symptoms.

Seizures A seizure may be heralded by an aura, which is caused by a focal seizure discharge and hence has localizing significance (Chap. 348). The aura is usually followed by a rapid return to normal or by a loss of consciousness. Injury from falling is frequent in a seizure and rare in syncope, since only in generalized seizures are protective reflexes abolished instantaneously. Sustained tonic-clonic movements are characteristic of convulsive seizures but brief clonic, or tonic-clonic, seizure-like activity can accompany fainting episodes. The period of unconsciousness tends to be longer in seizures than in syncope. Urinary incontinence is frequent in seizures and rare in syncope. The return of consciousness is prompt in syncope, slow after a seizure. Mental confusion, headache, and drowsiness are common sequelae of seizures, whereas physical weakness with a clear sensorium characterizes the postsyncopal state. Repeated spells of unconsciousness in a young person at a rate of several per day or month are more suggestive of epilepsy than syncope. See Table 348-7 for a comparison of seizures and syncope.

Hypoglycemia Severe hypoglycemia is usually due to a serious disease such as a tumor of the islets of Langerhans; advanced adrenal, pituitary, or hepatic disease; or to excessive administration of insulin.

Acute Hemorrhage Hemorrhage, usually within the gastrointestinal tract, is an occasional cause of syncope. In the absence of pain and hematemesis, the cause of the weakness, faintness, or even unconsciousness may remain obscure until the passage of a black stool.

Hysterical Fainting The attack is usually unattended by an outward display of anxiety. Lack of change in pulse and blood pressure or color of the skin and mucous membranes distinguish it from the vasodepressor faint.

APPROACH TO THE PATIENT The diagnosis of syncope is often challenging. The cause may only be apparent at the time of the event, leaving few, if any, clues when the patient is seen later by the physician. The physician should think first of those causes that constitute a therapeutic emergency. Among them are massive internal hemorrhage or myocardial in-
Figure 20-1 depicts an algorithmic approach to syncope. A careful history is the most important diagnostic tool, both to suggest the correct cause and to exclude important potential causes (Table 20-1). The nature of the events and their time course immediately prior to, during, and after an episode of syncope often provide valuable etiologic clues. Loss of consciousness in particular situations, such as during venipuncture, micturition, or with volume depletion, suggests an abnormality of vascular tone. The position of the patient at the time of the syncopal episode is important; syncope in the supine position is unlikely to be vasovagal and suggests an arrhythmia or a seizure. Syncope due to carotid sinus syndrome may occur when the individual is wearing a shirt with a tight collar, turning the head (turning to look while driving in reverse), or manipulating the neck (as in shaving). The patient’s medications must be noted, including nonprescription drugs or health store supplements, with particular attention to recent changes.

The physical examination should include evaluation of heart rate and blood pressure in the supine, sitting, and standing positions. In patients with unexplained recurrent syncope, an attempt to reproduce an attack may assist in diagnosis. Anxiety attacks induced by hyperventilation can be reproduced readily by having the patient breathe rapidly and deeply for 2 to 3 min. Cough syncope may be reproduced by inducing the Valsalva maneuver. Carotid sinus syncope should generally be avoided, even in patients with suspected carotid sinus hypersensitivity; it is a risky procedure that can cause a transient ischemic attack (TIA) or stroke in individuals with carotid atherosclerosis.

**Diagnostic Tests** The choice of diagnostic tests should be guided by the history and the physical examination. Measurements of serum electrolytes, glucose, and the hematocrit are usually indicated. Cardiac enzymes should be evaluated if myocardial ischemia is suspected. Blood and urine toxicology screens may reveal the presence of alcohol or other drugs. In patients with possible adrenocortical insufficiency, plasma aldosterone and mineralocorticoid levels should be obtained.

Although the surface electrocardiogram is unlikely to provide a definitive diagnosis, it may provide clues to the cause of syncope and should be performed in almost all patients. The presence of conduction abnormalities (PR prolongation and bundle branch block) suggests a bradycardia, whereas pathologic Q waves or prolongation of the QT interval suggests a ventricular tachyarrhythmia. Inpatients should undergo continuous electrocardiographic monitoring; outpatients should wear a Holter monitor for 24 to 48 h. Whenever possible, symptoms should be correlated with the occurrence of arrhythmias. Continuous electrocardiographic monitoring may establish the cause of syncope in as many as 15% of patients. Cardiac event monitors may be useful in patients with infrequent symptoms, particularly in patients with presyncope. The presence of a late potential on a signal-averaged electrocardiogram is associated with increased risk for ventricular tachyarrhythmias in patients with a prior myocardial infarction. Low-voltage (visually inapparent) T wave alternans is also associated with development of sustained ventricular arrhythmias.

**Invasive cardiac electrophysiologic testing** provides diagnostic and prognostic information regarding sinus node function, AV conduction, and supraventricular and ventricular arrhythmias (Chaps. 213 and 214). Prolongation of the sinus node recovery time (>1500 ms) is a specific finding (85 to 100%) for diagnosis of sinus node dysfunction but has a low sensitivity; continuous electrocardiographic monitoring is usually more effective for diagnosing this abnormality. Prolongation of the HV interval and conduction block below the His bundle indicate that His-Purkinje disease may be responsible for syncope. Programmed stimulation for ventricular arrhythmias is most useful in patients who have experienced a myocardial infarction; the sensitivity and specificity of this technique is lower in patients with normal hearts or those with heart disease other than coronary artery disease.

**Upright tilt table testing** is indicated for recurrent syncope, a single syncopal episode that caused injury, or a single syncopal event in a “high-risk” setting (pilot, commercial vehicle driver, etc.), whether or not there is a history of preexisting heart disease or prior vasovagal episodes. In susceptible patients, upright tilt at an angle between 60 and 80° for 30 to 60 min induces a vasovagal episode. The protocol can be shortened if upright tilt is combined with administration of drugs that cause venous pooling or increase adrenergic stimulation (isoproterenol, nitroglycerin, ephedrinium, or adenosine). The sensitivity and specificity of tilt table testing is difficult to ascertain because of the lack of validated criteria. Moreover, the reflexes responsible for vasovagal syncope can be elicited in most, if not all, individuals given the appropriate stimulus. The reported accuracy of the test ranges from 30 to 80%, depending on the population studied and the techniques used. Whereas the reproducibility of a negative test is 85 to 100%, the reproducibility of a positive tilt table test is only between 62 and 88%.

A variety of other tests may be useful to determine the presence of structural heart disease that may cause syncope. The echocardiogram with Doppler examination detects valvular, myocardial, and pericardial abnormalities. The echocardiogram is the “gold standard” for the diagnosis of hypertrophic cardiomyopathy and atrial myxoma. Cardiac cine magnetic resonance (MR) imaging provides an alternative noninvasive modality that may be useful for patients in whom diagnostic-quality echocardiographic images cannot be obtained. This test is also indicated for patients suspected of having arrhythmogenic right ventricular dysplasia or right ventricular outflow tract ventricular tachycardia. Both are associated
with right ventricular structural abnormalities that are better visualized on MR imaging than by echocardiogram. Exercise testing may detect ischemia or exercise-induced arrhythmias. In some patients, cardiac catheterization may be necessary to diagnose the presence or severity of coronary artery disease or valvular abnormalities. Ultrastiff computed tomographic scan, ventilation-perfusion scan, or pulmonary angiography is indicated in patients in whom syncope may be due to pulmonary embolus.

In possible cases of cerebrovascular syncope neuroimaging tests may be indicated, including Doppler ultrasound studies of the carotid and vertebrobasilar systems, MR imaging, MR angiography, and x-ray angiography of the cerebral vasculature (Chap. 349). Electroencephalography is indicated if seizures are suspected.

**TREATMENT**

The treatment of syncope is directed toward the underlying cause. This discussion will focus on disorders of autonomic control. Arrhythmias are discussed in Chaps. 213 and 214, valvular heart diseases in Chap. 219, and cerebrovascular disorders in Chap. 349.

Certain precautions should be taken regardless of the cause of syncope. At the first sign of symptoms, patients should make every effort to avoid injury should they lose consciousness. Patients with frequent episodes, or those who have experienced syncope without warning symptoms, should avoid situations in which sudden loss of consciousness might result in injury (e.g., climbing ladders, swimming alone, operating heavy machinery, driving). Patients should lower their head to the extent possible and preferably should lie down. Lowering the head by bending at the waist should be avoided because it may further compromise venous return to the heart. When appropriate, family members or other close contacts should be educated as to the problem. This will ensure appropriate therapy and may prevent delivery of inappropriate therapy (chest compressions associated with cardiopulmonary resuscitation) that may inflict trauma.

Patients who have lost consciousness should be placed in a position that maximizes cerebral blood flow, offers protection from trauma, and secures the airway. Whenever possible, the patient should be placed supine with the head turned to the side to prevent aspiration and the tongue from blocking the airway. Assessment of the pulse and direct cardiac auscultation may assist in determining if the episode is associated with a bradycardia or tachycardia. Clothing that fits tightly around the neck or waist should be loosened. Peripheral stimulation, such as by sprinkling cold water on the face, may be helpful. Patients should not be given anything by mouth or be permitted to rise until the sense of physical weakness has passed.

Patients with vasovagal syncope should be instructed to avoid situations or stimuli that have caused them to lose consciousness and to assume a recumbent position when premonitory symptoms occur. These behavioral modifications alone may be sufficient for patients with infrequent and relatively benign episodes of vasovagal syncope, particularly when loss of consciousness occurs in response to a specific stimulus. Tilt training (standing and leaning against a wall for progressively longer periods each day) has been used with limited success, particularly for those patients who have profound orthostatic intolerance. Episodes associated with intravascular volume depletion may be prevented by salt and fluid loading prior to provocative events.

Prescription drug therapy may be necessary when vasovagal syncope is resistant to these measures, when episodes occur frequently, or when syncope is associated with a significant risk for injury. β-Adrenergic receptor antagonists (metoprolol, 25 to 50 mg bid; atenolol, 25 to 50 mg qd; or nadolol, 10 to 20 mg bid; all starting doses), the most widely used agents, mitigate the increase in myocardial contractility that stimulates left ventricular outflow and also block central serotonin receptors. Serotonin reuptake inhibitors (paroxetine, 20 to 40 mg qd; or sertraline, 25 to 50 mg qd), appear to be effective for some patients. Bupropion SR (150 mg qd), another antidepressant, has also been used with success. β-Adrenergic receptor antagonists and serotonin reuptake inhibitors are well tolerated and are often used as first-line agents for younger patients. Hydrofludrocortisone (0.1 to 0.2 mg qd), a mineralocorticoid, promotes sodium retention, volume expansion, and peripheral vasoconstriction by increasing β-receptor sensitivity to endogenous catecholamines. Hydrofludrocortisone is useful for patients with intravascular volume depletion and those who also have postural hypotension. Proamantine (2.5 to 10 mg bid or tid), an α-agonist, has been used as a first-line agent for some patients. In a recent randomized controlled trial, proamamine was more effective than placebo in preventing syncope during an upright tilt-test. However, in some patients, proamamine and hydrofludrocortisone may cause a decrease in systemic blood pressure, a property that may be problematic for those with hypertension.

Disopyramide (150 mg bid), a vagolytic antiarrhythmic drug with negative inotropic properties, and another vagolytic, transdermal scopolamine, have been used to treat vasovagal syncope, as have theophylline and ephedrine. Side effects associated with these drugs have limited their use for this indication. Disopyramide is a type 1A antiarrhythmic drug and should be used with great caution, if at all, in patients who are at risk for ventricular arrhythmias. Although several clinical trials have suggested that pharmacologic therapy for vasovagal syncope is effective, long-term prospective randomized controlled trials have yet to be completed.

Permanent dual-chamber cardiac pacing is effective for patients with frequent episodes of vasovagal syncope and is indicated for those with prolonged asystole associated with vasovagal episodes. Patients in whom vasodilatation contributes to loss of consciousness may also experience symptomatic benefit from permanent pacing. Pacemakers that can be programmed to transiently pace at a high rate (90 to 100 beats/min) after a profound drop in the patient’s intrinsic heart rate are most effective.

Patients with orthostatic hypotension should be instructed to rise slowly and systematically (supine to seated, seated to standing) from the bed or a chair. Movement of the legs prior to rising facilitates venous return from the lower extremities. Whenever possible, medications that aggravate the problem (vasodilators, diuretics, etc.) should be discontinued. Elevation of the head of the bed [20 to 30 cm (8 to 12 in.))] and use of compression stockings may help.

Additional therapeutic modalities include an antigravity or g suit or compression stockings to prevent lower limb blood pooling; salt loading; and a variety of pharmacologic agents including sympathomimetic amines, monamine oxidase inhibitors, beta blockers, and levodopa. The treatment of orthostatic hypotension secondary to central or peripheral disorders of the autonomic nervous system is discussed in Chap. 354.

Glossopharyngeal neuralgia is treated with carbamazepine, which is effective for the syncope as well as for the pain. Patients with carotid sinus syndrome should be instructed to avoid clothing and situations that stimulate carotid sinus baroreceptors. They should turn their entire body, rather than just their head, when looking to the side. Those with intractable syncope due to the cardioinhibitory response to carotid sinus stimulation should undergo permanent pacemaker implantation.

Patients with syncope should be hospitalized when the episode may have resulted from a life-threatening abnormality or if recurrence with significant injury seems likely. These individuals should be admitted to a bed with continuous electrocardiographic monitoring. Patients who are known to have a normal heart and for whom the history strongly suggests vasovagal or situational syncope may be treated as outpatients if the episodes are neither frequent nor severe.

**DIZZINESS AND VERTIGO**

Dizziness is a common and often vexing symptom. Patients use the term to encompass a variety of sensations, including those that seem semantically appropriate (e.g., lightheadedness, faintness, spinning, giddiness) and those that are misleadingly inappropriate, such as mental confusion, blurred vision, headache, or tingling. Moreover, some
individuals with gait disorders caused by peripheral neuropathy, myelopathy, spasticity, parkinsonism, or cerebellar ataxia complain of “dizziness” despite the absence of vertigo or other abnormal cephalic sensations. In this context, the term dizziness is being used to describe disturbed ambulation. There may be mild associated lightheadedness, particularly with impaired sensation from the feet or poor vision; this is known as multiple-sensory-defect dizziness and occurs in elderly individuals who complain of dizziness only when walking. Decreased position sense (secondary to neuropathy or myelopathy) and poor vision (from cataracts or retinal degeneration) create an overreliance on the aging vestibular apparatus. A less precise but sometimes comforting designation to patients is benign disequilibrium of aging. Thus, a careful history is necessary to determine exactly what a patient who states, “Doctor, I’m dizzy,” is experiencing. After eliminating the misleading symptoms or gait disturbance, “dizziness” usually means either faintness (presyncope) or vertigo (an illusory or hallucinatory sense of movement of the body or environment, most often a feeling of spinning). Operationally, after obtaining the history, dizziness may be classified into three categories: (1) faintness, (2) vertigo, and (3) miscellaneous head sensations.

Faintness Prior to an actual faint (syncope), there are often prodromal presyncopal symptoms (faintness) reflecting ischemia to a degree insufficient to impair consciousness (see above).

Vertigo Vertigo is usually due to a disturbance in the vestibular system. The end organs of this system, situated in the bony labyrinth of the inner ear, consist of the three semicircular canals and the otolithic apparatus (utricle and saccule) on each side. The canals transduce angular acceleration, while the otoliths transduce linear acceleration and the static gravitational forces that provide a sense of head position in space. The neural output of the end organs is conveyed to the vestibular nuclei in the brainstem via the eighth cranial nerves. The principal projections from the vestibular nuclei are to the nuclei of cranial nerves III, IV, and VI; spinal cord; cerebral cortex; and cerebellum. The vestibuloocular reflex (VOR) serves to maintain visual stability during head movement and depends on direct projections from the vestibular nuclei to the sixth cranial nerve (abducens) nuclei in the pons and, via the medial longitudinal fasciculus, to the third (oculomotor) and fourth (trochlear) cranial nerve nuclei in the midbrain. These connections account for the nystagmus (to-and-fro oscillation of the eyes) that is an almost invariable accompaniment of vestibular dysfunction. The vestibular nerves and nuclei project to areas of the cerebellum (primarily the flocculus and nodulus) that modulate the VOR. The vestibulospinal pathways assist in the maintenance of postural stability. Projections to the cerebral cortex, via the thalamus, provide conscious awareness of head position and movement.

The vestibular system is one of three sensory systems subserving spatial orientation and posture; the other two are the visual system (retina to occipital cortex) and the somatosensory system that conveys peripheral information from skin, joint, and muscle receptors. The three stabilizing systems overlap sufficiently to compensate (partially or completely) for each other’s deficiencies. Vertigo may represent either physiologic stimulation or pathologic dysfunction in any of the three systems.

Physiologic Vertigo This occurs in normal individuals when (1) the brain is confronted with a mismatch among the three stabilizing sensory systems; (2) the vestibular system is subjected to unfamiliar head movements to which it is unadapted, such as in seasickness; (3) unusual head/neck positions, such as the extreme extension when painting a ceiling; or (4) following a spin. intersensory mismatch explains carsickness, height vertigo, and the visual vertigo most commonly experienced during motion picture chase scenes; in the latter, the visual sensation of environmental movement is unaccompanied by concomitant visual and somatosensory head movements. Spontaneous frequent transient effect of active head movement in the weightless zero-gravity environment, is another example of physiologic vertigo.

Pathologic Vertigo This results from lesions of the visual, somatosensory, or vestibular systems. Visual vertigo is caused by new or incorrect spectacles or by the sudden onset of an extracocular muscle paresis with diplopia; in either instance, CNS compensation rapidly counteracts the vertigo. Somatosensory vertigo, rare in isolation, is usually due to a peripheral neuropathy or myelopathy that reduces the sensory input necessary for central compensation when there is dysfunction of the vestibular or visual systems.

The most common cause of pathologic vertigo is vestibular dysfunction involving either its end organ (labyrinth), nerve, or central connections. The vertigo is frequently accompanied by nausea, jerk nystagmus, postural unsteadiness, and gait ataxia. Since vertigo increases with rapid head movements, patients tend to hold their heads still.

Labyrinthine Dysfunction This causes severe rotational or linear vertigo. When rotational, the hallucination of movement, whether of environment or self, is directed away from the side of the lesion. The fast phases of nystagmus beat away from the lesion side, and the tendency to fall is toward the side of the lesion, particularly in darkness or with the eyes closed.

Under normal circumstances, when the head is straight and immobile, the vestibular end organs generate a tonic resting firing frequency that is equal from the two sides. With any rotational acceleration, the anatomic positions of the semicircular canals on each side necessitate an increased firing rate from one and a commensurate decrease from the other. This change in neural activity is ultimately projected to the cerebral cortex, where it is summed with inputs from the visual and somatosensory systems to produce the appropriate conscious sense of rotational movement. After cessation of movement, the firing frequencies of the two end organs reverse; the side with the initially increased rate decreases, and the other side increases. A sense of rotation in the opposite direction is experienced; since there is no actual head movement, this hallucinatory sensation is physiologic postrotational vertigo.

Any disease state that changes the firing frequency of an end organ, producing unequal neural input to the brainstem and ultimately the cerebral cortex, causes vertigo. The symptom can be conceptualized as the cortex inappropriately interpreting the abnormal neural input as indicating actual head rotation. Transient abnormalities produce shortlived symptoms. With a fixed unilateral deficit, central compensatory mechanisms ultimately diminish the vertigo. Since compensation depends on the plasticity of connections between the vestibular nuclei and the cerebellum, patients with brainstem or cerebellar disease have diminished adaptive capacity, and symptoms may persist indefinitely. Compensation is always inadequate for severe fixed bilateral lesions despite normal cerebellar connections; these patients are permanently symptomatic.

Acute unilateral labyrinthine dysfunction is caused by infection, trauma, and ischemia. Often, no specific etiology is uncovered, and the nonspecific terms acute labyrinthitis, acute peripheral vestibulopathy, or vestibular neuritis are used to describe the event. The vertiginous attacks are brief and leave the patient with mild vertigo for several days. Infection with herpes simplex virus type 1 has been implicated. It is impossible to predict whether a patient recovering from the first bout of vertigo will have recurrent episodes. Labyrinthine ischemia, presumably due to occlusion of the labyrinthes branch of the internal auditory artery, may be the sole manifestation of vertebrobasilar insufficiency (Chap. 349); patients with this syndrome present with the abrupt onset of severe vertigo, nausea, and vomiting, but without tinnitus or hearing loss. Acute bilateral labyrinthine dysfunction is usually the result of toxins such as drugs or alcohol. The most common offending drugs are the anorglycoside antibiotics that damage the hair cells of the vestibular end organs and may cause a permanent disorder of equilibrium.

Recurrent unilateral labyrinthine dysfunction, in association with...
signs and symptoms of cochlear disease (progressive hearing loss and tinnitus), is usually due to Ménière’s disease (Chap. 26). When auditory manifestations are absent, the term vestibular neuronitis denotes recurrent monosymptomatic vertigo. TIAs of the posterior cerebral circulation (vertebrobasilar insufficiency) only infrequently cause recurrent vertigo without concomitant motor, sensory, visual, cranial nerve, or cerebellar signs (Chap. 349).

Positional vertigo is precipitated by a recumbent head position, either to the right or to the left. Benign paroxysmal positional (or positioning) vertigo (BPPV) of the posterior semicircular canal is particularly common. Although the condition may be due to head trauma, usually no precipitating factors are identified. It generally abates spontaneously after weeks or months. The vertigo and accompanying nystagmus have a distinct pattern of latency, fatigability, and habituation that differs from the less common central positional vertigo (Table 20-2) due to lesions in and around the fourth ventricle. Moreover, the pattern of nystagmus in posterior canal BPPV is distinctive. When supine, with the head turned to the side of the offending ear (bad ear down), the lower eye displays a large-amplitude torsional nystagmus, and the upper eye has a lesser degree of torsion combined with up-beating nystagmus. If the eyes are directed to the upper ear, the vertical nystagmus in the upper eye increases in amplitude. Mild dysequilibrium when upright may also be present.

A perilymphatic fistula should be suspected when episodic vertigo is precipitated by Valsalva or exertion, particularly upon a background of a stepwise progressive sensory-neural hearing loss. The condition is usually caused by head trauma or baro-trauma or occurs after middle ear surgery.

Vertigo of Vestibular Nerve Origin This occurs with diseases that involve the nerve in the petrous bone or the cerebellopontine angle. Although less severe and less frequently paroxysmal, it has many of the characteristics of labyrinthine vertigo. The adjacent auditory division of the eighth cranial nerve is usually affected, which explains the frequent association of vertigo with unilateral tinnitus and hearing loss. The most common cause of eighth cranial nerve dysfunction is a tumor, usually a schwannoma (acoustic neuroma) or a meningioma. These tumors grow slowly and produce such a gradual reduction of labyrinthine output that central compensatory mechanisms can prevent or minimize the vertigo; auditory symptoms of hearing loss and tinnitus are the most common manifestations.

Central Vertigo Lesions of the brainstem or cerebellum can cause acute vertigo, but associated signs and symptoms usually permit distinction from a labyrinthine etiology (Table 20-3). Occasionally, an acute lesion of the vestibulocerebellum may present with monosymptomatic vertigo indistinguishable from a labyrinthopathy.

Vertigo may be a manifestation of a migraine aura (Chap. 14), but some patients with migraine have episodes of vertigo unassociated with their headaches. Antimigrainous treatment should be considered in such patients with otherwise enigmatic vertiginous episodes.

Vestibular epilepsy, vertigo secondary to temporal lobe epileptic activity, is rare and almost always intermixed with other epileptic manifestations.

* In Ménière’s disease, the direction of the fast phase is variable.

Psychogenic Vertigo This is usually a concomitant of panic attacks (Chap. 371) or agoraphobia (fear of large open spaces, crowds, or leaving the safety of home) and should be suspected in patients so “incapacitated” by their symptoms that they adopt a prolonged housebound status. Most patients with organic vertigo attempt to function despite their discomfort. Organic vertigo is accompanied by nystagmus; a psychogenic etiology is almost certain when nystagmus is absent during a vertiginous episode.

Miscellaneous Head Sensations This designation is used, primarily for purposes of initial classification, to describe dizziness that is neither faintness nor vertigo. Cephalic ischemia or vestibular dysfunction may be of such low intensity that the usual symptomatology is not clearly identified. For example, a small decrease in blood pressure or a slight vestibular imbalance may cause sensations different from distinct faintness or vertigo but that may be identified properly during provocative testing techniques (see below). Other causes of dizziness in this category are hyperventilation syndrome, hypoglycemia, and the somatic symptoms of a clinical depression; these patients should all have normal neurologic examinations and vestibular function tests. Depressed patients often insist that the depression is “secondary” to the dizziness.

### Approach to the Patient

The most important diagnostic tool is a detailed history focused on the meaning of “dizziness” to the patient. Is it faintness (presyncope)? Is there a sensation of spinning? If either of these is affirmed and the neurologic examination is normal, appropriate investigations for the multiple causes of cephalic ischemia or vestibular dysfunction are undertaken.

When the meaning of “dizziness” is uncertain, provocative tests may be helpful. These office procedures simulate either cephalic ischemia or vestibular dysfunction. Cephalic ischemia is obvious if the dizziness is duplicated during maneuvers that produce orthostatic hypotension. Further provocation involves the Valsalva maneuver, which decreases cerebral blood flow and should reproduce ischemic symptoms.

Hyperventilation is the cause of dizziness in many anxious individuals; tingling of the hands and face may be absent. Forced hyperventilation for 1 min is indicated for patients with enigmatic dizziness and normal neurologic examinations.

The simplest provocative test for vestibular dysfunction is rapid rotation and abrupt cessation of movement in a swivel chair.
always induces vertigo that the patients can compare with their symptomatic dizziness. The intense induced vertigo may be unlike the spontaneous symptoms, but shortly thereafter, when the vertigo has all but subsided, a lightheadedness supervenes that may be identified as “my dizziness.” When this occurs, the dizzy patient, originally classified as suffering from “miscellaneous head sensations,” is now properly diagnosed as having mild vertigo secondary to a vestibulopathy.

Patients with symptoms of positional vertigo should be appropriately tested (Table 20-2). A final provocative and diagnostic vestibular test, requiring the use of Frenzel eyeglasses (self-illuminated goggles with convex lenses that blur out the patient’s vision, but allow the examiner to see the eyes greatly magnified), is vigorous head shaking in the horizontal plane for about 10 s. If nystagmus develops after the shaking stops, even in the absence of vertigo, vestibular dysfunction is demonstrated. The maneuver can then be repeated in the vertical plane. If the provocative tests establish the dizziness as a vestibular symptom, an evaluation of vestibular vertigo is undertaken.

Evaluation of Patients with Pathologic Vestibular Vertigo The evaluation depends on whether a central etiology is suspected (Table 20-3). If so, MR imaging of the head is mandatory. Such an examination is rarely helpful in cases of recurrent monosymptomatic vertigo with a normal neurologic examination. Typical BPPV requires no investigation after the diagnosis is made (Table 20-2).

Vestibular function tests serve to (1) demonstrate an abnormality when the distinction between organic and psychogenic is uncertain, (2) establish the side of the abnormality, and (3) distinguish between peripheral and central etiologies. The standard test is electronystagmography (calorics), where warm and cold water (or air) are applied, in a prescribed fashion, to the tympanic membranes, and the slow-phase velocities of the resultant nystagmus from the two are compared. A velocity decrease from one side indicates hypofunction (“canal paresis”). An inability to induce nystagmus with ice water denotes a “dead labyrinth.” Some institutions have the capability of quantitatively determining various aspects of the VOR using computer-driven rotational chairs and precise oculographic recording of the eye movements.

CNS disease can produce dizzy sensations of all types. Consequently, a neurologic examination is always required even if the history or provocative tests suggest a cardiac, peripheral vestibular, or psychogenic etiology. Any abnormality on the neurologic examination should prompt appropriate neurodiagnostic studies.

TREATMENT

Treatment of acute vertigo consists of bed rest (1 to 2 days maximum) and vestibular suppressant drugs such as antihistaminics (meclizine, dimenhydrinate, promethazine), tranquilizers with GABA-ergic effects (diazepam, clonazepam), phenothiazines (prochlorperazine), or glucocorticoids (Table 20-4). If the vertigo persists beyond a few days, most authorities advise ambulation in an attempt to induce central compensatory mechanisms, despite the short-term discomfort to the patient. Chronic vertigo of labyrinthine origin may be treated with a systematized vestibular rehabilitation program to facilitate central compensation.

BPPV is often self-limited but, when persistent, may respond dramatically to specific repositioning exercise programs designed to empty particulate debris from the posterior semicircular canal. One of these exercises, the Epley procedure, is graphically demonstrated, in four languages, on a website for use in both physician’s offices and self-treatment (www.iVertigo.net and www.tchain.com).

¶ For perilymphatic fistula and refractory cases of Ménière’s disease.
WEAKNESS, DISORDERS OF MOVEMENT, AND IMBALANCE

Richard K. Olney

Normal motor function requires integrated muscle activity with appropriate modulation by neuronal activity in the cerebral cortex, basal ganglia, cerebellum, and spinal cord. Symptoms and signs of motor system dysfunction may include weakness, fatigue, myalgias, spasms, cramps, dyskinetic movement, ataxia, imbalance, or disorders in the initiation or planning of movement.

WEAKNESS

Weakness is a reduction in normal power of one or more muscles. Limitation in rising from a seated position or combing hair suggests proximal weakness, whereas slapping of the feet while walking or limitation in opening jars suggests distal weakness. Increased fatigability or limitation in function due to pain is often confused with weakness by patients. Increased fatigability is the inability to sustain the performance of an activity that should be normal for a person of the same age, gender, and size.

Paralysis and the suffix “-plegia” indicate weakness that is so severe that it is complete or nearly complete. “Paresis” refers to weakness that is mild or moderate. The prefix “hem-” refers to one half of the body, “para-” to both legs, and “quadri-” to all four limbs.

Tone is the resistance of a muscle to passive stretch. Central nervous system (CNS) abnormalities that cause weakness generally produce spasticity, an increase in tone due to upper motor neuron disease. Spasticity is velocity-dependent, has a sudden release after reaching a maximum (the “clasp-knife” phenomenon), and predominantly affects antigravity muscles (i.e., upper limb flexors and lower limb extensors). Spasticity is distinct from rigidity and paratonia, two other types of increased tone. Rigidity is increased tone that is present throughout the range of motion (a “lead pipe” or “plastic” stiffness) and affects flexors and extensors equally. In some patients, rigidity has a cogwheel quality that is enhanced by voluntary movement of the contralateral limb (reinforcement). Rigidity occurs with certain extrapyramidal disorders such as Parkinson’s disease. Paratonia, also referred to as gegenhalten, is increased tone that varies irregularly in a manner that may seem related to the degree of relaxation, is present throughout the range of motion, and affects flexors and extensors equally. Paratonia usually results from disease of the frontal lobes. Weakness with decreased tone (flaccidity) or normal tone occurs with disorders of the motor unit, that is, a single lower motor neuron and all of the muscle fibers it innervates.

Three basic patterns of weakness can usually be recognized based on the signs summarized in Table 21-1. One result from upper motor neuron pathology, and the other two from disorders of the motor unit (lower motor neuron and myopathic weakness). Fasciculations and early atrophy help to distinguish lower motor neuron (neurogenic) weakness from myopathic weakness. A fasciculation is a visible or palpable twitch within a single muscle due to the spontaneous discharge of one motor unit. Lower motor neuron weakness also produces more prominent hypotonia and greater depression of tendon reflexes than does myopathic weakness.

PATHOGENESIS

Upper Motor Neuron Weakness

This pattern of weakness results from disorders that affect the upper motor neurons or their axons in the cerebral cortex, subcortical white matter, internal capsule, brainstem, or spinal cord (Fig. 21-1). Upper motor neuron lesions produce weakness through decreased activation of the lower motor neurons. In general, distal muscle groups are affected more severely than proximal ones, and axial movements are spared unless the lesion is severe and bilateral. With corticobulbar involvement, weakness is usually observed only in the lower face and tongue; extracocular, upper facial, pharyngeal, and jaw muscles are almost always spared. With bilateral corticobulbar lesions, pseudobulbar palsy often develops, in which dysarthria, dysphagia, dysphonia, and emotional lability accompany bilateral facial weakness. Spasticity accompanies upper motor neuron weakness but may not be present in the acute phase. Upper motor neuron lesions also affect the ability to perform rapid repetitive movements. Such movements are slow and coarse, but normal rhythmicity is maintained. Finger-nose-finger and heel-knee-shin are performed slowly but adequately.

Lower Motor Neuron Weakness

This pattern results from disorders of cell bodies of lower motor neurons in the brainstem motor nuclei and the anterior horn of the spinal cord, or from dysfunction of the axons of these neurons as they pass to skeletal muscle (Fig. 21-2). Weakness is due to a decrease in the number of motor units that can be activated, through a loss of the α motor neurons or disruption of their connections to muscle. With a decreased number of motor units, fewer muscle fibers are activated with full effort and maximum power is reduced. Loss of γ motor neurons does not cause weakness but decreases tension on the muscle spindles, which decreases muscular tone and contributes to less active tendon reflexes on examination. An absent tendon stretch reflex suggests involvement of the spindle afferent fibers.

When a motor unit becomes diseased, especially in anterior horn cell diseases, it may spontaneously discharge, producing a fasciculation. These isolated small twitches may be seen or felt clinically or recorded by electromyography (EMG). When α motor neurons or their axons degenerate, the denervated muscle fibers spontaneously discharge in a manner that cannot be seen or felt but can be recorded with EMG. These small single muscle fiber discharges are called fibrillation potentials. If lower motor neuron weakness is present, recruitment of motor units is delayed or reduced, with fewer than normal activated at a given discharge frequency. This contrasts with upper motor neuron weakness, in which a normal number of motor units are activated at a given frequency but in which the maximum discharge frequency is decreased.

Myopathic Weakness

This pattern of weakness is produced by disorders within the motor unit that affect the muscle fibers or the neuromuscular junctions.

Two types of muscle fibers exist. Type I muscle fibers are rich in mitochondria and oxidative enzymes, produce relatively low force, but have low energy demands that can be supplied by ongoing aerobic metabolism. They produce sustained postural and nonforceful movements. Type II muscle fibers are rich in glycolytic enzymes, can produce relatively high force, but have high energy demands that cannot be supplied for long by ongoing aerobic metabolism. Thus, these units can be activated maximally for only brief periods of time to produce high-force movements.

For graded voluntary movements, type I muscle fibers are activated earlier in recruitment. For each muscle fiber, if the nerve terminal releases a normal number of acetylcholine molecules presynaptically and a sufficient number of postsynaptic acetylcholine receptors are opened, the end plate reaches threshold and thereby generates an action potential that spreads across the muscle fiber membrane and into the transverse tubular system. This electrical excitation activates intracel-
Fatigable weakness is suggestive of myasthenia gravis or another neuromuscular junction disease. Some myopathies produce weakness through loss of contractile force of muscle fibers or through relatively selective involvement of the type II muscle fibers. These may not affect the size of individual motor unit action potentials observed with EMG and are detected by a discrepancy between the electrical activity and force of a muscle.

**Integrated Movements** Most purposeful movements require the integrated coordination of many muscle groups. Consider a simple movement, such as grasping a ball. The primary movement is a flexion of the thumb and fingers of one hand, with opposition of the thumb and little finger. This requires the contraction of several muscles, including flexor digitorum superficialis, flexor digitorum profundus, flexor pollicis longus, flexor pollicis brevis, opponens pollicis, and opponens digiti minimi. The prime movers for this action are called agonists. In order for the grasping to be smooth and forceful, the thumb and finger extensors need to relax at the same rate as the flexors contract. The muscles that act in a directly opposing manner to the agonists are antagonists. A secondary action of the thumb and finger flexors is to flex the wrist; because wrist flexion tends to weaken finger flexion if both occur, activation of wrist extensors assists the grasping movement. Muscles that produce such complementary movements are synergists. Finally, the arm needs to be held in a stable position as the grasp occurs, so that the ball is not knocked away before it is secured. Muscles that stabilize the arm position are fixators.

The coordination of activity by agonists, antagonists, synergists, and fixators is regulated by a three-level hierarchy of motor control. The lowest level of control is mediated through segmental reflexes in the spinal cord. These reflexes facilitate agonists and reciprocally inhibit the antagonists. Spinal segments also control rhythmic patterns of movement that involve more than a single pair of agonists and antagonists. For example, the lumbosacral spinal cord contains the basic programming for cyclical stepping movements that involve the synergistic activation of different muscle groups over time. The intermediate level of control is mediated through the descending bulbo-

Myopathic weakness is produced by a decrease in the number or contractile force of muscle fibers activated within the motor unit. With muscular dystrophies, inflammatory myopathies, or myopathies with muscle fiber necrosis, decreased numbers of muscle fibers survive within many motor units. As demonstrated with EMG, the size of each motor unit action potential is decreased so that motor units must be recruited more rapidly than normal to produce the power necessary for a certain movement. Neuromuscular junction diseases such as myasthenia gravis produce weakness in a similar manner, although the loss of muscle fibers within the motor unit is functional rather than actual. Furthermore, the number of muscle fibers activated can vary over time, depending on the state of rest of the neuromuscular junctions. Thus, fatigable weakness is suggestive of myasthenia gravis or another neuromuscular junction disease. Some myopathies produce weakness
spinal pathways, which integrate visual, proprioceptive, and vestibular feedback into the execution of an action. For example, the locomotor center in the midbrain is required to modify the cyclical stepping movements in order that balance be maintained and forward movement occurs. The highest level of control is mediated by the cerebral cortex. Superimposition of this highest level of control is necessary for activities such as walking to be goal-directed. Precise movements that are learned and improved through practice are also initiated and controlled by the motor cortex. Although only the agonists are directly activated, during the course of a complex sequence of actions such as playing the piano, the sequential activation of different groups of agonists for each note or chord is a part of the learned motor program. Further, the execution of these actions also involves input from the basal ganglia and cerebellar hemispheres to facilitate agonists, synergists, and fixators and to inhibit undesired antagonists.

Apraxia is a disorder of planning and initiating a skilled or learned movement (Chap. 23). Unilateral apraxia of the right hand may be due to a lesion of the left frontal lobe (especially anterior or inferior), the left temporoparietal region (especially the supramarginal gyrus), or their connections. Left body apraxia is produced by lesions of these regions in the right hemisphere or by lesions in the corpus callosum that disconnect the right temporoparietal or frontal regions from those on the left. Bilateral apraxia is often due to bilateral frontal lobe lesions or diffuse bilateral hemispheric disease.

Hemiparesis Hemiparesis results from an upper motor neuron lesion above the midcervical spinal cord; most lesions that produce hemiparesis are located above the foramen magnum. The presence of language disorders, cortical sensory disturbances, cognitive abnormalities, disorders of visual-spatial integration, apraxia, or seizures indicates a cortical lesion. Homonymous visual field defects reflect either a cortical or a subcortical hemispheric lesion. A “pure motor” hemiparesis of the face, arm, and/or leg is due to a small, discrete lesion in the posterior limb of the internal capsule, cerebral peduncle, or upper pons. Some brainstem lesions produce “crossed paralyses,” consisting of ipsilateral cranial nerve signs and contralateral hemiparesis (Chap. 349). The absence of cranial nerve signs or facial weakness suggests that a hemiparesis is due to a lesion in the high cervical spinal cord, especially if associated with ipsilateral loss of proprioception and contralateral loss of pain and temperature sense (the Brown-Séquard syndrome). However, most spinal cord lesions produce quadriparesis or paraparesis.

Acute or episodic hemiparesis usually has a vascular pathogenesis, either ischemia or a primary hemorrhage. Less commonly, hemorrhage may occur into brain tumors or from rupture of normal vessels due to trauma; the trauma may be trivial in patients who are anticoagulated or elderly. Less likely possibilities include a focal inflammatory lesion from multiple sclerosis, abscess, or sarcoidosis. Evaluation begins immediately with a computed tomography (CT) scan of the brain (Fig. 21–3). If CT is normal and an ischemic stroke is unlikely, magnetic resonance imaging (MRI) of the brain or cervical spine may be indicated.

Subacute hemiparesis that evolves over days or weeks has an extensive differential diagnosis. A common cause is subdural hematoma; this readily treatable condition must always be considered, especially in elderly or anticoagulated patients, even in the absence of a history of trauma. Infectious possibilities include cerebral bacterial abscess, fungal granuloma or meningitis, and parasitic infection. Weakness from primary and metastatic neoplasms may evolve over days to weeks. AIDS may present with subacute hemiparesis due to toxoplasmosis or primary CNS lymphoma. Noninfectious inflammatory processes, such as multiple sclerosis or, less commonly, sarcoidosis, are further considerations. If the brain MRI is normal and if cortical and hemispheric signs are not present, MRI of the cervical spine may be required.

Chronic hemiparesis that evolves over months is usually due to a neoplasm, an unruptured arteriovenous malformation, a chronic subdural hematoma, or a degenerative disease. The initial diagnostic test is often an MRI of the brain, especially if the clinical findings suggest brainstem pathology. If MRI of the brain is normal, the possibility of a foramen magnum or high cervical spinal cord lesion should be considered.

Paraparesis An intraspinal lesion at or below the upper thoracic spinal cord level is most commonly responsible. A sensory level over the trunk identifies the approximate level of the cord lesion. Paraparesis can also result from lesions at other locations that disturb upper motor neurons (especially parasagittal lesions and hydrocephalus) and lower motor neurons (anterior horn cell disorders, cauda equina syndromes, and occasionally peripheral neuropathies).

Acute or episodic paraparesis due to spinal cord disease may be difficult to distinguish from disorders affecting lower motor neurons or cerebral hemispheres. Recurrent episodes of paraparesis are often due to multiple sclerosis or to vascular malformations of the spinal cord. With acute spinal cord disease, the upper motor neuron deficit is usually associated with incontinence and a sensory disturbance of the lower limbs that extends rostrally to a level on the trunk; tone is typically flaccid, and tendon reflexes are absent. In such cases, the diagnostic approach begins with an imaging study of the spinal cord (Fig. 21–3). Compressive lesions (particularly epidural tumor, abscess, or

![FIGURE 21-3](https://www.mheducation.com/Assets/Media/3820578/21/21-3.png)
hematoma), spinal cord infarction (proprioception is usually spared), an arteriovenous fistula or other vascular anomaly, and transverse myelitis, among other causes, may be responsible (Chap. 356). Diseases of the cerebral hemispheres that produce acute paraparesis include anterior cerebral artery ischemia (shoulder shrug also affected), superior sagittal sinus or cortical venous thrombosis, and acute hydrocephalus. If upper motor neuron signs are associated with drowsiness, confusion, seizures, or other hemispheric signs but not a sensory level over the trunk, the diagnostic approach starts with an MRI of the brain. Paraparesis is part of the cauda equina syndrome, which may result from trauma to the low back, a midline disk herniation, or intraspinal tumor; although sphincters are affected, hip flexion is often spared, as is sensation over the anterolateral thighs. Rarely, paraparesis is caused by a rapidly evolving peripheral neuropathy such as Guillain-Barre syndrome (Chap. 365) or by a myopathy (Chap. 368). In such cases, electrophysiologic studies are diagnostically helpful and refocus the subsequent evaluation.

**Subacute or chronic paraparesis** with spasticity is caused by upper motor neuron disease. When there is associated lower limb sensory loss and sphincter involvement, a chronic spinal cord disorder is likely; these are discussed in Chap. 356. The clinical approach begins with an MRI of the spinal cord. If the imaging study is normal and spasticity is present, MRI of the brain may be indicated. If hemispheric signs are present, parasagittal meningioma or chronic hydrocephalus is likely and MRI of the brain is the initial test. In the rare situation when chronic paraparesis is due to lower motor neuron or myopathic etiology, the localization is usually suspected on clinical grounds by the absence of spasticity and confirmed by EMG and nerve conduction tests.

**Quadriparesis or Generalized Weakness** Generalized weakness may be due to disorders of the CNS or of the motor unit. Although the terms *quadriparesis* and *generalized weakness* are often used interchangeably, quadriparesis is more often chosen when an upper motor neuron cause is suspected and generalized weakness when a disease of the motor unit is likely. Weakness from CNS disorders is usually associated with changes in consciousness or cognition, with increased muscle tone and muscle stretch reflexes, and with alterations of sensation. Most neuromuscular causes of generalized weakness are associated with normal mental function, diminished muscle tone, and hypoactive muscle stretch reflexes. Exceptions are some causes of acute quadriparesis due to upper motor neuron disorders in which transient hypotonia is present. The major causes of intermittent weakness are listed in Table 21-2. A patient with generalized fatigability without objective weakness may have the chronic fatigue syndrome (Chap. 370).

**Acute quadriparesis** Acute quadriparesis with onset over minutes may result from disorders of upper motor neurons (e.g., anoxia, hypotension, brainstem or cervical cord ischemia, trauma, and systemic metabolic abnormalities) or muscle (electrolyte disturbances, certain inborn errors of muscle energy metabolism, toxins, or periodic paralyses). Onset over hours to weeks may, in addition to the above, be due to lower motor neuron disorders. Guillain-Barre syndrome (Chap. 365) is the most common lower motor neuron weakness that progresses over days to 4 weeks; the finding of an elevated protein level in the cerebrospinal fluid is helpful but may be absent early in the course. If stupor or coma is present, the evaluation begins with a CT scan of the brain. If upper motor neuron signs are present but the patient is alert, the initial test is usually an MRI of the cervical cord. If weakness is lower motor neuron, myopathic, or uncertain in origin, the clinical approach begins with blood studies for muscle enzymes and electrolytes and an EMG and nerve conduction study.

**Subacute or chronic quadriparesis** When quadriparesis due to upper motor neuron disease develops over weeks, months, or years, the distinction among disorders of the cerebral hemispheres, brainstem, and cervical spinal cord is usually possible by clinical criteria alone. The diagnostic approach begins with an MRI of the clinically suspected site of pathology. Lower motor neuron disease usually presents with weakness that is most profound distally, whereas myopathic weakness is typically proximal; the evaluation then begins with EMG and nerve conduction studies.

**Monoparesis** This is usually due to lower motor neuron disease, with or without associated sensory involvement. Upper motor neuron weakness occasionally presents with a monoparesis of distal and nonantigravity muscles. Myopathic weakness is rarely limited to one limb.

**Acute monoparesis** Distinguishing between upper and lower motor neuron disorders may be difficult clinically because tone and reflexes are frequently decreased in both at presentation. If the weakness is predominantly in distal and nonantigravity muscles and not associated with sensory impairment or pain, focal cortical ischemia is likely (Chap. 349); in this setting, diagnostic possibilities are similar to those for acute hemiparesis. Sensory loss and pain usually accompany acute lower motor neuron weakness. The distribution of weakness is commonly localized to a single nerve root or peripheral nerve within one limb but occasionally reflects involvement of the brachial or lumbar-sacral plexus. If lower motor neuron weakness is suspected, or if the pattern of weakness is uncertain, the clinical approach begins with an EMG and nerve conduction study.

**Subacute or chronic monoparesis** Weakness with atrophy of one limb that develops over weeks or months is almost always lower motor neuron in origin. If the weakness is associated with numbness, a peripheral nerve or spinal root origin is likely; uncommonly, the brachial or lumbosacral plexus is affected. If numbness is absent, anterior horn cell disease is likely. In either case, an electrodiagnostic study is indicated. If upper rather than lower motor neuron signs are present, a tumor, vascular malformation, or other cortical lesion affecting the precentral gyrus may be responsible. Alternatively, if the leg is affected, a small thoracic cord lesion, often a tumor or multiple sclerosis, may be present. In these situations, the approach begins with an imaging study of the suspicious area.

**Distal weakness** Involvement of two or four limbs distally suggests lower motor neuron or peripheral nerve disease. Acute distal lower limb weakness occurs occasionally from an acute toxic polyneuropathy or cauda equina syndrome. Distal symmetric weakness usually develops over weeks, months, or years and is due to metabolic, toxic, hereditary, degenerative, or inflammatory diseases of peripheral nerves (Chap. 363). With peripheral nerve disease, weakness is usually less severe than numbness. Anterior horn cell disease may begin distally but is typically asymmetric and is not associated with numbness (Chap. 353). Rarely, myopathies also present with distal weakness (Chap. 368). The first step in evaluation is an electrophysiologic study (Fig. 21-3).

**Proximal weakness** Proximal weakness of two or four limbs suggests a disorder of muscle or, less commonly, neuromuscular junction or anterior horn cell. Myopathy often produces symmetric weakness of the pelvic or shoulder girdle muscles (Chap. 368). Diseases of the

neuromuscular junction (such as myasthenia gravis) may present with symmetric proximal weakness (Chap. 366), often associated with ptosis, diplopia, or bulbar weakness and fluctuating in severity during the day. Extreme fatigability present in some cases of myasthenia gravis may even suggest episodic weakness, but strength rarely returns fully to normal. The proximal weakness of anterior horn cell disease is most often asymmetric, but may be symmetric if familial (Chap. 353). Numbness does not occur with any of these diseases. The evaluation usually begins with determination of the serum creatine kinase level and electromyographic studies.

**Weakness in a Restricted Distribution** In some patients, weakness does not fit any of the above patterns. Examples include weakness limited to the extracocular, hemifacial, bulbar, or respiratory muscles. If unilateral, restricted weakness is usually due to lower motor neuron or peripheral nerve disease, such as in a facial palsy (Chap. 355) or an isolated superior oblique muscle paresis (Chap. 25). Relatively symmetric weakness of extracocular or bulbar muscles is usually due to a myopathy (Chap. 367) or neuromuscular junction disorder (Chap. 366). Bilateral facia! palsy with areflexia suggests Guillain-Barre` syndrome (Chap. 365). Worsening of relatively symmetric weakness with fatigue is characteristic of neuromuscular junction disorders. Asymmetric bulbar weakness is usually due to motor neuron disease. Weakness limited to respiratory muscles is uncommon and is usually due to motor neuron disease, myasthenia gravis, or polymyositis/dermatomyositis (Chap. 369).

**SPASMS AND CRAMPS**

Spontaneous or exercise-related discomfort from muscles is usually benign. However, a number of disorders of the motor system are characteristically painful. Myalgias (Chap. 367) are pains that are felt in muscle; the term does not imply an involuntary contraction. *Spasms* and *cramps* refer to episodes of involuntary contraction of one or more muscles. Cramps are usually painful, whereas spasms are not necessarily uncomfortable.

Involuntary contraction of muscle may occur with disorders of the CNS, lower motor neuron, or muscle. Contractions that originate within the CNS and are associated with upper motor neuron signs are usually referred to as spasms and generally affect the flexors or extensors of one or more limbs. Those that originate within the CNS and are not associated with upper motor neuron signs include movement disorders discussed below, as well as the rare stiff-person syndrome and tetanus. Muscle rigidity from active muscle contraction can occur in the malignant hyperthermia syndrome, usually associated with general anesthesia. In the neuroleptic malignant syndrome, muscle rigidity arises from CNS overactivity. Involuntary contractions that originate in the lower motor neurons are usually cramps, occasionally tetany, or rarely neuromyotonia. Spasms that originate in muscle or muscle membrane generally manifest as delayed relaxation after voluntary contraction (myotonia or rarely a contracture). These conditions may be difficult to distinguish clinically but are often well characterized by EMG.

**Stiff-Person Syndrome** This rare syndrome is characterized by slowly progressive muscle stiffness and superimposed spasms. The stiffness commonly begins in the low back and spreads over months up the spine and into the limbs but not into the jaw. The gait becomes stiff, and there is hyperlordosis of the lumbar spine. Spasms are often produced by startle. Emotional stress tends to worsen the stiffness as well as the frequency and severity of spasms. The spontaneous motor activity disappears during sleep. The syndrome is often associated with diabetes mellitus and can be paraneoplastic, accompanying Hodgkin’s lymphoma, small cell cancer of the lung, and breast cancer. Most patients have a serum antibody against glutamic acid decarboxylase, an enzyme responsible for synthesis of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Stiffness results from loss of descending brainstem or segmental spinal inhibitory influences on the lower motor neurons. EMG studies reveal continuous motor unit activity that is similar to voluntary effort with preservation of the silent period to muscle stretch. Stiffness and spasms typically respond partially to treatment with baclofen or benzodiazepines.

**Tetanus** This rare hyperexcitable state results from exposure to tetanus toxin in patients infected with *Clostridium tetani* (Chap. 124). Painful spasms typically begin with jaw closure (trismus) and soon become generalized. EMG studies reveal continuous motor unit activity that is similar to voluntary effort except for loss of the silent period to muscle stretch.

**Cramps** These are the most common type of involuntary muscle contraction. Cramps are a painful contraction of a single muscle that produces a palpable knot within the muscle for seconds to minutes and is relieved by passive stretch of the muscle or spontaneously. EMG studies reveal motor unit activity that has too high a discharge frequency to be voluntary. If cramps are associated with weakness, the weakness is almost always lower motor neuron in origin. When strength is normal, no definable condition is usually found, although dehydration, hypothyroidism, or uremia is occasionally present. If prominent, membrane stabilizing drugs, such as carbamazepine, may provide symptomatic benefit.

**Tetany** Tetany is characterized by contraction of distal muscles of the hands (carpal spasm with extension of interphalangeal joints and adduction and flexion of the metacarpalphalangeal joints) and feet (pedal spasm) and is associated with tingling around the mouth and distally in the limbs. Tetany with carpopedal spasms is a common manifestation of hypocalcemia or respiratory alkalosis (even from hyperventilation). EMG studies reveal single or more often grouped motor unit discharges at low discharge frequency.

**Neuromyotonia (Isaac’s Syndrome)** Neuromyotonia is characterized by muscle stiffness at rest that persists during sleep and by delayed relaxation after voluntary effort. Distal limb muscles are usually affected most severely, but all skeletal muscle may be involved. Gait may be stiff, and close inspection of the muscle reveals undulation of the overlying skin due to continuous muscle fiber contractions (myokymia). The continuous muscle fiber activity generates heat, and excessive sweating is common. EMG studies commonly reveal myokymic discharges, especially in familial cases. Rarely, EMGs record high-frequency neuromyotonic discharges. Autoantibodies against voltage-gated potassium channels have been demonstrated in some cases, and plasma exchange may be effective.

**Myotonia** This is a nonpainful delay in the relaxation of muscle after voluntary activity. Delay in opening the hand after a forceful grip (grip myotonia) is common. These disorders are usually familial and worsen in cold weather. EMG demonstrates a waxing and waning discharge of individual muscle fibers.

**Contracture** A painful inability to relax a muscle after voluntary activity due to energy depletion characterizes certain metabolic disorders with failure of energy production, such as myophosphorylase deficiency (McArdle’s disease). EMG studies reveal electrical silence.

**MOVEMENT DISORDERS**

In these disorders, abnormal movements (or dyskinesias) occur due to a disturbance of fluency and speed of voluntary movement or the presence of unintended extra movements. Because they are so distinct from the pyramidal disorders that cause upper motor neuron weakness, movement disorders are often referred to as extrapyramidal diseases. *Hyperkinetic movement disorders* are those in which an excessive amount of spontaneous motor activity is seen or in which abnormal involuntary movements occur. *Hypokinetic movement disorders* are characterized by akinesia or bradykinesia, in which purposeful motor activity is absent or reduced (“poverty of movement”).

**PATHOGENESIS** Movement disorders result from disease of the basal ganglia, paired subcortical gray matter structures consisting of the caudate and the putamen (which together are called the striatum), the
internal and external segments of the globus pallidus, the subthalamic nucleus, and the substantia nigra (see Chap. 351).

Parkinson’s disease  the prototypic hypokinetic movement disorder, results from a loss of dopaminergic neurons in the substantia nigra pars compacta. This leads to less excitation of striatal neurons that express the D1 type of dopamine receptors and less inhibition of D2 striatal neurons, both contributing to reduced facilitation of cortically initiated movement. The resting tremor of Parkinson’s disease is less readily explained by this model but may result from effects on cholinergic interneurons in the striatum. Huntington’s disease (Chap. 350), a hyperkinetic movement disorder, may be explained by selective loss of D3 striatal neurons, resulting in disinhibition of cortically initiated movements without normal feedback control. The pathogenesis of hemiballismus is similar—a direct lesion of the glutamatergic neurons in the subthalamic nucleus (usually from a stroke) leads to disinhibition of thalamocortical projections.

Hyperkinetic Movement Disorders  Abnormal involuntary movements may be rhythmical or irregular. Those that are rhythmically termed tremors, with the uncommon exception of palatal and segmental myoclonus. Tremors are divided into three types: rest, postural, and intention tremor. A rest tremor is maximal at rest and becomes less prominent with activity. A gradual onset is characteristic of parkinsonism and is commonly associated with bradykinesia and cogwheel rigidity (Chap. 351). A rest tremor that develops acutely is usually due to toxins [such as exposure to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)] or dopamine blocking drugs (such as phenothiazines). A postural tremor is maximal while limb posture is actively maintained against gravity; it is lessened by rest and is not markedly enhanced during voluntary movement toward a target. A postural tremor that develops acutely is usually due to toxic or metabolic factors (for example, hyperthyroidism) or stress. The insidious onset of a postural tremor suggests a benign or familial essential tremor. An intention tremor is most prominent during voluntary movement toward a target and is not present during postural maintenance or at rest. It is a sign of cerebellar disease (Chap. 352). Astereixis, which may superficially resemble a tremor, is an intermittent inhibition of muscle contraction that occurs with metabolic encephalopathy (Chap. 257). This leads, for example, to a momentary and repetitive partial flexion of the wrists during attempted sustained wrist extension. Irregular involuntary movements are characterized by their speed and location, and by whether they can be suppressed voluntarily. The slowest are athetosis and dystonia. Athetosis is a slow, writhing, sinuous movement that occurs nearly continuously in distal muscles. Dystonia is a slowly varying but nearly continuous deviation of posture about one or more joints; it may occur in a proximal or distal limb or in axial structures. Dystonia is a more sustained deviation of posture than athetosis, although these two phenomena overlap considerably.

The further evaluation of athetosis and dystonia is discussed in Chap. 351.

Among the rapid irregular movements, tics are controlled with voluntary effort, while the others are not. Tics often occur repetitively in a single location but are sometimes multifocal. Chorea, hemiballismus, and myoclonus are rapid, irregular jerks that cannot be voluntarily suppressed. Hemiballismus manifests as a sudden and often violent flinging movement of a proximal limb, usually an arm. Hemiballismus usually develops acutely due to infarction of the contralateral subthalamic nucleus but occasionally develops subacutely or chronically due to other lesions of this nucleus. Chorea is a rapid, jerky, irregular movement that tends to occur in the distal limbs or face but may also occur in proximal limbs and trunk. Acute or subacute onset is usually due to toxins including excess levodopa or dopamine-agonist therapy or, less often, neuroleptics, birth control pills, pregnancy (chorea gravidarum), hyperthyroidism, or the antiphospholipid syndrome. In children, it may be associated with rheumatic fever and, in such cases, is referred to as Sydenham’s chorea. The gradual onset of chorea is typical of degenerative neurologic diseases, such as Huntington’s disease.

Myoclonus is a rapid, brief, irregular movement that is usually multifocal. Myoclonus can occur spontaneously at rest, in response to sensory stimuli, or with voluntary movements. It is a symptom that occurs in a wide variety of metabolic and neurologic disorders. Post-thyroidic intention myoclonus is a special myoclonic syndrome that occurs as a sequel to transient cerebral anoxia. Myoclonus may result from lipid storage disease, encephalitis, prion diseases, or metabolic encephalopathies due to respiratory failure, chronic renal failure, hepatic failure, or electrolyte imbalance. Myoclonus is also a feature of certain types of epilepsy (Chap. 348). Palatal and segmental myoclonus are uncommon rhythmic forms of myoclonus that may resemble tremor; they are caused by structural disease of the brainstem or spinal cord at the level of the abnormal movement.

Hypokinetic Movement Disorders  These manifest as bradykinesia, with a masked, expressionless facial appearance, loss of associated limb movements during walking, and rigid and en bloc turning. If bradykinesia is associated only with a rest tremor, cogwheel rigidity, or impairment of postural reflexes (especially with a tendency to fall backwards), Parkinson’s disease is likely. If cognitive, language, upper motor neuron, sensory, or autonomic signs are also present, a multisystem degenerative neurologic disease is present. These disorders are discussed in Chaps. 351, 352, and 354.

IMBALANCE AND DISORDERS OF GAIT

Balance is the impaired ability to maintain the intended orientation of the body in space. It is generally manifest as difficulty in maintaining an upright posture while standing or walking; a severe imbalance may also affect the ability to maintain posture while seated. Patients with imbalance commonly complain of a feeling of unsteadiness or dysequilibrium. Whereas imbalance and unsteadiness are synonymous, dysequilibrium implies the additional component of impaired spatial orientation even while lying down. Patients with dysequilibrium commonly also experience vertigo, defined as an hallucination of rotatory movement.

PATHOGENESIS of Imbalance and Limb Ataxia  Imbalance results from disorders of the vestibular, sensory, or cerebellar systems, whereas limb ataxia is produced by disorders of the sensory or cerebellar systems. Asymmetric vestibular sensory input to the brainstem and cerebellum produces asymmetric imbalance, but not limb ataxia. Sensory ataxia is caused by lesions that affect the peripheral sensory fibers; dorsal root ganglia cells; posterior columns of the spinal cord; or lemniscal system in the brainstem, thalamus, or parietal cortex (Chap. 22). Impairment of the proprioceptive sensory feedback to the cerebellum, basal ganglia, and cortex produces sensory ataxia. Sensory ataxia results in imbalance and disturbs the fluency and integration of limb movements that can be partially alleviated by visual feedback. Imbalance with cerebellar ataxia results from disorders of proprioceptive, spinocerebellar, or vestibular sensory input; the integration of these inputs in the brainstem or midline cerebellar vermis or flocculonodular lobe; or the motor output to the spinal neurons that control muscles of the proximal limbs and trunk. Cerebellar limb ataxia results from disorders of the spinocerebellar and corticopontocerebellar inputs, the integration of these inputs in the intermediate and lateral cerebellum, or the output to the spinal neurons (via the red nucleus and rubrospinal tract) or to the cortex. These pathways ensure adequate speed, fluency, and integration of limb movements. The lateral cerebellar hemispheres coordinate a polysynaptic feedback circuit that modulates cortically initiated limb movement.

Disorders of Gait  Walking is one of the most complicated motor activities. Cylindrical stepping movements produced by the lumbosacral spinal cord centers are modified by cortical, basal ganglionic, brainstem, and cerebellar influences based on proprioceptive, vestibular, and visual feedback.
Imbalance  A guide to interpretation of imbalance without weakness is presented in Fig. 21-4.

**Imbalance with cerebellar ataxia** typically produces truncal ataxia, which is usually revealed during the process of rising from a chair, assuming the upright stance with the feet together, or performing some other activity while standing. Once a desired position is reached, imbalance may be surprisingly mild. As walking begins, the imbalance recurs. Patients usually learn to lessen the imbalance by walking with the legs widely separated. The imbalance is usually not lateralized; may be accompanied by symmetric nystagmus; and is caused by toxic, metabolic, inflammatory, or neurodegenerative diseases. Asymmetric cerebellar ataxia suggests structural disease from ischemia, tumor, or other mass lesion.

Cerebellar limb ataxia is characterized by dysmetria (irregular errors in amplitude and force of movements); intention tremor (accentuation as the target is approached); dysdiadochokinesia (errors in rhythm, velocity, or force); and excessive rebound of outstretched arms against a resistance that is suddenly removed. Muscle tone is often modestly reduced; this contributes to the abnormal rebound due to decreased activation of segmental spinal cord reflexes and also to pendi- dular reflexes, i.e., a tendency for a tendon reflex to produce multiple swings to and fro after a single tap. If involvement is asymmetric, lateralized imbalance is common and usually associated with asymmetric nystagmus. For further discussion of cerebellar diseases, see Chap. 352.

**Imbalance with vestibular dysfunction** is characterized by a consistent tendency to fall to one side. The patient commonly complains of vertigo rather than imbalance, especially if the onset is acute. Acute vertigo associated with lateralized imbalance but no other neurologic signs is often due to disorders of the semicircular canal (Chap. 20); the presence of other neurologic signs suggests brainstem ischemia (Chap. 349) or multiple sclerosis (Chap. 359). When the vestibular dysfunction is peripheral, positional nystagmus and vertigo tend to resolve if a provocative position is maintained (extension) or repeated (habituation). Lateralized imbalance of gradual onset or persisting for >2 weeks, accompanied by nystagmus, may result from lesions of the semicircular canal or vestibular nerve, brainstem, or cerebellum.

**Imbalance with sensory ataxia** is characterized by marked worsening when visual feedback is removed. The patient can often assume the upright stance with feet together cautiously with eyes open. With eye closure, balance is rapidly lost (positive Romberg sign) in various directions at random. Sensory examination reveals impairment of proprioception at the toes and ankles, usually associated with an even more prominent abnormality of vibratory perception. Prompt evaluation for vitamin B12 deficiency is important, as this disorder is reversible if recognized early. Depression or absence of reflexes points to peripheral nerve disorders. Spasticity with extensor plantar responses suggests posterior column and spinal cord disorders. Rarely, sensory ataxia produces lateralized imbalance. In these cases, the disorder is usually in the parietal lobe or thalamus, but may also be due to an asymmetric sensory neuropathy or posterior column disease.

Sensory limb ataxia is similar to other forms of imbalance occur, but the fundamental problem is usually a primary disorder of strength, extrapyramidal function, or cortical initiation of movement, as indicated in Fig. 21-4.

**Abnormal Gait** Each of the disorders discussed in this chapter produces a characteristic gait disturbance. If the neurologic examination is normal except for an abnormal gait, diagnosis may be difficult even for the experienced clinician.

***Hemiparetic gait*** characterizes spastic hemiparesis. In its most severe form, an abnormal posture of the limbs is produced by spasticity. The arm is abducted and internally rotated, with flexion of the elbow, wrist, and fingers and with extension of the hip, knee, and ankle. Forward swing of the spastic leg during walking requires abduction and circumduction at the hip, often with contralateral tilt of the trunk to prevent the toes catching on the floor as the leg is advanced. In its mildest form, the affected arm is held in a normal position, but swings less than the normal arm. The affected leg is flexed less than the normal leg during its forward swing and is more externally rotated. A hemiparetic gait is a common residual sign of a stroke.

**Paraparetic gait** is a walking pattern in which both legs are moved in a slow, stiff manner with circumduction, similar to the leg movement in a hemiparetic gait. In many patients, the legs tend to cross with each forward swing ("scissoring"). A paraparetic gait is a common sign of spinal cord disease and also occurs in cerebral palsy.

Steppage gait is produced by weakness of ankle dorsiflexion. Because of the partial or complete foot drop, the leg must be lifted higher than usual to avoid catching the toe on the floor during the forward swing of the leg. If unilateral, steppage gait is usually due to L5 radiculopathy, sciatic neuropathy, or peroneal neuropathy. If bilateral, it
is the common result of a distal polyneuropathy or lumbosacral polyradiculopathy.

Waddling gait results from proximal lower limb weakness, most often from myopathy but occasionally from neuromuscular junction disease or a proximal symmetric muscular atrophy. With weakness of hip flexion, the trunk is tilted away from the leg that is being moved to lift the hip and provide extra distance between the foot and the floor, and the pelvis is rotated forward to assist with forward motion of the leg. Because pelvic girdle weakness is customarily bilateral, the pelvic lift and rotation alternate from side to side, giving the waddling appearance to the gait.

Parkinsonian gait is characterized by a forward stoop, with modest flexibility at the hips and knees. The arms are flexed at the elbows and adducted at the shoulders, often with a 4- to 6-Hz resting pronation-supination tremor but little other movement, even during walking. Walking is initiated slowly by leaning forward and maintained with short rapid steps, during which the feet shuffle along the floor. The pace tends to accelerate (festination) as the upper body gradually leans further ahead of the feet, whether movement is forward (propulsion) or backward (retropulsion). The postural instability leads to falls (Chap. 351).

Apraxic gait results from bilateral frontal lobe disease with impaired ability to plan and execute sequential movements. This gait superficially resembles that of parkinsonism, in that the posture is stooped and any steps taken are short and shuffling. However, initiation and maintenance of walking are impaired in a different manner. Each movement that is required for walking can usually be performed, if tested in isolation while sitting or lying. However, when asked to step forward while standing, a long pause often occurs before any attempt is made to flex at the hip and advance, as if the patient is “glued to the ground.” Once walking is initiated, it is not maintained, even in an abnormal festinating manner. Rather, after one or several steps are taken, walking is stopped for several seconds or longer. The process is then repeated. Dementia and incontinence may coexist.

Choreoathetotic gait is characterized by an intermittent, irregular movement that disrupts the smooth flow of a normal gait. Flexion or extension movements at the hip are common and unpredictable but readily observed as a pelvic lurch.

Cerebellar ataxic gait is a broad-based gait disorder in which the speed and length of stride varies irregularly from step to step. With midline cerebellar disease, as in alcoholics, posture is erect but the feet are separated; lower limb ataxia is commonly present as well. With disease of the cerebellar hemispheres, limb ataxia and nystagmus are commonly present as well.

Sensory ataxic gait may resemble a cerebellar gait, with its broad-based stance and difficulty with change in position. However, although balance may be maintained with the eyes open, loss of visual input through eye closure results in rapid loss of balance with a fall (positive Romberg sign), unless the physician assists the patient.

Vestibular gait is one in which the patient consistently tends to fall to one side, whether walking or standing. Cranial nerve examination usually demonstrates an asymmetric nystagmus. The possibilities of unilateral sensory ataxia and hemiparesis are excluded by the findings of normal proprioception and strength.

Astasia-abasia is a typical hysterical gait disorder. Although the patient usually has normal coordination of leg movements in bed or while sitting, the patient is unable to stand or walk without assistance. If distracted, stationary balance is sometimes maintained and several steps are taken normally, followed by a dramatic demonstration of imbalance with a lunge toward the examiner’s arms or a nearby bed.

NORMAL SENSATION

Normal somatic sensation reflects a continuous day and night monitoring process that occupies considerable moment-to-moment nervous system capacity. Little of this activity reaches consciousness under ordinary conditions. In contrast, disordered sensation, particularly if experienced as painful, is alarming and dominates the sufferer’s attention. Abnormalities of sensation, especially if painful, tend to make those suffering seek medical help. The physician must be able to recognize abnormal sensations by how they are described, know their type and likely site of origin, and understand their implications. For a consideration of pain, see Chap. 11.

POSITIVE AND NEGATIVE PHENOMENA

Abnormal sensory phenomena may be divided into two categories, positive and negative. The prototypical positive phenomenon is tingling (pins-and-needles), and the principal negative phenomenon is numbness. In addition to tingling, positive sensory phenomena include other altered sensations that are described as pricking, bandlike, lightning-like shooting feelings (lancinations), aching, knife-like, twisting, drawing, pulling, tightening, burning, searing, electrical, or raw feelings. These descriptors are frequently the actual words used by patients. Such sensations are usually experienced as painful, but not necessarily.

Positive phenomena usually result from trains of impulses generated at a site or sites of lowered threshold or heightened excitability along a sensory pathway, either peripheral or central. The nature and severity of an abnormal sensation depend on the number, rate, timing, and distribution of ectopic impulses and the type and function of nerve tissue in which they arise. Because positive phenomena represent excessive activity in sensory pathways, they are not necessarily associated with sensory deficit (loss) upon examination.

Negative phenomena represent loss of sensory function and are characterized by diminished or absent feeling, often experienced as numbness. In contrast to positive phenomena, negative phenomena are accompanied by abnormal findings on sensory examination. In disorders affecting peripheral sensation, it is estimated that at least half the afferent axons innervating a given site are lost or functionless before sensory deficit can be demonstrated by clinical examination. This threshold varies according to how rapidly sensory nerve fibers have lost function. If the rate of loss is slow and chronic, lack of cutaneous feeling may be unnoticed by the patient and difficult to demonstrate on examination, even though few sensory fibers are functioning. Rapidly evolving sensory abnormality usually evokes both positive and negative phenomena that are readily noticed. Subclinical degrees of sensory dysfunction not demonstrable on clinical sensory examination may be revealed by sensory nerve conduction studies or somatosensory evoked potentials (Chap. 359). Sensory symptoms may be either positive or negative, but sensory signs on examination are always a measure of negative phenomena.

TERMINOLOGY

Words used to characterize sensory disturbance are descriptive and have been arrived at mainly by convention. Paresthesia and dysesthesia are general terms used to denote sensory symptoms (positive phenomena) and are usually stated in the plural form. Paresthesias usually refer to tingling or pins-and-needles sensations but may also include a wide variety of other abnormal sensations, ex-
cepting pain. Sometimes “paresthesias” carry the implication that the abnormal sensations are perceived without an apparent stimulus. Dysesthesia is a more general term denoting all types of abnormal sensations, even painful ones, whether a stimulus is evident or not.

While paresthesias and dysesthesias refer to sensations described by patients, another set of terms refers to sensory abnormalities found on examination. These include hypesthesia or hypoesthesia (reduction of cutaneous sensation to a specific type of testing such as pressure, light touch, and warm or cold stimuli); anesthesia (complete absence of skin sensation to the same stimuli plus pinprick); and hypalgiesia (referring to reduced pain perception, i.e., nociception, such as the pricking quality elicited by a pin). Hyperesthesia means pain in response to touch. Similarly, allosthenia describes the situation in which a nonpainful stimulus, once perceived, is experienced as painful, even excruciating. An example is elicitation of a painful sensation by application of a vibrating tuning fork. Hyperalgesia denotes severe pain in response to a mildly noxious stimulus, and hyperpathia, a broad term, encompasses all the phenomena described by hyperesthesia, allosthenia, and hyperalgesia. With hyperpathia, the threshold for a sensory stimulus is increased and the perception is delayed, but once felt, is unduly painful.

Disorders of deep sensation, arising from muscle spindles, tendons, and joints, affect proprioception (position sense). Manifestations include imbalance (particularly with eyes closed or in the dark), clumsiness of precision movements, and unsteadiness of gait, which are referred to collectively as sensory ataxia (Chap. 21). Other findings on examination usually, but not invariably, include reduced or absent joint position and vibratory sensibility and absent deep tendon reflexes in the affected limbs. Romberg’s sign is positive, which means that the patient sways or topples when asked to stand with feet close together. Such patients are severely disabled.

ANATOMY OF SENSATION Cutaneous afferent innervation is conveyed by a rich variety of receptors, both naked nerve endings (nociceptors and thermoreceptors) and encapsulated terminals (mechanoreceptors). Each type of receptor has its own set of sensitivities to specific stimuli, size and distinctness of receptive fields, and adaptational qualities. Much of the knowledge about these receptors has come from the development of techniques to study single intact nerve fibers intraneurally in awake, unanesthetized human subjects. It is possible not only to record from single nerve fibers, large or small, but also to stimulate single fibers in isolation. A single impulse, whether elicited by a natural stimulus or evoked by electrical microstimulation, in a large myelinated afferent fiber may be both perceived and localized.

Afferent fibers of all sizes in peripheral nerve trunks traverse the dorsal roots and enter the dorsal horn of the spinal cord (Fig. 22-1). From there the smaller fibers take a different route to the parietal cortex than the larger fibers. The polysynaptic projections of the smaller fibers (unmyelinated and small myelinated), which subserve mainly nociception, temperature sensibility, and touch, cross and ascend in the opposite anterior and lateral columns of the spinal cord, through the brainstem, to the ventral posterolateral (VPL) nucleus of the thalamus, and ultimately project to the postcentral gyrus of the parietal cortex (Chap. 11). This is referred to as the spinothalamic pathway, or anterolateral system. The larger fibers, which subserve tactile and position sense and kinesthesia, project rostrally in the posterior column on the same side of the spinal cord and make their first synapse in the gracile or cuneate nuclei of the lower medulla. The second-order neuron decussates and ascends in the medial lemniscus located medially in the medulla and in the tegmentum of the pons and midbrain and synapses in the VPL nucleus. The third-order neuron projects to the thalamus and terminates in the postcentral gyrus of the parietal cortex; this large fiber system is referred to as the posterior column–medial lemniscal pathway (lemniscal, for short). Note that although the lemniscal and the anterolateral pathways both project up the spinal cord to the thalamus, it is the (crossed) anterolateral pathway that is referred to as the spinothalamic tract, by convention.

Although the fiber types and functions that make up the spinothalamic and lemniscal systems are relatively well known, it has been found that many other fibers, particularly those associated with touch, pressure, and position sense, ascend in a diffusely distributed pattern both ipsilaterally and contralaterally in the anterolateral quadrants of the spinal cord. This explains why an individual with a complete lesion of the posterior columns of the spinal cord may have little sensory deficit on examination.

EXAMINATION OF SENSATION The main components of the sensory examination are tests of primary sensation. These include the sense of pain, touch, vibration, joint position, and thermal sensation, both hot and cold (Table 22-1). Detailed descriptions of how to perform the various tests of the sensory examination can be found in standard texts (see “Bibliography”).

Some general principles pertain. The examiner must depend on patient responses, particularly when testing cutaneous sensation (pin, touch, warm or cold). This subjective element complicates the interpretation of the sensory examination. Further, some patients are only partially examinable. In a stuporous patient, sensory examination is reduced to observing the briskness of withdrawal in response to a pinch or other noxious stimulus. Comparison of response on one side of the body to the other is essential. In the alert but uncooperative patient, cutaneous sensation may be unexamimable. However, it is usually possible to get some idea of proprioceptive function by noting the patient’s best performance of movements requiring balance and precision. Frequently, patients present with sensory symptoms that do not fit anatomic localization and that are accompanied by either no abnormalities or gross inconsistencies on examination. The examiner should then consider whether the sensory symptoms are a disguised request.
for help with psychological or situational problems. Discretion must be used in pursuing this possibility. Finally, sensory examination of a patient who has no neurologic complaints can be brief and consist of pin, touch, and vibration testing in the hands and feet plus evaluation of stance and gait, including the Romberg maneuver. Evaluation of stance and gait also tests the integrity of motor and cerebellar systems.

**PRIMARY SENSATION** (See Table 22-1)
The sense of pain is usually tested with a clean pin, asking the patient to focus on the pricking or unpleasant quality of the stimulus and not just the pressure or touch sensation elicited. Areas of hypalgesia should be mapped by proceeding radially from the most hypalgesic site (Figs. 22-2 and 22-3).

Temperature sensation, to both hot and cold, is probably best tested with water flasks filled with water of the desired temperature, using a thermometer to verify the temperature. This is impractical in most settings. An alternative way to test cold sensation is to touch a metal object, such as a tuning fork at room temperature, to the skin. For testing warm temperatures, the tuning fork or other metal object may be held under warm water of the desired temperature and then used. Both cold and warm should be tested because different receptors respond to each.

Touch is usually tested with a wisps of cotton or a fine camelhair brush. In general, it is better to avoid testing touch on hairy skin because of the profusion of sensory endings that surround each hair follicle.

Joint position testing is a measure of proprioception, one of the most important functions of the sensory system. With the patient keeping eyes closed, joint position is tested in the great toe and in the fingers. If errors are made in recognizing the direction of passive movements of the toe or the finger, more proximal joints should be tested. A test of proximal joint position sense, primarily at the shoulder, is performed by asking the patient to bring the two index fingers together with arms extended and eyes closed. Normal individuals can do this accurately, with errors of a centimeter or less.

The sense of vibration is tested with a tuning fork, preferably a large one that vibrates at 128 Hz. Vibration is usually tested at bony prominences, beginning distally at the malleoli of the ankles, and at the knuckles. If abnormalities are found, more proximal sites can be examined. Vibratory thresholds at the same site in the patient and the examiner may be compared for control purposes.

**QUANTITATIVE SENSORY TESTING** Effective sensory testing devices have been developed over the past two decades. Quantitative sensory testing is particularly useful for serial evaluation of cutaneous sensation in clinical trials. Threshold testing for touch and vibratory and thermal sensation is the most widely used application.

**CORTICAL SENSATION** The most commonly used tests of cortical function are two-point discrimination, touch localization, and bilateral simultaneous stimulation and tests for graphesthesia and stereognosis. Abnormalities of these sensory tests, in the presence of normal primary sensation in an alert cooperative patient, signify a lesion of the parietal cortex or thalamocortical projections to the parietal lobe. If primary sensation is altered, these cortical discriminative functions will usually be abnormal, too. Comparisons should always be made between analogous sites on the two sides of the body because the deficit with a specific parietal lesion is likely to be hemispatial. Side-to-side comparisons hold true for all cortical sensory testing.

Two-point discrimination is tested by special calipers, the points of which may be set from 2 mm to several centimeters apart and then applied simultaneously to the site to be tested. The pulp of the finger tips is a common site to test; a normal individual can distinguish about 3-mm separation of points there.

**Touch localization** is usually carried out by light pressure for an instant with the examiner’s fingertip, asking the patient, whose eyes are closed, to identify the site of touch with his or her fingertip. **Bilateral simultaneous stimulation** at analogous sites (e.g., the dorsa of both hands) can be carried out to determine whether the perception of touch is extinguished consistently on one side or the other. The phenomenon is referred to as **extinction**. **Graphesthesia** means the capacity to recognize with eyes closed letters or numbers drawn by the examiner’s fingertip on the palm of the hand. Once again, the comparison of one side with the other is of prime importance. Inability to recognize numbers or letters is termed **agraphesthesia**.

**Stereognosis** refers to the ability to identify common objects by palpation, recognizing their shape, texture, and size. Common standard objects are the best test objects, such as a marble, a paper clip, or coins. Patients with normal stereognosis should be able to distinguish a dime from a penny and a nickel from a quarter without looking. Patients should only be allowed to feel the object with one hand at a time. If they are unable to identify it in one hand, it should be placed in the other for comparison. Individuals unable to identify common objects and coins in one hand who can do so in the other are said to have **astereognosis** of the abnormal hand.

**LOCALIZATION OF SENSORY ABNORMALITIES**

Sensory symptoms and signs can result from lesions at almost any level of the nervous system, including parietal cortex, deep white matter, thalamus, brainstem, spinal cord, spinal root, peripheral nerve, and sensory receptor. Noting the distribution and nature of sensory symptoms and signs is the most important way to localize their source. The extent, configuration, symmetry, quality, and severity are the key observations.

Dysesthesias without sensory findings by examination can be difficult to interpret. To illustrate, tingling dysesthesias in an acral distribution (hands and feet) can be systemic in origin, e.g., secondary to hyperventilation, or can be induced by a medication, such as the diuretic acetazolamide. Distal dysesthesias can also be an early event in an evolving polyneuropathy or can herald a myelopathy, such as with vitamin B₁₂ deficiency. Sometimes distal dysesthesias have no definable basis. In contrast, dysesthesias that correspond to a particular peripheral nerve territory denote a lesion of that nerve trunk. For instance, dysesthesias restricted to the fifth digit and the adjacent one-half of the fourth finger on one hand reliably point to disorder of the ulnar nerve, most commonly at the elbow.

**NERVE AND ROOT** In focal nerve trunk lesions severe enough to cause a deficit, sensory abnormalities are readily mapped and generally have discrete boundaries (Figs. 22-2 and 22-3). Root lesions, referred to as radicular, are frequently accompanied by deep, aching pain along the
course of the related nerve trunk. With compression of a fifth lumbar (L5) or first sacral (S1) root, as may occur with a ruptured intervertebral disc, sciatica (radicular pain relating to the sciatic nerve trunk) is a frequent manifestation (Chap. 15). With a lesion affecting a single root, sensory deficit in the distribution of that root is often minimal or not demonstrable at all. This is because adjacent root territories overlap extensively.

Polyneuropathies are generally graded, distal, and symmetric in distribution of deficit (Chap. 363). Dysesthesias begin in the toes and ascend symmetrically, followed by numbness. When dysesthesias reach the knees, they have usually also appeared in the fingertips. The process appears to be nerve length–dependent, and the deficit is often described as “stocking-glove” in type. Although most polyneuropathies are pansensory and affect all modalities of sensation, selective sensory dysfunction according to nerve fiber size may occur. In polyneuropathies that affect small nerve fibers selectively, the hallmark is burning, painful dysesthesias with reduced pinprick and thermal sensation but with sparing of proprioception, motor function, and even deep tendon jerks. Touch is variably involved, but when spared, the sensory pattern is referred to as sensory dissociation. Sensory dissociation patterns can be seen with spinal cord lesions (see below) as well as with small fiber neuropathies. In contrast to small fiber polyneuropathies, large fiber polyneuropathies are characterized by position sense deficit, imbalance, absent tendon jerks, and variable motor dysfunction but preservation of most cutaneous sensation. Dysesthesias, if present at all, tend to be tingling or bandlike.

FIGURE 22-2 Anterior view of dermatomes (left) and cutaneous areas (right) supplied by individual peripheral nerves. (Modified from MB Carpenter and J Sutin, in Human Neuroanatomy, 8th ed, Baltimore, Williams & Wilkins, 1983.)

SPINAL CORD (See also Chap. 356) If the spinal cord is transected, all sensation is lost below the level of transection. Bladder and bowel function are also lost, as is motor function. Hemisection of the spinal cord produces the Brown-Séquard syndrome, which involves absent pain and temperature sensation on the opposite side below the lesion, and loss of proprioceptive sensation and loss of motor power on the same side below the lesion (see Figs. 22-1 and 356-1). Dissociated sensory deficit patterns (see above) are also a sign of spinothalamic tract involvement in the spinal cord, especially if the deficit is unilateral and has an upper level on the torso. Bilateral spinothalamic tract involvement occurs with lesions affecting the center of the spinal cord, such as happens with expansion of the central canal in syringomyelia. Sensory dissociation is characteristic of syringomyelia.

BRAINSTEM Harlequin patterns of sensory disturbance, in which one side of the face and the opposite side of the body are affected, localize to the lateral medulla. Here a small lesion may damage both the ipsilateral descending trigeminal tract and ascending spinothalamic fibers subserving the opposite arm, leg, and hemitortorso (see “Lateral medullary syndrome” in Fig. 349-8). In the tegmentum of the pons and midbrain, where the lemniscal and spinothalamic tracts merge, a lesion here causes pansensory loss on the contralateral side.

THALAMUS Hemisensory disturbance with tingling numbness from head to foot is often thalamic in origin but can also be anterior parietal. If abrupt in onset, the lesion is likely to be due to a small stroke (lacunar infarction), particularly if localized to the thalamus. Occasionally, with lesions affecting the VPL nucleus or adjacent white matter, a syndrome of thalamic pain, also called Déjerine-Roussy syndrome, may ensue. This persistent, unrelenting hemipainful state is
areas, collectively known as the rest is subsumed by unimodal, heteromodal, paralimbic, and limbic sensory and motor areas constitute 10% of the cerebral cortex. The common pathway for coordinating complex motor acts. The primary into cortical circuitry, whereas the primary motor areas provide a final common pathway for coordinating complex motor acts. The primary sensory and motor areas constitute 10% of the cerebral cortex. The rest is subsumed by unimodal, heteromodal, paralimbic, and limbic areas, collectively known as the association cortex (Fig. 23-1). The association cortex mediates the integrative processes that subserve cognition, emotion, and behavior. A systematic testing of these mental functions is necessary for the effective clinical assessment of the association cortex and its diseases.

According to current thinking, there are no centers for “hearing words,” “perceiving space,” or “storing memories.” Cognitive and behavioral functions (domains) are coordinated by intersecting large-scale neural networks that contain interconnected cortical and subcortical components. The network approach to higher cerebral function has at least four implications of clinical relevance: (1) a single domain such as language or memory can be disrupted by damage to any one of several areas, as long as these areas belong to the same network; (2) damage confined to a single area can give rise to multiple deficits, involving the functions of all networks that intersect in that region; (3) damage to a network component may give rise to minimal or transient deficits if other parts of the network undergo compensatory reorganization; and (4) individual anatomic sites within a network display a relative (but not absolute) specialization for different behavioral aspects of the relevant function. Five anatomically defined large-scale networks are most relevant to clinical practice: a perisylvian network for language; a parietofrontal network for spatial cognition; an occipitotemporal network for face and object recognition; a limbic network for retentive memory; and a prefrontal network for attention and behavior.

THE LEFT PERISYLVIAN NETWORK FOR LANGUAGE: APHASIAS AND RELATED CONDITIONS

Language allows the communication and elaboration of thoughts and experiences by linking them to arbitrary symbols known as words. The neural substrate of language is composed of a distributed network centered in the perisylvian region of the left hemisphere. The posterior pole of this network is known as Wernicke’s area and includes the posterior third of the superior temporal gyrus and a surrounding rim of inferior parietal and midtemporal cortex. An essential function of Wernicke’s area is to transform sensory inputs into their neural word representations so that these can establish the distributed associations that give the word its meaning. The anterior pole of the language network, known as Broca’s area, includes the posterior part of the inferior frontal gyrus and a surrounding rim of prefrontal heteromodal focal sensory seizures are tingling or numbness or both, but additional, more complex sensations may occur, such as a rushing feeling, a sense of warmth, or a sense of movement without detectable motion. Likely sites of unilateral symptom origin are in the arm or hand, face, leg, or foot, and symptoms often spread as in a Jacksonian march. Duration of seizures is variable; they may be transient, lasting only seconds, or they may persist for an hour or more. Focal motor features, like clonic jerking, can supervene, and seizures often become generalized with loss of consciousness and tonic-clonic jerking. On occasion, symptoms occur in a symmetric bilateral fashion, for instance, in both hands, as a result of involvement of the second sensory area (unilaterally) located in the rolandic area at and just above the Sylvian fissure.

The cerebral cortex of the human brain contains approximately 20 billion neurons spread over an area of 2.5 m². The primary sensory areas provide an obligatory portal for the entry of sensory information into cortical circuitry, whereas the primary motor areas provide a final common pathway for coordinating complex motor acts. The primary sensory and motor areas constitute 10% of the cerebral cortex. The rest is subsumed by unimodal, heteromodal, paralimbic, and limbic areas, collectively known as the association cortex (Fig. 23-1). The association cortex mediates the integrative processes that subserve cognition, emotion, and behavior. A systematic testing of these mental functions is necessary for the effective clinical assessment of the association cortex and its diseases.

According to current thinking, there are no centers for “hearing words,” “perceiving space,” or “storing memories.” Cognitive and behavioral functions (domains) are coordinated by intersecting large-scale neural networks that contain interconnected cortical and subcortical components. The network approach to higher cerebral function has at least four implications of clinical relevance: (1) a single domain such as language or memory can be disrupted by damage to any one of several areas, as long as these areas belong to the same network; (2) damage confined to a single area can give rise to multiple deficits, involving the functions of all networks that intersect in that region; (3) damage to a network component may give rise to minimal or transient deficits if other parts of the network undergo compensatory reorganization; and (4) individual anatomic sites within a network display a relative (but not absolute) specialization for different behavioral aspects of the relevant function. Five anatomically defined large-scale networks are most relevant to clinical practice: a perisylvian network for language; a parietofrontal network for spatial cognition; an occipitotemporal network for face and object recognition; a limbic network for retentive memory; and a prefrontal network for attention and behavior.

THE LEFT PERISYLVIAN NETWORK FOR LANGUAGE: APHASIAS AND RELATED CONDITIONS

Language allows the communication and elaboration of thoughts and experiences by linking them to arbitrary symbols known as words. The neural substrate of language is composed of a distributed network centered in the perisylvian region of the left hemisphere. The posterior pole of this network is known as Wernicke’s area and includes the posterior third of the superior temporal gyrus and a surrounding rim of inferior parietal and midtemporal cortex. An essential function of Wernicke’s area is to transform sensory inputs into their neural word representations so that these can establish the distributed associations that give the word its meaning. The anterior pole of the language network, known as Broca’s area, includes the posterior part of the inferior frontal gyrus and a surrounding rim of prefrontal heteromodal focal sensory seizures are tingling or numbness or both, but additional, more complex sensations may occur, such as a rushing feeling, a sense of warmth, or a sense of movement without detectable motion. Likely sites of unilateral symptom origin are in the arm or hand, face, leg, or foot, and symptoms often spread as in a Jacksonian march. Duration of seizures is variable; they may be transient, lasting only seconds, or they may persist for an hour or more. Focal motor features, like clonic jerking, can supervene, and seizures often become generalized with loss of consciousness and tonic-clonic jerking. On occasion, symptoms occur in a symmetric bilateral fashion, for instance, in both hands, as a result of involvement of the second sensory area (unilaterally) located in the rolandic area at and just above the Sylvian fissure.
cortex. An essential function of this area is to transform neural word representations into their articulatory sequences so that the words can be uttered in the form of spoken language. The sequencing function of Broca’s area also appears to involve the ordering of words into sentences that contain a meaning-appropriate syntax (grammar). Wernicke’s and Broca’s areas are interconnected with each other and with additional perisylvian, temporal, prefrontal, and posterior parietal regions, making up a neural network subserving the various aspects of language function. Damage to any one of these components or to their interconnections can give rise to language disturbances (aphasia). Aphasia should be diagnosed only when there are deficits in the formal aspects of language such as naming, word choice, comprehension, spelling, and syntax. Dysarthria and mutism do not, by themselves, lead to a diagnosis of aphasia. The language network shows a left hemisphere dominance pattern in the vast majority of the population. In approximately 90% of right handers and 60% of left handers, aphasia occurs only after lesions of the left hemisphere. In some individuals no hemispheric dominance for language can be discerned, and in some others (including a small minority of right handers) there is a right hemisphere dominance for language. A language disturbance occurring after a right hemisphere lesion in a right hander is called crossed aphasia.

**CLINICAL EXAMINATION** The clinical examination of language should include the assessment of naming, spontaneous speech, comprehension, repetition, reading, and writing. A deficit of naming (anomia) is the single most common finding in aphasic patients. When asked to name common objects (pencil or wristwatch), the patient may fail to come up with the appropriate word, may provide a circumlocutory description of the object (“the thing for writing”), or may come up with the wrong word (paraphasia). If the patient offers an incorrect but legitimate word (“pen” for “pencil”), the naming error is known as a semantic paraphasia; if the word approximates the correct answer but is phonetically inaccurate (“plintil” for “pencil”), it is known as a phonemic paraphasia. Asking the patient to name body parts, geometric shapes, and component parts of objects (lapel of coat, cap of pen) can elicit mild forms of anomia in patients who can otherwise name common objects. In most anomas, the patient cannot retrieve the appropriate name when shown an object but can point to the appropriate object when the name is provided by the examiner. This is known as a one-way (or retrieval-based) naming deficit. A two-way naming deficit exists if the patient can neither provide nor recognize the correct name, indicating the presence of a language comprehension impairment. Spontaneous speech is described as “fluent” if it maintains appropriate output volume, phrase length, and melody or as “non-fluent” if it is sparse, halting, and average utterance length is below four words. The examiner should also note if the speech is paraphasic or circumlocutious; if it shows a relative paucity of substantive nouns and action verbs versus function words (prepositions, conjunctions); and if word order, tenses, suffixes, prefixes, plurals, and possessives are appropriate. **Comprehension** can be tested by assessing the patient’s ability to follow conversation, by asking yes-no questions (“Can a dog fly?”; “Does it snow in summer?”) or asking the patient to point to appropriate objects (“Where is the source of illumination in this room?”). Statements with embedded clauses or passive voice construction (“If a tiger is eaten by a lion, which animal stays alive?”) help to assess the ability to comprehend complex syntactic structure. Commands to close or open the eyes, stand up, sit down, or roll over should not be used to assess overall comprehension since appropriate responses aimed at such axial movements can be preserved in patients who otherwise have profound comprehension deficits. **Repetition** is assessed by asking the patient to repeat single words, short sentences, or strings of words such as “No ifs, ands, or buts.” The testing of repetition with tongue-twisters such as “hippopotamus” or “Irish constabulary” provides a better assessment of dysarthria and pallilalia than aphasia. Aphasic patients may have little difficulty with tongue-twisters but have a particularly hard time repeating a string of function words. It is important to make sure that the number of words does not exceed the patient’s attention span. Otherwise, the failure of repetition becomes a reflection of the narrowed attention span rather than an indication of an aphasic deficit. **Reading** should be assessed for deficits in reading aloud as well as comprehension. **Writing** is assessed for spelling errors, word order, and grammar. **Alexia** describes an inability to either read aloud or comprehend single words and simple sentences; **agraphia** (or dysgraphia) is used to describe an acquired deficit in the spelling or grammar of written language. The correspondence between individual deficits of language function and lesion location does not display a rigid one-to-one relationship and should be conceptualized within the context of the distributed network model. Nonetheless, the classification of aphasic patients into specific clinical syndromes helps to determine the most likely anatomic distribution of the underlying neurologic disease and has implications for etiology and prognosis (Table 23-1). Aphasic syndromes can be divided into “central” syndromes, which result from damage to the two epicenters of the language network (Broca’s and Wernicke’s areas), and “disconnection” syndromes, which arise from lesions that interrupt the functional connectivity of these centers with each other and with the other components of the language network. The syndromes outlined below are idealizations; pure syndromes occur rarely.

**Wernicke’s Aphasia** Comprehension is impaired for spoken and written language. Language output is fluent but is highly paraphasic and circumlocutious. The tendency for paraphasic errors may be so pronounced that it leads to strings of neologisms, which form the basis of what is known as “jargon aphasia.” Speech contains large numbers of function words (e.g., prepositions, conjunctions) but few substantive nouns or verbs that refer to specific actions. The output is therefore voluminous but uninformative. For example, a patient attempts to describe how his wife accidentally threw away something important, perhaps his dentures: “We don’t need it anymore, she says. And they happened to be in that dropfoli...” So she says we won’t need it anymore. . . . I didn’t think we’d use it. And now if I have any problems anybody coming

a month from now, 4 months from now, or 6 months from now, I have
a new dentist. Where my two . . . two little pieces of dentist that I
use . . . that I . . . all gone. If she throws the whole thing away . . . visit
some friends of hers and she can’t throw them away.”

Gestures and pantomime do not improve communication. The pa-
tient does not seem to realize that his or her language is incomprehen-
sible and may appear angry and impatient when the examiner fails to
decipher the meaning of a severely paraphrastic statement. In some pa-
tients this type of aphasia can be associated with severe agitation and
paranoid behaviors. One area of comprehension that may be preserved
is the ability to follow commands aimed at axial musculature. The
dissociation between the failure to understand simple questions (“What
is your name”) in a patient who rapidly closes his or her eyes, sits up,
or rolls over when asked to do so is characteristic of Wernicke’s apha-
sia and helps to differentiate it from deafness, psychiatric disease, or
malingering. Patients with Wernicke’s aphasia cannot express their
thoughts in meaning-appropriate words and cannot decode the mean-
ing of words in any modality of input. This aphasia therefore has
expressive as well as receptive components. Repetition, naming, read-
ing, and writing are also impaired.

The lesion site most commonly associated with Wernicke’s aphasia
is the posterior portion of the language network and tends to involve
at least parts of Wernicke’s area. An embolus to the inferior division
of the middle cerebral artery, and to the posterior temporal or angular
branches in particular, is the most common etiology (Chap. 349). In-
tracerebral hemorrhage, severe head trauma, or neoplasm are other
causes. A coexisting right hemi- or superior quadrantanopia is com-
mon, and mild right nasolabial flattening may be found, but otherwise
the examination is often unrevealing. The parasphasic, neologistic
speech in an agitated patient with an otherwise unremarkable neuro-
logic examination may lead to the suspicion of a primary psychiatric
disorder such as schizophrenia or mania, but the other components
characteristic of acquired aphasia and the absence of prior psychiatric
disease usually settle the issue. Some patients with Wernicke’s aphasia
due to intracerebral hemorrhage or head trauma may improve as the
hemorrhage or the injury heals. In most other patients, prognosis for
recovery is guarded.

Broca’s Aphasia Speech is nonfluent, labored, interrupted by many
word-finding pauses, and usually dysartric. It is impoverished in
function words but enriched in meaning-appropriate nouns and verbs.
Abnormal word order and the inappropriate deployment of bound mor-
phemes (word endings used to denote tenses, possessives, or plural)
lead to a characteristic agrammatism. Speech is telegraphic and pithy
but quite informative. In the following passage, a patient with Broca’s
aphasia describes his medical history: “I see . . . the dotor, dotor sent
me . . . Bosson. Go to hospital. Dotor . . . kept me beside. Two,
tee days, doctor send me home.”

Output may be reduced to a grunt or single word (“yes” or “no”),
which is emitted with different intonations in an attempt to express
approval or disapproval. In addition to fluency, naming and repetition
are also impaired. Comprehension of spoken language is intact, except
for syntactically difficult sentences with passive voice structure or em-
bedded clauses. Reading comprehension is also preserved, with the
occasional exception of a specific inability to read small grammatical
words such as conjunctions and pronouns. The last two features indi-
cate that Broca’s aphasia is not just an “expressive” or “motor” dis-
order and that it may also involve a comprehension deficit for function
words and syntax. Patients with Broca’s aphasia can be tearful, easily
frustrated, and profoundly depressed. Insight into their condition is
preserved, in contrast to Wernicke’s aphasia. Even when spontaneous
speech is severely dysarthric, the patient may be able to display a
relatively normal articulation of words when singing. This dissociation
has been used to develop specific therapeutic approaches (melodic
intonation therapy) for Broca’s aphasia. Additional neurologic deficits
usually include right facial weakness, hemiparesis or hemiplegia, and
a buccofacial apraxia characterized by an inability to carry out motor
commands involving oropharyngeal and facial musculature (e.g., pa-
tients are unable to demonstrate how to blow out a match or suck
through a straw). Visual fields are intact. The cause is most often
infarction of Broca’s area (the inferior frontal convolution; “B” in Fig.
23-1) and surrounding anterior perisylvian and insular cortex, due to
occlusion of the superior division of the middle cerebral artery (Chap.
349). Mass lesions including tumor, intracerebral hemorrhage, or ab-
scess may also be responsible. Small lesions confined to the posterior
part of Broca’s area may lead to a nonaphasic and often reversible
deficit of speech articulation, usually accompanied by mild right facial
weakness. When the cause of Broca’s aphasia is stroke, recovery of
language function generally peaks within 2 to 6 months, after which
time further progress is limited.

Global Aphasia Speech output is nonfluent, and comprehension of
spoken language is severely impaired. Naming, repetition, reading,
and writing are also impaired. This syndrome represents the combined
dys-
function of Broca’s and Wernicke’s areas and usually results from
strokes that involve the entire middle cerebral artery distribution in the
left hemisphere. Most patients are initially mute or say a few words,
such as “hi” or “yes.” Related signs include right hemiplegia, hemi-
sensory loss, and homonymous hemianopia. Occasionally, a patient
with a lesion in Wernicke’s area will present with a global aphasia that
soon resolves into Wernicke’s aphasia.

Conduction Aphasia Speech output is fluent but paraphrastic, comprehen-
sion of spoken language is intact, and repetition is severely impaired.
Naming and writing are also impaired. Reading aloud is impaired, but
reading comprehension is preserved. The lesion sites spare Broca’s
and Wernicke’s areas but may induce a functional disconnection be-
tween the two so that neural word representations formed in
Wernicke’s area and adjacent regions cannot be conveyed to Broca’s
area for assembly into corresponding articulatory patterns. Occasion-
ally, a Wernicke’s area lesion gives rise to a transient Wernicke’s
aphasia that rapidly resolves into a conduction aphasia. The paraphasic
output in conduction aphasia interferes with the ability to express
meaning, but this deficit is not nearly as severe as the one displayed
by patients with Wernicke’s aphasia. Associated neurologic signs in
conduction aphasia vary according to the primary lesion site.

Nonfluent Transcortical Aphasia (Transcortical Motor Aphasia) The features
are similar to those of Wernicke’s aphasia, but repetition is intact and agrammatism
may be less pronounced. The neurologic examination may be other-
wise intact, but a right hemiparesis can also exist. The lesion site
disconnects the intact language network from prefrontal areas of the
brain and usually involves the anterior watershed zone between ante-
rior and middle cerebral artery territories or the supplementary motor
cortex in the territory of the anterior cerebral artery.

 Fluent Transcortical Aphasia (Transcortical Sensory Aphasia) Clinical fea-
tures are similar to those of Wernicke’s aphasia, but repetition is intact.
The lesion site disconnects the intact core of the language network
from other temporoparietal association areas. Associated neurologic
findings may include hemianopia. Cerebrovascular lesions (e.g., in-
farctions in the posterior watershed zone) or neoplasms that involve
the temporoparietal cortex posterior to Wernicke’s area are the most
common causes.

Isolation Aphasia This rare syndrome represents a combination of the
two transcortical aphasias. Comprehension is severely impaired, and
there is no purposeful speech output. The patient may parrot fragments
of heard conversations (echolalia), indicating that the neural mecha-
nisms for repetition are at least partially intact. This condition repre-
sents the pathologic function of the language network when it is iso-
lated from other regions of the brain. Broca’s and Wernicke’s areas
tend to be spared, but there is damage to the surrounding frontal, pa-
rietal, and temporal cortex. Lesions are patchy and can be associated
with anoxia, carbon monoxide poisoning, or complete watershed zone
infarctions.
Anomnic Aphasia This form of aphasia may be considered the “minimal dysfunction” syndrome of the language network. Articulation, comprehension, and repetition are intact, but confrontation naming, word finding, and spelling are impaired. Speech is enriched in function words but impoverished in substantive nouns and verbs denoting specific actions. Language output is fluent but paraphasic, circumlocutory, and uninformative. The lesion sites can be anywhere within the left hemisphere language network, including the middle and inferior temporal gyri. Anomic aphasia is the single most common language disturbance seen in head trauma, metabolic encephalopathy, and Alzheimer’s disease. The language impairment of Alzheimer’s disease almost always leads to fluent aphasias (e.g., anomic, Wernicke’s, con- 
temporary language disturbance). The insidious onset and relentless progression of nonfluent language disturbances (Broca’s or nonfluent transcortical aphasia) can be seen in primary progressive aphasia, a degenerative syndrome most commonly associated with focal nonspecific neuronal loss or Pick’s disease.

Pure Word Deafness This is not a true aphasic syndrome because the language deficit is modality-specific. The most common lesions are either bilateral or left-sided in the superior temporal gyrus. The net effect of the underlying lesion is to interrupt the flow of information from the unimodal auditory association cortex to Wernicke’s area. Patients have no difficulty understanding written language and can express themselves well in spoken or written language. They have no difficulty interpreting and reacting to environmental sounds since primary auditory cortex and subcortical auditory relays are intact. Since auditory information cannot be conveyed to the language network, however, it cannot be decoded into neural word representations and the patient reacts to speech as if it were in an alien tongue that cannot be deciphered. Patients cannot repeat spoken language but have no difficulty naming objects. In time, patients with pure word deafness teach themselves lip reading and may appear to have improved. There may be no additional neurologic findings, but agitated paranoid reactions are frequent in the acute stages. Cerebrovascular lesions are the most frequent cause.

Pure Alexia without Agraphia This is the visual equivalent of pure word deafness. The lesions (usually a combination of damage to the left occipital cortex and to a posterior sector of the corpus callosum—the splenium) interrupt the flow of visual input into the language network. There is usually a right hemianopia, but the core language network remains unaffected. The patient can understand and produce spoken language, name objects in the left visual hemifield, repeat, and write. However, the patient acts as if illiterate when asked to read even the simplest sentence because the visual information from the written words (presented to the intact left visual hemifield) cannot reach the language network. Objects in the left hemifield may be named accurately because they activate nonvisual associations in the right hemisphere, which, in turn, can access the language network through transcortical pathways anterior to the splenium. Patients with this syndrome may also lose the ability to name colors, although they can match colors. This is known as a color anomia. The most common etiology of pure alexia is a vascular lesion in the territory of the posterior cerebral artery or an infiltrating neoplasm in the left occipital cortex that involves the optic radiations as well as the crossing fibers of the splenium. Since the posterior cerebral artery also supplies medial temporal components of the limbic system, the patient with pure alexia may also experience an amnesia, but this is usually transient because the limbic lesion is unilateral.

Aphasia There is an acute onset of severely impaired fluency (often mutism), which cannot be accounted for by corticobulbar, cerebellar, or extrapyramidal dysfunction. Recovery is the rule and involves an intermediate stage of hoarse whispering. Writing, reading, and comprehension are intact, so this is not a true aphasic syndrome. Partial lesions of Broca’s area or subcortical lesions that undercut its connections with other parts of the brain may be present. Occasionally, the lesion site is on the medial aspects of the frontal lobes and may involve the supplementary motor cortex of the left hemisphere.

Apraxia This generic term designates a complex motor deficit that cannot be attributed to pyramidal, extrapyramidal, cerebellar, or sensory dysfunction and that does not arise from the patient’s failure to understand the nature of the task. The form that is most frequently encountered in clinical practice is known as ideomotor apraxia. Commands to perform a specific motor act (“cough,” “blow out a match”) or to pantomime the use of a common tool (a comb, hammer, straw, or toothbrush) in the absence of the real object cannot be followed. The patient’s ability to comprehend the command is ascertained by demonstrating multiple movements and establishing that the correct one can be recognized. Some patients with this type of apraxia can imitate the appropriate movement (when it is demonstrated by the examiner) and show no impairment when handed the real object, indicating that the sensorimotor mechanisms necessary for the movement are intact. Some forms of ideomotor apraxia represent a disconnection of the language network from pyramidal motor systems; commands to execute complex movements are understood but cannot be conveyed to the appropriate motor areas, even though the relevant motor mechanisms are intact. Buccofacial apraxia involves apraxic deficits in movements of the face and mouth. Limb apraxia encompasses apraxic deficits in movements of the arms and legs. Ideomotor apraxia is almost always caused by lesions in the left hemisphere and is commonly associated with aphasic syndromes, especially Broca’s aphasia and conduction aphasia. Its presence cannot be ascertained in patients with language comprehension deficits. The ability to follow commands aimed at axial musculature (“close the eyes,” “stand up”) is subserved by different pathways and may be intact in otherwise severely aphasic and apraxic patients. Patients with lesions of the anterior corpus callosum can display a special type of ideomotor apraxia confined to the left side of the body. Since the handling of real objects is not impaired, ideomotor apraxia, by itself, causes no major limitation of daily living activities.

Ideational apraxia refers to a deficit in the execution of a goal-directed sequence of movements in patients who have no difficulty executing the individual components of the sequence. For example, when asked to pick up a pen and write, the sequence of uncapping the pen, placing the cap at the opposite end, turning the point towards the writing surface, and writing may be disrupted, and the patient may be seen trying to write with the wrong end of the pen or even with the removed cap. These motor sequencing problems are usually seen in the context of confusional states and dementias rather than focal lesions associated with aphasic conditions. Limbic-kinetic apraxia involves a clumsiness in the actual use of tools that cannot be attributed to sensory, pyramidal, extrapyramidal, or cerebellar dysfunction. This condition can emerge in the context of focal premotor cortex lesions or corticobasal ganglionic degeneration.

Gerstmann’s Syndrome The combination of acalculia (impairment of simple arithmetic), dysgraphia (impaired writing), finger anomaia (an inability to name individual fingers such as the index or thumb), and right-left confusion (an inability to tell whether a hand, foot, or arm of the patient or examiner is on the right or left side of the body) is known as Gerstmann’s syndrome. In making this diagnosis it is important to establish that the finger and left-right naming deficits are not part of a more generalized anomaia and that the patient is not otherwise aphasic. When Gerstmann’s syndrome is seen in isolation, it is commonly associated with damage to the inferior parietal lobule (especially the angular gyrus) in the left hemisphere.

Aprosodia Variations of melodic stress and intonation influence the meaning and impact of spoken language. For example, the two statements “He is clever,” and “He is clever?” contain an identical word choice and syntax but convey vastly different messages because of differences in the intonation and stress with which the statements are uttered. This aspect of language is known as prosody. Damage to perisylvian areas in the right hemisphere can interfere with speech prosody and can lead to syndromes of aprosodia. Damage to right hemisphere
regions corresponding to Wernicke’s area can selectively impair decoding of speech prosody, whereas damage to right hemisphere regions corresponding to Broca’s area yields a greater impairment in the ability to introduce meaning-appropriate prosody into spoken language. The latter deficit is the most common type of aprosodia identified in clinical practice—the patient produces grammatically correct language with accurate word choice but the statements are uttered in a monotone that interferes with the ability to convey the intended stress and affect. Patients with this type of aprosodia give the mistaken impression of being depressed or indifferent.

**Subcortical Aphasia** Damage to subcortical components of the language network (e.g., the striatum and thalamus of the left hemisphere) can also lead to aphasia. The resulting syndromes contain combinations of deficits in the various aspects of language but rarely fit the specific patterns described in Table 23-1. An atomic aphasia accompanied by dysarthria or a fluent aphasia with hemiparesis should raise the suspicion of a subcortical lesion site.

**THE PARietoFRONTAL NETWORK FOR SPATIAL ORIENTATION: NEGLECT AND RELATED CONDITIONS**

**HEMISPATIAL NEGLECT** Adaptive orientation to significant events within the extrapersonal space is subserved by a large-scale network containing three major cortical components. The cingulate cortex provides access to a limbic-motivational mapping of the extrapersonal space, the posterior parietal cortex to a sensorimotor representation of salient extrapersonal events, and the frontal eye fields to motor strategies for attentional behaviors (Fig. 23-2). Subcortical components of this network include the striatum and the thalamus. Contrallesional hemispatial neglect represents one outcome of damage to any of the cortical or subcortical components of this network. The traditional view that hemispatial neglect always denotes a parietal lobe lesion is inaccurate. In keeping with this anatomic organization, the clinical manifestations of neglect display three behavioral components: sensory events (or their mental representations) within the neglected hemisphere have a lesser impact on overall awareness; there is a paucity of exploratory and orienting acts directed toward the neglected hemispace; and the patient behaves as if the neglected hemispace was motivationally devalued.

According to one model of spatial cognition, the right hemisphere directs attention within the entire extrapersonal space, whereas the left hemisphere directs attention mostly within the contralateral right hemispace. Consequently, unilateral left hemisphere lesions do not give rise to much contralesional neglect since the ipsilateral attentional mechanisms of the right hemisphere can compensate for the loss of the contralaterally directed attentional functions of the left hemisphere. Unilateral right hemisphere lesions, however, give rise to severe contralesional left hemispatial neglect because the unaffected left hemisphere does not contain ipsilateral attentional mechanisms. This model is consistent with clinical experience, which shows that contralesional neglect is more common, severe, and lasting after damage to the right hemisphere than after damage to the left hemisphere. Severe neglect for the right hemisphere is rare, even in left handers with left hemisphere lesions.

Patients with severe neglect may fail to dress, shave, or groom the left side of the body; may fail to eat food placed on the left side of the tray; and may fail to read the left half of sentences. When the examiner draws a large circle [12 to 15 cm (5 to 6 in.) in diameter] and asks the patient to place the numbers 1 to 12 as if the circle represented the face of a clock, there is a tendency to crowd the numbers on the right side and leave the left side empty. When asked to copy a simple line drawing, the patient fails to copy detail on the left; and when asked to write, there is a tendency to leave an unusually wide margin on the left.

Two bedside tests that are useful in assessing neglect are simultaneous bilateral stimulation and visual target cancellation. In the former, the examiner provides either unilateral or simultaneous bilateral stimulation in the visual, auditory, and tactile modalities. Following right hemisphere injury, patients who have no difficulty detecting unilateral stimuli on either side experience the bilaterally presented stimulus as coming only from the right. This phenomenon is known as extinction and is a manifestation of the sensory-representational aspect of hemispatial neglect. In the target detection task, targets (e.g., As) are interspersed with foils (e.g., other letters of the alphabet) on a 21.5 to 28.0 cm (8.5 to 11 in.) sheet of paper and the patient is asked to circle all the targets. A failure to detect targets on the left is a manifestation of the exploratory deficit in hemispatial neglect (Fig. 23-3A). Hemianopia, by itself, does not interfere with performance in this task since the patient is free to turn the head and eyes to the left. The normal tendency in target detection tasks is to start from the left upper quadrant and move systematically in horizontal or vertical sweeps. Some patients show a tendency to start the process from the right and proceed in a haphazard fashion. This represents a subtle manifestation of left neglect, even if the patient eventually manages to detect all the appropriate targets. Some patients with neglect may also deny the existence of hemiparesis and may even deny ownership of the paralyzed limb, a condition known as anosognosia.

Cerebrovascular lesions and neoplasms in the right hemisphere are the most common causes of hemispatial neglect. Depending on the site of the lesion, the patient with neglect may also have hemiparesis, hemihypesthesia, and hemianopia on the left, but these are not invariant findings. The majority of patients display considerable improvement of hemispatial neglect, usually within the first several weeks.

**BÁLINT’S SYNDROME, SIMULTANAGNOSIA, DRESSING APRAXIA, AND CONSTRUCTION APRAXIA** Bilateral involvement of the network for spatial attention, especially its parietal components, leads to a state of severe spatial disorientation known as Bálint’s syndrome. Bálint’s syndrome involves deficits in the orderly visuomotor scanning of the environment (ocularmotor apraxia) and in accurate manual reaching toward visual targets (optic ataxia). The third and most dramatic component of Bálint’s syndrome is known as simultanagnosia and reflects an
inability to integrate visual information in the center of gaze with more peripheral information. The patient gets stuck on the detail that falls in the center of gaze without attempting to scan the visual environment for additional information. The patient with simultanagnosia “misses the forest for the trees.” Complex visual scenes cannot be grasped in their entirety, leading to severe limitations in the visual identification of objects and scenes. For example, a patient who is shown a table and then asked to name the object may look at its circular base and ignore the larger ones. This is a manifestation of simultanagnosia.

A modification of the letter cancellation task described above can be used for the bedside diagnosis of simultanagnosia. In this modification, some of the targets (e.g., As) are made to be much larger than the others [7.5 to 10 cm vs 2.5 cm (3 to 4 in. vs 1 in.) in height], and all targets are embedded among foils. Patients with simultanagnosia display a counterintuitive but characteristic tendency to miss the larger targets (Fig. 23-3B). This occurs because the information needed for the identification of the larger targets cannot be confined to the immediate line of gaze and requires the integration of visual information across a more extensive field of view. The greater difficulty in the detection of the larger targets also indicates that poor acuity is not responsible for the impairment of visual function and that the problem is central rather than peripheral. Bálint’s syndrome results from bilateral dorsal parietal lesions; common settings include watershed infarction between the middle and posterior cerebral artery territories, hypoglycemia, sagittal sinus thrombosis, or atypical forms of Alzheimer’s disease. In patients with Bálint’s syndrome due to stroke, bilateral visual field defects (usually inferior quadrantanopias) are common.

Another manifestation of bilateral (or right-sided) dorsal parietal lobe lesions is dressing apraxia. The patient with this condition is unable to align the body axis with the axis of the garment and can be seen struggling as he or she holds a coat from its bottom or extends his or her arm into a fold of the garment rather than into its sleeve. Lesions that involve the posterior parietal cortex also lead to severe difficulties in copying simple line drawings. This is known as a construction apraxia and is much more severe if the lesion is in the right hemisphere. In some patients with right hemisphere lesions, the drawing difficulties are confined to the left side of the figure and represent a manifestation of hemispatial neglect; in others, there is a more universal deficit in reproducing contours and three-dimensional perspective. Dressing apraxia and construction apraxia represent special instances of a more general disturbance in spatial orientation.

**THE OCCIPITOTEMPORAL NETWORK FOR FACE AND OBJECT RECOGNITION: PROSOPAGNOSIA AND OBJECT AGNOSIA**

Perceptual information about faces and objects is initially encoded in primary (striate) visual cortex and adjacent (upstream) peristriate visual association areas. This information is subsequently relayed first to the downstream visual association areas of occipitotemporal cortex and then to other heteromodal and paralimbic areas of the cerebral cortex. Bilateral lesions in the fusiform and lingual gyri of occipitotemporal cortex disrupt this process and interfere with the ability of otherwise intact perceptual information to activate the distributed multimodal associations that lead to the recognition of faces and objects. The resultant face and object recognition deficits are known as prosopagnosia and visual object agnosia.

The patient with prosopagnosia cannot recognize familiar faces, including, sometimes, the reflection of his or her own face in the mirror. This is not a perceptual deficit since prosopagnosic patients can easily tell if two faces are identical or not. Furthermore, a prosopagnosic patient who cannot recognize a familiar face by visual inspection alone can use auditory cues to reach appropriate recognition if allowed to listen to the person’s voice. The deficit in prosopagnosia is therefore modality-specific and reflects the existence of a lesion that prevents the activation of otherwise intact multimodal templates by relevant visual input. Damasio has pointed out that the deficit in prosopagnosia
is not limited to the recognition of faces but that it can also extend to
the recognition of individual members of larger generic object groups.
For example, prosopagnosic patients characteristically have no diffi-
culty with the generic identification of a face as a face or of a car as
a car, but they cannot recognize the identity of an individual face or
the make of an individual car. This reflects a visual recognition deficit
for proprietary features that characterize individual members of an
object class. When recognition problems become more generalized and
extend to the generic identification of common objects, the condition
is known as visual object agnosia. In contrast to prosopagnosic pa-
tients, those with object agnosia cannot recognize a face as a face or
a car as a car.

It is important to distinguish visual object agnosia from anomia.
The patient with anomia cannot name the object but can describe its
use. In contrast, the patient with visual agnosia is unable either to name
a visually presented object or to describe its use. The characteristic
lesions in prosopagnosia and visual object agnosia consist of bilateral
infarctions in the territory of the posterior cerebral arteries. Associated
deficits can include visual field defects (especially superior quadrant-
anopias) or a centrally based color blindness known as achromatopsia.
Rarely, the responsible lesion is unilateral. In such cases, prosopag-
nosia is associated with lesions in the right hemisphere and object
agnosia with lesions in the left.

THE LIMBIC NETWORK FOR MEMORY: AMNESIAS

Limbic and paralimbic areas (such as the hippocampus, amygdala, and
entorhinal cortex), the anterior and medial nuclei of the thalamus, the
medial and basal parts of the striatum, and the hypothalamus collect-
vively constitute a distributed network known as the limbic system (see
Fig. 350-1). The behavioral affiliations of this network include the
coordination of emotion, motivation, autonomic tone, and endocrine
function. An additional area of specialization for the limbic network,
and the one which is of most relevance to clinical practice, is that of
declarative (conscious) memory for recent episodes and experiences.
A disturbance in this function is known as an amnestic state. In
the absence of deficits in motivation, attention, language, or visuospatial
function, the clinical diagnosis of a persistent global amnestic state is
always associated with bilateral damage to the limbic network, usually
within the hippocampal-entorhinal complex or the thalamus.

Although the limbic network is the site of damage for amnestic states,
it is almost certainly not the storage site for memories. Mem-
ories are stored in widely distributed form throughout the cerebral
cortex. The role attributed to the limbic network is to bind these
distributed fragments into coherent events and experiences that can
sustain conscious recall. Damage to the limbic network does not nec-
essarily destroy memories but interferes with their conscious (declar-
ative) recall in coherent form. The individual fragments of information
remain preserved despite the limbic lesions and can sustain what is
known as implicit memory. For example, patients with amnestic states
can acquire new motor or perceptual skills, even though they may have
no conscious knowledge of the experiences that led to the acquisition
of these skills.

The memory disturbance in the amnestic state is multimodal and
includes retrograde and anterograde components. The retrograde am-
nesia involves an inability to recall experiences that occurred before
the onset of the amnestic state. Relatively recent events are more vul-
nerable to retrograde amnesia than more remote and more extensively
consolidated events. A patient who comes to the emergency room
complaining that he cannot remember his identity but who can re-
member the events of the previous day is almost certainly not suffering
from a neurologic cause of memory disturbance. The second and most
important component of the amnestic state is the anterograde amnesia,
which indicates an inability to store, retain, and recall new knowledge.

Patients with amnestic states cannot remember what they ate a few
minutes ago or the details of an important event they may have ex-
perienced a few hours ago. In the acute stages, there may also be a
tendency to fill in memory gaps with inaccurate, fabricated, and often
implausible information. This is known as confabulation. Patients with
the amnestic syndrome forget that they forget and tend to deny the
existence of a memory problem when questioned.

The patient with an amnestic state is almost always disoriented,
especially to time. Accurate temporal orientation and accurate knowl-
dge of current news rule out a major amnestic state. The anterograde
component of an amnestic state can be tested with a list of four to five
words read aloud by the examiner up to five times or until the patient
can immediately repeat the entire list without intervening delay. In
the next phase of testing, the patient is allowed to concentrate on the
words and to rehearse them internally for at least 1 min. The final phase of the testing involves a retention period of
5 to 10 min, during which the patient is engaged in other tasks.

Adequate recall at the end of this interval requires offline storage,
retention, and retrieval. Amnestic patients fail this phase of the task
and may even forget that they were given a list of words to remember.
Accurate recognition of the words by multiple choice in a patient who
cannot recall them indicates a less severe memory disturbance that
affects mostly the retrieval stage of memory. The retrograde compo-
nent of an amnesia can be assessed with questions related to autobi-
ographical or historical events. The anterograde component of amnestic
states is usually much more prominent than the retrograde component.

In rare instances, usually associated with temporal lobe epilepsy or
benzodiazepine intake, the retrograde component may dominate.

The assessment of memory can be quite challenging. Bedside eval-
uations may only detect the most severe impairments. Less severe
memory impairments, as in the case of patients with temporal lobe
epilepsy, mild head injury or early dementia, require quantitative eval-
uations by neuropsychologists. Confusional states caused by toxic-
metabolic encephalopathies and some types of frontal lobe damage
interfere with attentional capacity and lead to secondary memory im-
pairments, even in the absence of any limbic lesions. This sort of
memory impairment can be differentiated from the amnestic state by
the presence of additional impairments in the attention-related tasks
described below in the section on the frontal lobes.

Many neurologic diseases can give rise to an amnestic state. These
include tumors (of the sphenoid wing, posterior corpus callosum, thal-
amus, or medial temporal lobe), infarctions (in the territories of
the anterior or posterior cerebral arteries), head trauma, herpes simplex
encephalitis, Wernicke-Korsakoff encephalopathy, paraneoplastic lim-
bic encephalitis, and degenerative dementias such as Alzheimer’s or
Pick’s disease. The one common denominator of all these diseases is
that they lead to the bilateral lesions within one or more components
in the limbic network, most commonly the hippocampus, entorhinal
cortex, the mammillary bodies of the hypothalamus, and the limbic
thalamus. Occasionally, unilateral left-sided lesions can give rise to an
amnestic state, but the memory disorder tends to be transient. De-
pending on the nature and distribution of the underlying neurologic
disease, the patient may also have visual field deficits, eye movement
limitations, or cerebellar findings.

Transient global amnesia is a distinctive syndrome usually seen in
late middle age. Patients become acutely disoriented and repeatedly
ask who they are, where they are, what they are doing. The spell is
characterized by anterograde amnesia (inability to retain new infor-
mation) and a retrograde amnesia for relatively recent events that oc-
curred before the onset. The syndrome usually resolves within 24 to
48 h and is followed by the filling-in of the period affected by the
retrograde amnesia, although there is persistent loss of memory for the
events that occurred during the ictus. Recurrences are noted in ap-
proximately 20% of patients. Migraine, temporal lobe seizures, and
transient ischemic events in the posterior cerebral territory have been
postulated as causes of transient global amnesia. The absence of as-
associated neurologic findings may occasionally lead to the incorrect
diagnosis of a psychiatric disorder.
THE PREFRONTAL NETWORK FOR ATTENTION AND BEHAVIOR

Approximately one-third of all the cerebral cortex in the human brain is located in the frontal lobes. The frontal lobes can be subdivided into motor-premotor, dorsolateral prefrontal, medial prefrontal, and orbitofrontal components. The terms frontal lobe syndrome and prefrontal cortex refer only to the last three of these four components. These are the parts of the cerebral cortex that show the greatest phylogenetic expansion in primates and especially in humans. The dorsolateral prefrontal, medial prefrontal, and orbitofrontal areas, and the subcortical structures with which they are interconnected (i.e., the head of the caudate and the dorsomedial nucleus of the thalamus), collectively make up a large-scale network that coordinates exceedingly complex aspects of human cognition and behavior.

The prefrontal network plays an important role in behaviors that require an integration of thought with emotion and motivation. There is no simple formula for summarizing the diverse functional affiliations of the prefrontal network. Its integrity appears important for the simultaneous awareness of context, options, consequences, relevance, and emotional impact so as to allow the formulation of adaptive inferences, decisions, and actions. Damage to this part of the brain impairs mental flexibility, reasoning, hypothesis formation, abstract thinking, foresight, judgment, the online (attentive) holding of information, and the ability to inhibit inappropriate responses. Behaviors impaired by prefrontal cortex lesions, especially those related to the manipulation of mental content, are often referred to as “executive functions.”

Even very large bilateral prefrontal lesions may leave all sensory, motor, and basic cognitive functions intact while leading to isolated but dramatic alterations of personality and behavior. The most common clinical manifestations of damage to the prefrontal network take the form of two relatively distinct syndromes. In the frontal abulic syndrome, the patient shows a loss of initiative, creativity, and curiosity and displays a pervasive emotional blandness and apathy. In the frontal disinhibition syndrome, the patient becomes socially disinhibited and shows severe impairments of judgment, insight, and foresight. The dissociation between intact intellectual function and a total lack of even rudimentary common sense is striking. Despite the preservation of all essential memory functions, the patient cannot learn from experience and continues to display inappropriate behaviors without appearing to feel emotional pain, guilt, or regret when such behaviors repeatedly lead to disastrous consequences. The impairments may emerge only in real-life situations when behavior is under minimal external control and may not be apparent within the structured environment of the medical office. Testing judgment by asking patients what they would do if they detected a fire in a theater or found a stamped and addressed envelope on the road is not very informative since patients who answer these questions wisely in the office may still act very foolishly in the more complex real-life setting. The physician must therefore be prepared to make a diagnosis of frontal lobe disease on the basis of historic information alone even when the office examination of mental state may be quite intact.

The abulic syndrome tends to be associated with damage to the dorsolateral prefrontal cortex, and the disinhibition syndrome with the medial prefrontal or orbitofrontal cortex. These syndromes tend to arise almost exclusively after bilateral lesions, most frequently in the setting of head trauma, stroke, ruptured aneurysms, hydrocephalus, tumors (including metastaases, glioblastoma, and falx or olfactory groove meningiomas), or focal degenerative diseases. Unilateral lesions confined to the prefrontal cortex may remain silent until the pathology spreads to the other side. The emergence of developmentally primitive reflexes, also known as frontal release signs, such as grasping (elicited by stroking the palm) and sucking (elicited by stroking the lips) are seen primarily in patients with large structural lesions that extend into the premotor components of the frontal lobes or in the context of metabolic encephalopathies. The vast majority of patients with prefrontal lesions and frontal lobe behavioral syndromes do not display these reflexes.

Damage to the frontal lobe disrupts a variety of attention-related functions including working memory (the transient online holding of information), concentration span, the scanning and retrieval of stored information, the inhibition of immediate but inappropriate responses, and mental flexibility. The capacity for focusing on a trend of thought and the ability to voluntarily shift the focus of attention from one thought or stimulus to another can become impaired. Digit span (which should be seven forward and five reverse) is decreased; the recitation of the months of the year in reverse order (which should take less than 15 s) is slowed; and the fluency in producing words starting with a, f, or s that can be generated in 1 min (normally 12 or more per letter) is diminished even in nonaphasic patients. Characteristically, there is a progressive slowing of performance as the task proceeds; e.g., the patient asked to count backwards by 3s may say “100, 97, 94, . . . 91, . . . 88,” etc., and may not complete the task. In “go–no-go” tasks (where the instruction is to raise the finger upon hearing one tap but to keep it still upon hearing two taps), the patient shows a characteristic inability to keep still in response to the “no go” stimulus; mental flexibility (tested by the ability to shift from one criterion to another in sorting or matching tasks) is impoverished; distractibility by irrelevant stimuli is increased; and there is a pronounced tendency for impersistence and perseveration.

These attentional deficits disrupt the orderly registration and retrieval of new information and lead to secondary memory deficits. Such memory deficits can be differentiated from the primary memory impairments of the amnestic state by showing that they improve when the attentional load of the task is decreased. Working memory (also known as immediate memory) is an attentional function based on the temporary online holding of information. It is closely associated with the integrity of the prefrontal network and the ascending reticular activating system. Retentive memory, on the other hand, depends on the stable (offline) storage of information and is associated with the integrity of the limbic network. The distinction of the underlying neural mechanisms is illustrated by the observation that severely amnestic patients who cannot remember events that occurred a few minutes ago may have intact if not superior working memory capacity as shown in tests of digit span.

Lesions in the caudate nucleus or in the dorsomedial nucleus of the thalamus (subcortical components of the prefrontal network) can also produce a frontal lobe syndrome. This is one reason why the mental state changes associated with degenerative basal ganglia diseases, such as Parkinson’s or Huntington’s disease, may take the form of a frontal lobe syndrome. Because of its widespread connections with other regions of association cortex, one essential computational role of the prefrontal network is to function as an integrator, or “orchestrator,” for other networks. Bilateral multifocal lesions of the cerebral hemispheres, none of which are individually large enough to cause specific cognitive deficits such as aphasia or neglect, can collectively interfere with the connectivity and integrating function of prefrontal cortex. A frontal lobe syndrome is the single most common behavioral profile associated with a variety of bilateral multilobar brain diseases including metabolic encephalopathy, multiple sclerosis, vitamin B12 deficiency, and others. In fact, the vast majority of patients with the clinical diagnosis of a frontal lobe syndrome tend to have lesions that do not involve prefrontal cortex but involve either the subcortical components of the prefrontal network or its connections with other parts of the brain. In order to avoid making a diagnosis of “frontal lobe syndrome” in a patient with no evidence of frontal cortex disease, it is advisable to use the diagnostic term frontal network syndrome, with the understanding that the responsible lesions can lie anywhere within this distributed network.

The patient with frontal lobe disease raises potential dilemmas in differential diagnosis: the abulia and blandness may be misinterpreted as depression, and the disinhibition as idiopathic mania or acting-out. Appropriate intervention may be delayed while a treatable tumor keeps...
expanding. An informed approach to frontal lobe disease and its behavioral manifestations may help to avoid such errors.

**CARING FOR THE PATIENT WITH DEFICITS OF HIGHER CEREBRAL FUNCTION**

Some of the deficits described in this chapter are so complex that they may bewilder not only the patient and family but also the physician. It is imperative to carry out a systematic clinical evaluation in order to characterize the nature of the deficits and explain them in lay terms to the patient and family. Such an explanation can allay at least some of the anxieties, address the mistaken impression that the deficit (e.g., social disinhibition or inability to recognize family members) is psychologically motivated, and lead to practical suggestions for daily living activities. The consultation of a skilled neuropsychologist may aid in the formulation of diagnosis and management. Patients with simultanagnosia, for example, may benefit from the counterintuitive instruction to stand back when they cannot find an item so that a greater search area falls within the immediate field of gaze. Some patients with frontal lobe disease can be extremely irritable and abusive to spouses and yet display all the appropriate social graces during the visit to the medical office. In such cases, the history may be more important than the bedside examination in charting a course of treatment.

Reactive depression is common in patients with higher cerebral dysfunction and should be treated. These patients may be sensitive to the usual doses of antidepressants or anxiolytics and deserve a careful titration of dosage. Brain damage may cause a dissociation between feeling states and their expression, so that a patient who may superficially appear jocular could still be suffering from an underlying depression that deserves to be treated. In many cases, agitation may be controlled with reassurance. In other cases, treatment with benzodiazepines or sedating antidepressants may become necessary. The use of neuroleptics for the control of agitation should be reserved for refractory cases since extrapyramidal side effects are frequent in patients with coexisting brain damage.

Spontaneous improvement of cognitive deficits due to acute neurologic lesions is common. It is most rapid in the first few weeks but may continue for up to 2 years, especially in young individuals with single brain lesions. The mechanisms for this recovery are incompletely understood. Some of the initial deficits appear to arise from remote dysfunction (diaschisis) in parts of the brain that are interconnected with the site of initial injury. Improvement in these patients may reflect, at least in part, a normalization of the remote dysfunction. Other mechanisms may involve functional reorganization in surviving neurons adjacent to the injury or the compensatory use of homologous structures, e.g., the right superior temporal gyrus with recovery from Wernicke’s aphasia. In some patients with large lesions involving Broca’s and Wernicke’s areas, only Wernicke’s area may show contralateral compensatory reorganization (or bilateral functionality), giving rise to a situation where a lesion that should have caused a global aphasia becomes associated with a residual Broca’s aphasia. Prognosis for recovery from aphasia is best when Wernicke’s area is spared. Cognitive rehabilitation procedures have been used in the treatment of higher cortical deficits. There are few controlled studies, but some do show a benefit of rehabilitation in the recovery from hemispatial neglect and aphasia. Some types of deficits may be more prone to recovery than others. For example, patients with nonfluent aphasias are more likely to benefit from speech therapy than patients with fluent aphasias and comprehension deficits. In general, lesions that lead to a denial of illness (e.g., anosognosia) are associated with cognitive deficits that are more resistant to rehabilitation. The recovery of higher cortical dysfunction is rarely complete. Periodic neuropsychological assessment is necessary for quantifying the pace of the improvement and for generating specific recommendations for cognitive rehabilitation, modifications in the home environment, and the timetable for returning to school or work.

In general medical practice, most patients with deficits in higher cognitive functions will be suffering from dementia. There is a mistaken belief that dementias are anatomically diffuse and that they cause global cognitive impairments. This is only true at the terminal stages. During most of the clinical course, dementias are exquisitely selective with respect to anatomy and cognitive pattern. Alzheimer’s disease, for example, causes the greatest destruction in medial temporal areas belonging to the memory network and is clinically characterized by a correspondingly severe amnesia. There are other dementias where memory is intact. Frontal lobe dementia results from a selective degeneration of the frontal lobe and leads to a gradual dissolution of behavior and complex attention. Primary progressive aphasia is characterized by a gradual atrophy of the left perisylvian language network and leads to a progressive dissolution of language that can remain isolated for up to 10 years. An enlightened approach to the differential diagnosis and treatment of these patients requires an understanding of the principles that link neural networks to higher cerebral functions.

**24 SLEEP DISORDERS**

Charles A. Czeisler, John W. Winkelman, Gary S. Richardson

Disturbed sleep is among the most frequent health complaints physicians encounter. More than one-half of adults in the United States experience at least intermittent sleep disturbances. For most, it is an occasional night of poor sleep or daytime sleepiness. However, at least 15 to 20% of adults report chronic sleep disturbance or misalignment of circadian timing, which can lead to serious impairment of daytime functioning. In addition, such problems may contribute to or exacerbate medical or psychiatric conditions. Thirty years ago, many such complaints were treated with hypnotic medications without further diagnostic evaluation. Since then, a distinct class of sleep and arousal disorders has been identified.

**PHYSIOLOGY OF SLEEP AND WAKEFULNESS**

Most adults sleep 7 to 8 h per night, although the timing, duration, and internal structure of sleep vary among healthy individuals and as a function of age. At the extremes, infants and the elderly have frequent interruptions of sleep. In the United States, adults of intermediate age tend to have one consolidated sleep episode per day, although in some cultures sleep may be divided into a midafternoon nap and a shortened night sleep. Two principal systems govern the sleep-wake cycle: one actively generates sleep and sleep-related processes and another times sleep within the 24-h day. Either intrinsic abnormalities in these sys-
false.

**STATES AND STAGES OF SLEEP** States and stages of human sleep are defined on the basis of characteristic patterns in the electroencephalogram (EEG), the electrooculogram (EOG)—a measure of eye-movement activity—and the surface electromyogram (EMG) measured on the chin and neck. The continuous recording of this array of electrophysiologic parameters to define sleep and wakefulness is termed polysomnography.

Polysomnographic profiles define two states of sleep: (1) rapid-eye-movement (REM) sleep, and (2) non-rapid-eye-movement (NREM) sleep. NREM sleep is further subdivided into four stages, characterized by increasing arousal threshold and slowing of the cortical EEG. REM sleep is characterized by a low-amplitude, mixed-frequency EEG similar to that of NREM stage 1 sleep. The EOG shows bursts of REM similar to those seen during eyes-open wakefulness. Chin EMG activity is absent, reflecting the brainstem-mediated muscle atonia that is characteristic of that state.

**ORGANIZATION OF HUMAN SLEEP** Normal nocturnal sleep in adults displays a consistent organization from night to night (Fig. 24-1). After sleep onset, sleep usually progresses through NREM stages 1 to 4 within 45 to 60 min. Slow-wave sleep (NREM stages 3 and 4) predominates in the first third of the night and comprises 15 to 25% of total nocturnal sleep time in young adults. The percentage of slow-wave sleep is influenced by several factors, most notably age (see below). Prior sleep deprivation increases the rapidity of sleep onset and both the intensity and amount of slow-wave sleep.

The first REM sleep episode usually occurs in the second hour of sleep. More rapid onset of REM sleep in a young adult (particularly if <30 min) may suggest pathology such as endogenous depression, narcolepsy, circadian rhythm disorders, or drug withdrawal. NREM and REM alternate through the night with an average period of 90 to 110 min (the “ultradian” sleep cycle). Overall, REM sleep constitutes 20 to 25% of total sleep, and NREM stages 1 and 2 are 50 to 60%.

Age has a profound impact on sleep state organization (Fig. 24-1). Slow-wave sleep is most intense and prominent during childhood, decreasing sharply at puberty and across the second and third decades of life. After age 30, there is a progressive decline in the amount of slow-wave sleep, and the amplitude of delta EEG activity comprising slow-wave sleep is profoundly reduced. The depth of slow-wave sleep, as measured by the arousal threshold to auditory stimulation, also decreases with age. In the otherwise healthy older person, slow-wave sleep may be completely absent, particularly in males.

A different age profile exists for REM sleep than for slow-wave sleep. In infancy, REM sleep may comprise 50% of total sleep time, and the percentage is inversely proportional to developmental age. The amount of REM sleep falls off sharply over the first postnatal year as a mature REM-NREM cycle develops; thereafter, REM sleep occupies a relatively constant percentage of total sleep time.

**NEUROANATOMY OF SLEEP** Experimental studies in animals have variously implicated the medullary reticular formation, the thalamus, and the basal forebrain in the generation of sleep, while the brainstem reticular formation, the midbrain, the subthalamus, the thalamus, and the basal forebrain have all been suggested to play a role in the generation of wakefulness or EEG arousal.

Current hypotheses suggest that the capacity for sleep and wakefulness generation is distributed along an axial “core” of neurons extending from the brainstem rostrally to the basal forebrain. Complex commingling of neuronal groups occurs at many points along this brainstem—forebrain axis. A cluster of γ-aminobutyric acid (GABA) and galaninergic neurons in the ventrolateral preoptic (VLPO) hypothalamus is selectively activated coincident with sleep onset. These neurons project to and inhibit histaminergic cell groups in the tuberomammillary nucleus that are important to the ascending arousal system, suggesting that the hypothalamic VLPO neurons may play a key executive role in sleep regulation.

Specific regions in the pons are associated with the neurophysiologic correlates of REM sleep. Small lesions in the dorsal pons result in the loss of the descending muscle inhibition normally associated with REM sleep; microinjections of the cholinergic agonist carbachol into the pontine reticular formation appear to produce a state with all of the features of REM sleep. These experimental manipulations are mimicked by pathologic conditions in humans and animals. In narcolepsy, for example, abrupt, complete, or partial paralysis (cataplexy) occurs in response to a variety of stimuli. In dogs with this condition, physostigmine, a central cholinesterase inhibitor, increases the frequency of cataplectic attacks, while atropine decreases their frequency. Conversely, in REM sleep behavior disorder (see below), patients suffer from incomplete motor inhibition during REM sleep, resulting in involuntary, occasionally violent movement during REM sleep.

**NEUROCHEMISTRY OF SLEEP** Early experimental studies that focused on the raphe nuclei of the brainstem appeared to implicate serotonin as the primary sleep-promoting neurotransmitter, while catecholamines were considered to be responsible for wakefulness. Subsequent work has demonstrated that the raphe-serotonergic system may facilitate sleep but is not necessary for its expression. Pharmacologic studies of sleep and wakefulness suggest roles for other neurotransmitters as well. Pontine cholinergic neurotransmission is known to play a role in REM sleep generation. The alerting influence of caffeine implicates adenosine, whereas the hypnotic effect of benzodiazepines and barbiturates suggests a role for endogenous ligands of the GABA<sub>A</sub> receptor complex. A newly characterized neuropeptide, hypocretin (orexin), has recently been implicated in the pathophysiology of narcolepsy (see below), but its role in normal sleep regulation remains to be defined.

A variety of sleep-promoting substances have been identified, although it is not known whether or not they are involved in the endogenous sleep-wake regulatory process. These include prostaglandin D<sub>2</sub>, delta sleep—inducing peptide, muramyl dipeptide, interleukin 1, fatty acid primary amides, and melatonin. The hypnotic effect of these substances is commonly limited to NREM or slow-wave sleep, although peptides that increase REM sleep have also been reported. Many putative “sleep factors,” including interleukin 1 and prostaglandin D<sub>2</sub>, are immunologically active as well, suggesting a link between immune function and sleep-wake states.

**PHYSIOLOGY OF CIRCADIAN RHYTHMICITY** The sleep-wake cycle is the most evident of the many 24-h rhythms in humans. Prominent daily varia-
tions also occur in endocrine, thermoregulatory, cardiac, pulmonary, renal, gastrointestinal, and neurobehavioral functions. At the molecular level, endogenous circadian rhythmicity is driven by self-sustain-
ing transcriptional/translational feedback loops (Fig. 24-2). In evaluating a daily variation in humans, it is important to distinguish between those rhythmic components passively evoked by periodic environmental or behavioral changes (e.g., the increase in blood pressure and heart rate upon assumption of the upright posture) and those ac-

tively driven by an endogenous oscillatory process (e.g., the circadian variation in plasma cortisol that persists under a variety of environ-

mental and behavioral conditions).

While it is now recognized that many peripheral tissues in mam-

mals have circadian clocks that regulate diverse physiologic processes, these independent tissue-specific oscillations are coordinated by a cen-

tral neural pacemaker located in the suprachiasmatic nuclei (SCN) of the hypothalamus. Bilateral destruction of these nuclei results in a loss of the endogenous circadian rhythm of locomotor activity, which can be restored only by transplantation of the same structure from a donor animal. The genetically determined period of this endogenous neural oscillator, which averages ~24.2 h in humans, is normally synchron-

ized to the 24-h period of the environmental light-dark cycle. Small differences in circadian period underlie variations in diurnal prefer-

cence, with the circadian period shorter in morning than in evening types. Entrainment of mammalian circadian rhythms by the light-dark cycle is mediated via the retinohypothalamic tract, a monosynaptic

pathway that links specialized, photoreceptive retinal ganglion cells directly to the SCN. Humans are exquisitely sensitive to the resetting
effects of light, particularly at the blue end (~460 to 480 nm) of the visible spectrum.

The timing and internal architecture of sleep are directly coupled to the output of the endogenous circadian pacemaker. Paradoxically, the endogenous circadian rhythms of sleep tendency, sleepiness, and REM sleep propensity all peak near the habitual wake time, just after the nadir of the endogenous circadian temperature cycle, whereas the circadian wake propensity rhythm peaks 1 to 3 h before the habitual bedtime. These rhythms are thus timed to oppose the homeostatic de-
cline of sleep tendency during the habitual sleep episode and the rise of sleep tendency throughout the usual waking day, respectively. Mis-

alignment of the output of the endogenous circadian pacemaker with the desired sleep-wake cycle can, therefore, induce insomnia, de-

creased alertness, and impaired performance evident in night-shift workers and airline travelers.

**BEHAVIORAL CORRELATES OF SLEEP STATES AND STAGES** Polysomnographic staging of sleep correlates with behavioral changes during specific states and stages. During the transitional state between wakefulness and sleep (stage 1 sleep), subjects may respond to faint auditory or visual signals without “awakening.” Memory incorporation is inhib-

ited at the onset of NREM stage 1 sleep, which may explain why individuals aroused from that transitional sleep stage frequently deny having been asleep. Such transitions may intrude upon behavioral wakefulness after sleep deprivation, notwithstanding attempts to re-

main continuously awake (see “Shift-Work Sleep Disorder,” below).

Awakenings from REM sleep are associated with recall of vivid dream imagery >80% of the time. The reliability of dream recall in-

creases with REM sleep episodes occurring later in the night. Imagery may also be reported after NREM sleep interruptions, though these typically lack the detail and vividness of REM sleep dreams. The in-

cidence of NREM sleep dream recall can be increased by selective REM sleep deprivation, suggesting that REM sleep and dreaming per-

se are not inexorably linked.

**PHYSIOLOGIC CORRELATES OF SLEEP STATES AND STAGES** All major physi-

ologic systems are influenced by sleep. Changes in cardiovascular function include a decrease in blood pressure and heart rate during NREM and particularly during slow-wave sleep. During REM sleep, phasic activity (bursts of eye movements) is associated with variability in both blood pressure and heart rate mediated principally by the vau-

gus. Cardiac dysrhythmias may occur selectively during REM sleep. Respiratory function also changes. In comparison to relaxed wakeful-

ness, respiratory rate becomes more regular during NREM sleep (es-

pecially slow-wave sleep) and tonic REM sleep and becomes very irregular during phasic REM sleep. Minute ventilation decreases in NREM sleep out of proportion to the decrease in metabolic rate at sleep onset, resulting in a higher P_{CO_{2}}.

Endocrine function also varies with sleep. Slow-wave sleep is as-

sociated with secretion of growth hormone, while sleep in general is associated with augmented secretion of prolactin. Sleep has a complex effect on the secretion of luteinizing hormone (LH): during puberty, sleep is associated with increased LH secretion, whereas sleep in the mature woman inhibits LH secretion in the early follicular phase of the menstrual cycle. Sleep onset (and probably slow-wave sleep) is associated with inhibition of thyroid-stimulating hormone and of the adrenocorticotropic hormone–cortisol axis, an effect that is superim-

posed on the prominent circadian rhythms in the two systems.

The pineal hormone melatonin is secreted predominantly at night in both day- and night-active species, reflecting the direct modulation of pineal activity by the circadian pacemaker through a circuital neu-

ral pathway from the SCN to the pineal gland. Melatonin secretion is not dependent upon the occurrence of sleep, persisting in individuals kept awake at night. In addition, exogenous melatonin increases sleep-

iness and may potentiate sleep when administered to good sleepers attempting to sleep during daylight hours at a time when endogenous melatonin levels are low. The efficacy of melatonin as a sleep-promo-

ting therapy for patients with insomnia is currently not known.

Sleep is also accompanied by alterations of thermoregulatory func-

tion. NREM sleep is associated with an attenuation of thermoregu-

latory responses to either heat or cold stress, and animal studies of thermosensitive neurons in the hypothalamus document an NREM-

sleep-dependent reduction of the thermoregulatory set-point. REM sleep is associated with complete absence of thermoregulatory respon-

siveness, effectively resulting in functional poikilothermy. However, the potential adverse impact of this failure of thermoregulation is blunted by inhibition of REM sleep by extreme ambient temperatures.

---

**FIGURE 24-2** Model of the molecular feedback loop at the core of the mammalian circadian clock. The positive element of the feedback loop (+) is the transcriptional activation of the Per1 gene (and probably other clock genes) by a heterodimer of the transcription factors CLOCK and BMAL1 (also called MOP3) bound to an E-box DNA regulatory element. The Per1 transcript and its product, the clock component PER1 protein, accumulate in the cell cytoplasm. As it accumulates, the PER1 protein is re-

activated by inhibiting the activity of the CLOCK-BMAL1 transcription factor heterodimer. As a consequence of this action, the concentration of PER1 and other clock proteins in the inhibitory complex falls, allowing CLOCK-BMAL1 to activate transcription of Per1 and other genes and begin another cycle. The dynamics of the 24-h molecular cycle are controlled at several levels, including regulation of the rate of PER protein degradation by casein kinase-1 epsilon (CK1ε). Additional limbs of this genetic regulatory network, omitted for the sake of clarity, are thought to contribute stability. Question marks denote putative clock proteins, such as Timeless (TIM), as yet lacking genetic proof of a role in the mammalian clock me-

chanism. (Copyright © Charles I. Weitz, Ph.D., Department of Neurobiology, Harvard Medical School.)
DISORDERS OF SLEEP AND WAKEFULNESS

EVALUATION OF INSOMNIA

Insomnia is the complaint of inadequate sleep; it can be classified according to the nature of sleep disruption and the duration of the complaint. Insomnia is subdivided into difficulty falling asleep (sleep onset insomnia), frequent or sustained awakenings (sleep maintenance insomnia), early morning awakenings (sleep offset insomnia), or persistent sleepiness despite sleep of adequate duration (nonrestorative sleep). Similarly, the duration of the symptom influences diagnostic and therapeutic considerations. An insomnia complaint lasting one to several nights (within a single episode) is termed transient insomnia and is typically the result of situational stress or a change in sleep schedule or environment (e.g., jet lag). Short-term insomnia lasts from a few days to 3 weeks. Disruption of this duration is usually associated with more protracted stress, such as recovery from surgery or short-term illness. Long-term insomnia, or chronic insomnia, lasts for months or years and, in contrast with short-term insomnia, requires a thorough evaluation of underlying causes (see below). Chronic insomnia is often a waxing and waning disorder, with spontaneous or stressor-induced exacerbations.

An occasional night of poor sleep, typically in the setting of stress or excitement about external events, is both common and without lasting consequences. However, persistent insomnia can lead to impaired daytime function, injury due to accidents, and the development of major depression. In addition, there is emerging evidence that individuals with chronic insomnia have increased utilization of health care resources, even after controlling for co-morbid medical and psychiatric disorders.

All insomnias can be exacerbated and perpetuated by behaviors that are not conducive to initiating or maintaining sleep. Inadequate sleep hygiene is characterized by a behavior pattern prior to sleep or a bedroom environment that is not conducive to sleep. Noise or light in the bedroom can interfere with sleep, as can a bed partner with periodic limb movements during sleep or one who snores loudly. Clocks can heighten the anxiety about the time it has taken to fall asleep. Drugs that act on the central nervous system, large meals, vigorous exercise, or hot showers just before sleep may interfere with sleep onset. Many individuals participate in stressful work-related activities in the evening, producing a state incompatible with sleep onset. In preference to hypnotic medications, patients should be counseled to avoid stressful activities before bed, develop a soporific bedtime ritual, and to prepare and reserve the bedroom environment for sleeping. Consistent, regular rising times should be maintained daily, including weekends.

Patients may seek help from a physician because of one of several symptoms: (1) an acute or chronic inability to sleep adequately at night (insomnia); (2) chronic fatigue, sleepiness, or tiredness during the day; or (3) a behavioral manifestation associated with sleep itself. Complaints of insomnia or excessive daytime sleepiness should be viewed as symptoms (much like fever or pain) of underlying disorders. Knowledge of the differential diagnosis of these presenting complaints is essential to identify the underlying medical disorder. Only then can appropriate treatment, rather than non-specific approaches (e.g., over-the-counter sleeping aids), be applied. Diagnoses of exclusion, such as primary insomnia, should be made only after other diagnoses have been ruled out. Table 24-1 outlines the diagnostic and therapeutic approach to the patient with a complaint of excessive daytime sleepiness.

A careful history is essential. In particular, the duration, severity, and consistency of the symptoms are important along with the patient’s estimate of the consequences of reported sleep loss on waking function. Information from a friend or family member can be invaluable; some patients may be unaware of, or will underreport, such potentially embarrassing symptoms as heavy snoring or falling asleep while driving.

Completion by the patient of a day-by-day sleep-work-drug log for at least 2 weeks can help the physician better understand the nature of the complaint. Work times and sleep times (including daytime naps and nocturnal awakenings) as well as drug and alcohol use, including caffeine and hypnotics, should be noted each day. In addition, the sleep times should be recorded.

Polysomnography is necessary for the diagnosis of specific disorders such as narcolepsy and sleep apnea and may be of utility in other settings as well. In addition to the three electrophysiologic variables used to define sleep states and stages, the standard clinical polysomnogram includes measures of respiration (respiratory effort, air flow, and oxygen saturation), anterior tibialis EMG, and electrocardiogram. Evaluation of penile tumescence during nocturnal sleep can also help determine whether the cause of erectile dysfunction in a patient is psychogenic or organic (Chap. 43).

(psychophysiolgic insomnia, see below), amplification of the time spent awake (sleep-state misperception), physiologic hyper arousal, and poor sleep hygiene (see above) may all be present. As these processes may be both causes and consequences of chronic insomnia, many individuals will have a progressive course to their symptoms in which the severity is proportional to the chronicity, and much of the complaint may persist even after effective treatment of the initial inciting etiology. Treatment of primary insomnia is often directed to each of the putative contributing factors: behavior therapies for anxiety and negative conditioning (see below), pharmacotherapy for mood/ anxiety disorders, an emphasis on maintenance of good sleep hygiene, and intermittent hypnics for exacerbations of the insomnia.

If insomnia persists after treatment of these contributing factors, empirically pharmacotherapy is often used on a nightly or intermittent basis. A variety of sedative compounds are used for this purpose. Alcohol and antihistamines are the most commonly used nonprescription sleep aids. The former may help with sleep onset, but is associated with sleep disruption during the night and can escalate into abuse, dependence, and withdrawal in the predisposed individual. Antihistamines may be of benefit when used intermittently, but produce rapid tolerance and have multiple side effects (especially anticholinergic), which limit their use. Benzodiazepine receptor agonists are the most effective and well-tolerated class of medications for insomnia. The broad range of half-lives allows flexibility in the duration of sedative action. Zaleplon (5 to 20 mg), with a half-life of 1 to 2 h, zolpidem (5 to 10 mg) and triazolam (0.125 to 0.25 mg), with half-lives of 2 to 3 h, and temazepam (15 to 30 mg) and lorazepam (0.5 to 2 mg), with half-lives of 6 to 12 h, are the most commonly prescribed agents in this family. Generally, side effects are minimal if the dose is kept low and the serum concentration is minimized during the waking hours (by using the shortest-acting, effective agent). However, with even brief continuous use, rebound insomnia can occur upon discontinuation. There are only limited data supporting sustained efficacy of benzodiazepine receptor agonists; caution should be exercised in long-term use. The likelihood of rebound insomnia and tolerance can be minimized by short durations of treatment, intermittent use, or gradual tapering of the dose. For acute insomnia, nightly use of a benzodiazepine receptor agonist for a maximum of 2 to 4 weeks is advisable. For chronic insomnia, intermittent use is recommended. Benzodiazepine receptor agonists should be avoided, or used very judiciously, in patients with a history of substance abuse. The heterocyclic antidepresants (trazodone, amitriptyline, and doxepin) are the most commonly prescribed alternatives to benzodiazepine receptor agonists due to their lack of abuse potential and lower cost. Trazodone (25 to 100 mg) is used more commonly than the tricylic antidepressants as it has a much shorter half-life (5 to 9 h), has much less anticholinergic activity (sparking patients, particularly the elderly, constipation, urinary retention, and tachycardia), is associated with less weight gain, and is much safer in overdose. The risk of priapism is small (~1 in 10,000).

Psychophysiolgic Insomnia Persistent psychophysiolgic insomnia is a behavioral disorder in which patients are preoccupied with a perceived inability to sleep adequately at night. The sleep disturbance is often triggered by an emotionally stressful event; however, the poor sleep habits and beliefs about sleep acquired during the stressful period persist long after the initial incident. Such patients become hyperaroused by their own persistent efforts to sleep or the sleep environment, and the insomnia is a conditioned or learned response. They may be able to fall asleep more easily at unscheduled times (when not trying) or outside the home environment. Polysomnographic recording in patients with psychophysiolgic insomnia reveals an objective sleep disturbance, often with an abnormally long sleep latency; frequent nocturnal awakenings; and an increased amount of stage 1 transitional sleep. Rigorous attention should be paid to sleep hygiene and correction of counterproductive, arousing behaviors before bedtime. Behavioral therapies are the treatment of choice, with only intermittent use of medications. When patients are awake for >20 min, they should read or perform other relaxing activities to distract themselves from insomnia-related anxiety. In addition, bedtime and waketime should be scheduled to restrict time in bed to be equal to their perceived total sleep time. This will generally produce sleep depriva- tion, greater sleep drive, and, eventually, better sleep. Time in bed can then be gradually expanded.

SECONDARY INSOMNIA This typically develops after a change in the sleeping environment (e.g., in an unfamiliar hotel or hospital bed) or before or after a significant life event, such as a change of occupation, loss of a loved one, illness, or anxiety over a deadline or examination. Increased sleep latency, frequent awakenings from sleep, and early morning awakening can all occur. Recovery is generally rapid, usually within a few weeks. Treatment is symptomatic, with intermittent use of hypnotics and resolution of the underlying stress. Altitude insomnia describes a sleep disturbance that is a common consequence of exposure to high altitude. Periodic breathing of the Cheyne-Stokes type occurs during NREM sleep about half the time at high altitude, with restoration of a regular breathing pattern during REM sleep. Both hypoxia and hypocapnia are thought to be involved in the development of periodic breathing. Frequent awakenings and poor quality sleep characterize altitude insomnia, which is generally worse on the first few nights at high altitude but may persist. Treatment with acetazolamide can decrease time spent in periodic breathing and substantially reduce hypoxia during sleep.

Insomnia Associated with Mental Disorders Approximately 80% of patients with psychiatric disorders describe sleep complaints. There is considerable heterogeneity, however, in the nature of the sleep disturbance both between conditions and among patients with the same condition. Depression can be associated with sleep onset insomnia, sleep maintenance insomnia, or early morning wakfulness. However, hypersomnia occurs in some depressed patients, especially adolescents and those with either bipolar or seasonal (fall/winter) depression (Chap. 371). Indeed, sleep disturbance is an important vegetative sign of depression and may commence before any mood changes are perceived by the patient. Consistent polysomnographic findings in depression include decreased REM sleep latency, lengthened first REM sleep episode, and shortened first NREM sleep episode; however, these findings are not specific for depression, and the extent of these changes varies with age and somatologies. Depressed patients also show decreased slow-wave sleep and reduced sleep continuity.

In mania and hypomania, sleep latency is increased and total sleep time can be reduced. Patients with anxiety disorders tend not to show the changes in REM sleep and slow-wave sleep seen in endogenously depressed patients. Chronic alcoholics lack slow-wave sleep, have decreased amounts of REM sleep (as an acute response to alcohol), and have frequent arousals throughout the night. This is associated with impaired daytime alertness. The sleep of chronic alcoholics may remain disturbed for years after discontinuance of alcohol usage. Sleep architecture and physiology are disturbed in schizophrenia (with a decreased amount of stage 4 sleep and a lack of augmentation of REM sleep following REM sleep deprivation); chronic schizophrenics often show day-night reversal, sleep fragmentation, and insomnia.

Insomnia Associated with Neurologic Disorders A variety of neurologic diseases result in sleep disruption through both indirect, nonspecific mechanisms (e.g., pain in cerebral spondylosis or low back pain) or by impairment of central neural structures involved in the generation and control of sleep itself. For example, dementia from any cause has been associated with disturbances in the timing of the sleep-wake cycle, often characterized by nocturnal wandering and an exacerbation of symptomatology at night (so-called sundowning). Epilepsy may rarely present as a sleep complaint (Chap. 348). Often the history is of abnormal behavior, at times with convulsive movements during sleep, and the differential diagnosis includes REM sleep behavior disorder, narcolepsy with sleep apnea syndrome, and periodic movements of sleep (see above). Diagnosis requires nocturnal EEG recording. Other neurologic diseases associated with abnormal movements, such as
Parkinson’s disease, hemiballismus, Huntington’s chorea, and Gilles de la Tourette syndrome (Chap. 351), are also associated with disrupted sleep, presumably through secondary mechanisms. However, the abnormal movements themselves are greatly reduced during sleep. Headache syndromes (migraine or cluster headache) may show sleep-associated exacerbations (Chap. 14) by unknown mechanisms.

Fatal familial insomnia is a rare hereditary disorder caused by degeneration of anterior and dorsomedial nuclei of the thalamus. Insomnia is a prominent early symptom. Progressively, the syndrome produces autonomic dysfunction, dysarthria, myoclonus, coma, and death. The pathogenesis is a mutation in the prion gene (Chap. 362).

Insomnia Associated with Other Medical Disorders A number of medical conditions are associated with disruptions of sleep. The association is frequently nonspecific, e.g., that between sleep disruption and chronic pain from rheumatologic disorders. Attention to this association is important in that sleep-associated symptoms are often the presenting complaint. Treatment of the underlying medical disorder or symptom is the most useful approach. Sleep disruption can also result from the appropriate use of drugs such as glucocorticoids (see below).

One prominent association is between sleep disruption and asthma. In many asthmatics there is a prominent daily variation in airway resistance that results in marked increases in asthmatic symptoms at night, especially during sleep. In addition, treatment with theophylline-based compounds, adrenergic agonists, or glucocorticoids can independently disrupt sleep. When sleep disruption is a side effect of asthma treatment, inhaled glucocorticoids (e.g., beclomethasone) that do not disrupt sleep may provide a useful alternative.

Cardiac ischemia may also be associated with sleep disruption. The ischemia itself may result from increases in sympathetic tone as a result of sleep apnea. Patients may present with complaints of nightmares or vivid, disturbing dreams, with or without awareness of the more classic symptoms of angina or of the sleep disordered breathing. Treatment of the sleep apnea may substantially improve the angina and the nocturnal sleep quality. Paroxysmal nocturnal dyspnea can also occur as a consequence of sleep-associated cardiac ischemia that causes pulmonary congestion exacerbated by the recumbent posture. Chronic obstructive pulmonary disease is also associated with sleep disruption, as is cystic fibrosis, menopause, hyperthyroidism, gastroesophageal reflux, chronic renal failure, and liver failure.

Polysomnographic recordings of (A) obstructive sleep apnea and (B) periodic limb movement of sleep. Note the snoring and reduction in air flow in the presence of continued respiratory effort, associated with the subsequent oxygen desaturation (upper panel). Periodic limb movements occur with a relatively constant intermovement interval and are associated with changes in the EEG and heart rates acceleration (lower panel). Abbreviations: R.A.T., right anterior tibialis; L.A.T., left anterior tibialis. (From the Division of Sleep Medicine, Brigham and Women’s Hospital.)
sleepiness is usually adequate, objective quantification is sometimes necessary.

Hypothyroidism) or in abnormal sleep (e.g., fibromyalgia). Disruption also results in chronic sleep disruption (e.g., sleep apnea in the setting of disorders such as fibromyalgia (Chap. 315), chronic fatigue syndrome (Chap. 370), or endocrine deficiencies such as hypothyroidism (Chap. 320) or Addison’s disease (Chap. 321). While clinical evaluation of the complaint of excessive sleepiness is usually adequate, objective quantification is sometimes necessary. Assessment of daytime functioning as an index of the adequacy of sleep can be made with the multiple sleep latency test (MSLT), which involves repeated measurement of sleep latency (time to onset of sleep) under standardized conditions during a day following quantified nocturnal sleep. The average latency across four to six tests (administered every 2 h across the waking day) provides an objective measure of daytime sleep tendency. Disorders of sleep that result in pathologic daytime somnolence can be reliably distinguished with the MSLT. In addition, the multiple measurements of sleep onset may identify direct transitions from wakefulness to REM sleep that are suggestive of specific pathologic conditions (e.g., narcolepsy).

**NARCOLEPSY** Narcolepsy is both a disorder of the ability to sustain wakefulness voluntarily and a disorder of REM sleep regulation (Table 24–2). The classic “narcolepsy tetrad” consists of excessive daytime somnolence plus three specific symptoms related to an intrusion of REM sleep characteristics (e.g., muscle atonia, vivid dream imagery) into the transition between wakefulness and sleep: (1) sudden weakness or loss of muscle tone without loss of consciousness, often elicited by emotion (cataplexy); (2) hallucinations at sleep onset (hypnogogic hallucinations) or upon awakening (hypnopompic hallucinations); and (3) muscular paralysis upon awakening (sleep paralysis). The severity of cataplexy varies, as patients may have two to three attacks per day or per decade. Some patients with objectively confirmed narcolepsy (see below) may show no evidence of cataplexy. In those with cataplexy, the extent and duration of an attack may also vary, from a transient sagging of the jaw lasting a few seconds to rare cases of flaccid paralysis of the entire voluntary musculature for up to 20 to 30 min. Symptoms of narcolepsy typically begin in the second decade, although the onset ranges from ages 5 to 50. Once established, the disease is chronic without remissions. Secondary forms of narcolepsy have been described (e.g., after head trauma).

Narcolepsy affects about 1 in 4000 people in the United States and appears to have a genetic basis. Recently, several convergent lines of evidence suggest that the hypothalamic neuropeptide hypocretin (orexin) is involved in the pathogenesis of narcolepsy: (1) a mutation in the hypocretin receptor 2 gene has been associated with canine narcolepsy; (2) hypocretin “knockout” mice that are genetically unable to produce this neuropeptide exhibit a phenotype, as assessed by behavioral and electrophysiologic criteria, that is similar to human narcolepsy; and (3) cerebrospinal fluid levels of hypocretin are reduced in most patients who have narcolepsy with cataplexy. The inheritance pattern of narcolepsy in humans is more complex than in the canine model. However, almost all narcoleptics with cataplexy are positive for HLA DQB1*0602 (Chap. 296), suggesting that an autoimmune process may be responsible.

**Diagnosis** The diagnostic criteria continue to be a matter of debate. Certainly, objective verification of excessive daytime somnolence, typically with MSLT mean sleep latencies <8 min, is an essential if nonspecific diagnostic feature. Other conditions that cause excessive sleepiness, such as sleep apnea or chronic sleep restriction, must be rigorously excluded. The other objective diagnostic feature of narcolepsy is the presence of REM sleep in at least two of the naps during the MSLT. Abnormal regulation of REM sleep is also manifested by

the appearance of REM sleep immediately or within minutes after sleep onset in 50% of narcoleptic patients, a rarity in unaffected individuals maintaining a conventional sleep-wake schedule. The REM-related phenomena of the classic narcolepsy tetrad are variably present. There is increasing evidence that narcoleptics with cataplexy (one-half to two-thirds of patients) may represent a more homogeneous group than those without this symptom. However, a history of cataplexy can be difficult to establish reliably. Hypnagogic and hypnomenopausal hallucinations and sleep paralysis are often found in narcoleptic individuals and may be present in only one-half of narcoleptics. Nocturnal sleep disruption is commonly observed in narcolepsy but is also a nonspecific symptom. Similarly, a history of "automatic behaviors" during wakefulness (a trancelike state during which simple motor behaviors persist) is not specific for narcolepsy and serves principally to corroborate the presence of daytime somnolence.

**TREATMENT**

The treatment of narcolepsy is symptomatic. Somnolence is treated with wake-promoting therapeutics. Modafinil is now the drug of choice, particularly with fewer side effects than older stimulants and has a long half-life; 200 to 400 mg is given as a single daily dose. Older drugs such as methylphenidate (10 mg bid to 20 mg qid or dextroamphetamine (10 mg bid) are still used as alternatives, particularly in refractory patients.

Treatment of the REM-related phenomena cataplexy, hypnagogic hallucinations, and sleep paralysis requires the potent REM sleep suppression produced by antidepressant medications. The tricyclic antidepressants [e.g., protriptyline (10 to 40 mg/d) and clomipramine (25–50 mg/d)] and the selective serotonin reuptake inhibitors (SSRIs) [e.g., fluoxetine (10 to 20 mg/d)] are commonly used for this purpose. Efficacy of the antidepressants is limited largely by anticholinergic side effects (tricyclics) and by sleep disturbance and sexual dysfunction (SSRIs). Adequate nocturnal sleep time and planned daytime naps (when possible) are important preventative measures.

**SLEEP APNEA SYNDROMES**

Respiratory dysfunction during sleep is a common, serious cause of excessive daytime somnolence as well as of disturbed nocturnal sleep. An estimated 2 to 5 million people in the United States have a reduction or cessation of breathing for 10 to 150 s, from 30 to several hundred times every night during sleep. These episodes may be due to either an occlusion of the airway (obstructive sleep apnea), absence of respiratory effort (central sleep apnea), or a combination of these factors (mixed sleep apnea) (Fig. 24-3). Failure to recognize and treat these conditions appropriately may lead to impairment of daytime alertness; increased risk of sleep-related motor vehicle accidents; hypertension and other serious cardiovascular complications; and increased mortality. Sleep apnea is particularly prevalent in overweight men and in the elderly, yet it is estimated to remain undiagnosed in 80 to 90% of affected individuals. This is unfortunate since effective treatments are available. *Readers are referred to Chap. 247 for a comprehensive review of the diagnosis and treatment of patients with these conditions.*

**PARASOMNIAS**

The term parasomnia refers to abnormal behaviors that arise from or occur during sleep. A continuum of parasomnias arise from NREM sleep, from brief confusional arousals to sleepwalking and night terrors. The presenting complaint is usually related to the behavior itself, but the parasomnias can disturb sleep continuity or lead to mild impairments in daytime alertness. Only one parasomnia is known to occur in REM sleep, i.e., REM sleep behavior disorder (RBD; see below).

**Sleepwalking (Somnambulism)**

Patients affected by this disorder carry out automatic motor activities that range from simple to complex. Individuals may leave the bed, walk, urinate inappropriately, eat, or exit from the house while remaining only partially aware. Full arousal may be difficult, and some patients may respond to attempted awakening with agitation or even violence. Sleepwalking arises from stage 3 or 4 NREM sleep and is most common in children and adolescents, when these sleep stages are most robust. Episodes are usually isolated but may be recurrent in 1 to 6% of patients. The cause is unknown, though it has a familial basis in roughly one-third of cases.

**Sleep Terrors**

This disorder, also called *pavor nocturnus*, occurs primarily in young children during the first several hours after sleep onset, in stages 3 and 4 of NREM sleep. The child suddenly screams, exhibiting autonomic arousal with sweating, tachycardia, and hyperventilation. The individual may be difficult to arouse and rarely recalls the episode on awakening in the morning. Recurrent attacks are rare. Parents are usually reassured to learn that the condition is self-limited and benign, and that no specific therapy is indicated. Both sleep terrors and sleepwalking represent abnormalities of arousal. In contrast, *nightmares* (dream anxiety attacks) occur during REM sleep and cause full arousal, with intact memory for the unpleasant episode.

**REM Sleep Behavior Disorder**

RBD is a rare condition that is distinct from other parasomnias in that it occurs during REM sleep. It primarily afflicts men of middle age or older, many of whom have a history of prior neurologic disease. In fact, over one-third of patients will go on to develop Parkinson’s disease (Chap. 351) within 10 to 20 years. Presenting symptoms consist of agitated or violent behavior during sleep, reported by a bed partner. In contrast to typical somnambulism, injury to patient or bed partner is not uncommon, and, upon awakening, the patient reports vivid, often unpleasant, dream imagery. The principal differential diagnosis is that of nocturnal seizures, which can be excluded with polysomnography. In RBD, seizure activity is absent on the EEG, and disinhibition of the usual motor atonia is observed in the EMG during REM sleep, at times associated with complex motor behaviors. The pathogenesis is unclear, but damage to brainstem areas mediating descending motor inhibition during REM sleep may be responsible. In support of this hypothesis are the remarkable similarities between RBD and the sleep of animals with bilateral lesions of the pontine tegmentum in areas controlling REM sleep motor inhibition. Treatment with clonazepam (0.5 to 1.0 mg qhs) provides sustained improvement in almost all reported cases.

**Sleep Bruxism**

Bruxism is an involuntary, forceful grinding of teeth during sleep that affects 10 to 20% of the population. The patient is usually unaware of the problem. The typical age of onset is 17 to 20 years, and spontaneous remission usually occurs by age 40. Sex distribution appears to be equal. In many cases, the diagnosis is made during dental examination, damage is minor, and no treatment is indicated. In more severe cases, treatment with a rubber tooth guard is necessary to prevent disfiguring tooth injury. Stress management or, in some cases, biofeedback can be useful when bruxism is a manifestation of psychological stress. There are anecdotal reports of benefit using benzodiazepines.

**Sleep Enuresis**

Bedwetting, like sleepwalking and night terrors, is another parasomnia that occurs during sleep in the young. Before age 5 or 6, nocturnal enuresis should probably be considered a normal feature of development. The condition usually improves spontaneously at puberty, has a prevalence in late adolescence of 1 to 3%, and is rare in adulthood. In older patients with enuresis a distinction must be made between primary and secondary enuresis, the latter being defined as bedwetting in patients who have been fully continent for 6 to 12 months. Treatment of primary enuresis is reserved for patients of appropriate age (>5 or 6 years) and consists of bladder training exercises and behavioral therapy. Urologic abnormalities are more common in primary enuresis and must be assessed by urologic examination. Important causes of secondary enuresis include emotional disturbances, urinary tract infections or malformations, cauda equina lesions, epilepsy, sleep apnea, and certain medications. Symptomatic pharmacotherapy is usually accomplished with desmopressin (0.2 mg qhs), oxybutynin chloride (5 to 10 mg qhs) or imipramine (10 to 50 mg qhs).

**Miscellaneous Parasomnias**

Other clinical entities fulfill the definition of a parasomnia in that they occur selectively during sleep and are as-
associated with some degree of sleep disruption. Examples include *jac-tatio capitis nocturna* (nocturnal headbanging), sleep talking, nocturnal paroxysmal dystonia, and nocturnal leg cramps.

**CIRCADIAN RHYTHM SLEEP DISORDERS**

A subset of patients presenting with either insomnia or hypersomnia may have a disorder of sleep timing rather than sleep generation. Disorders of sleep timing can be either organic (i.e., due to an intrinsic defect in the circadian pacemaker or its input from entraining stimuli) or environmental (i.e., due to a disruption of exposure to entraining stimuli from the environment). Regardless of etiology, the symptoms reflect the influence of the underlying circadian pacemaker on sleep-wake function. Thus, effective therapeutic approaches should aim to entrain the oscillator at an appropriate phase.

**Rapid Time-Zone Change (Jet Lag) Syndrome**

More than 60 million people experience transmeridian air travel annually, which is often associated with excessive daytime sleepiness, sleep onset insomnia, and frequent arousals from sleep, particularly in the latter half of the night. Gastrointestinal discomfort is common. The syndrome is transient, typically lasting 2 to 4 days depending on the number of time zones crossed, the direction of travel, and the traveler’s age and phase-shifting capacity. Travelers who spend more time outdoors reportedly adapt more quickly than those who remain in hotel rooms, presumably due to bright (outdoor) light exposure. Avoidance of antecedent sleep loss and obtaining nap sleep on the afternoon prior to overnight travel greatly reduces the difficulty of extended wakefulness. Laboratory studies suggest that submilligram doses of the pineal hormone melatonin can enhance sleep efficiency, but only if taken when endogenous melatonin concentrations are low (i.e., during biologic daytime), and furthermore that melatonin may induce phase shifts in human rhythms. A large-scale clinical trial evaluating the safety and efficacy of melatonin as a treatment for jet lag and other circadian sleep disorders is needed.

**Shift-Work Sleep Disorder**

More than 7 million workers in the United States regularly work at night, either on a permanent or rotating schedule. In addition, each week millions elect to remain awake at night to meet deadlines, drive long distances, or participate in recreational activities, leading to both sleep loss and misalignment of their circadian rhythms with respect to their sleep-wake cycle. Chronic shift workers have higher rates of cardiac, gastrointestinal, and reproductive disorders. Studies of regular night-shift workers indicate that the circadian timing system usually fails to adapt successfully to such inverted schedules. This leads to a misalignment between the desired work-rest schedule and the output of the pacemaker and in disturbed daytime sleep. Sleep deprivation, increased length of time awake prior to work, and misalignment of circadian phase produce decreased alertness and performance, increased reaction time, and increased risk of performance lapses, thereby resulting in greater safety hazards among night workers and other sleep-deprived individuals. Sleep disturbance nearly doubles the risk of a fatal work accident.

Sleep onset is associated with marked attenuation in perception of both auditory and visual stimuli and lapses of consciousness. The sleepy individual may thus attempt to perform routine and familiar motor tasks during the transition state between wakefulness and sleep (stage 1 sleep) in the absence of adequate sensory input from the environment. Motor vehicle operators are especially vulnerable to sleep-related accidents since the sleep-deprived driver or operator often fails to heed the warning signs of fatigue. Such attempts to override the powerful biologic drive for sleep by the sheer force of will can yield a catastrophic outcome when sleep processes intrude involuntarily upon the waking brain. Such intrusions typically last only seconds but are known on occasion to persist for longer durations. These frequent brief intrusions of stage 1 sleep into behavioral wakefulness are a major component of the impaired psychomotor performance seen with sleepiness. There is a significant increase in the risk of sleep-related, fatal-to-the-driver highway crashes in the early morning and late afternoon hours, coincident with bimodal peaks in the daily rhythm of sleep tendency.

Safety programs should promote education about sleep and increase awareness of the hazards associated with night work and should be aimed at minimizing both circadian disruption and sleep deprivation. The work schedule should minimize: (1) exposure to night work, (2) the frequency of shift rotation so that shifts do not rotate more than once every 2 to 3 weeks, (3) the number of consecutive night shifts, and (4) the duration of night shifts. In fact, shift durations of >18 h should be universally recognized as increasing the risk of sleep-related errors and performance lapses. Caffeine is undoubtedly the most widely used sleep-promoting drug, but it cannot forestall sleep indefinitely and does not shield users from sleep-related performance lapses. Postural changes, exercise, and strategic placement of nap opportunities can sometimes temporarily reduce the risk of fatigue-related performance lapses. Properly timed exposure to bright light can facilitate rapid adaptation to night-shift work. An adequate number of safe highway rest areas, shoulder rumble strips, and strict enforcement and compliance monitoring of hours-of-service policies are needed to reduce the risk of sleep-related transportation crashes.

**Delayed Sleep Phase Syndrome**

Delayed sleep phase syndrome is characterized by: (1) reported sleep onset and wake times intracatably later than desired, (2) actual sleep times at nearly the same clock hours daily, and (3) essentially normal all-night polysomnography except for delayed sleep onset. Patients exhibit an abnormally delayed endogenous circadian phase, with the temperature minimum during the constant routine occurring later than normal. This delayed phase could be due to: (1) an abnormally long, genetically determined intrinsic period of the endogenous circadian pacemaker; (2) an abnormally reduced phase-advancing capacity of the pacemaker; or (3) an irregular prior sleep-wake schedule, characterized by frequent nights when the patient chooses to remain awake well past midnight (for social, school, or work reasons). In most cases, it is difficult to distinguish among these factors, since patients with an abnormally long intrinsic period are more likely to “choose” such late-night activities because they are unable to sleep at that time. Patients tend to be young adults. This self-perpetuating condition can persist for years and does not usually respond to attempts to reestablish normal bedtime hours. Treatment methods involving bright-light phototherapy during the morning hours or melatonin administration in the evening hours show promise in these patients, although the relapse rate is high.

**Advanced Sleep Phase Syndrome**

Advanced sleep phase syndrome (ASPS) is the converse of the delayed sleep phase syndrome. Most commonly, this syndrome occurs in older people, 15% of whom report that they cannot sleep past 5 A.M., with twice that number complaining that they wake up too early at least several times per week. Patients with ASPS experience excessive daytime sleepiness during the evening hours, when they have great difficulty remaining awake, even in social settings. Typically, patients awaken from 3 to 5 A.M. each day, often several hours before their desired wake times. In addition to age-related ASPS, an early-onset familial variant of this condition has also been reported. In one such family, autosomal dominant ASPS was due to a missense mutation in a circadian clock component (PER2, as shown in Fig. 24-2) that altered the circadian period. Patients with ASPS may benefit from bright-light phototherapy during the evening hours, designed to reset the circadian pacemaker to a later hour.

**Non-24-Hour Sleep-Wake Disorder**

This condition can occur when the maximal phase-advancing capacity of the circadian pacemaker is not adequate to accommodate the difference between the 24-h geophysical day and the intrinsic period of the pacemaker in the patient. Alternatively, patients’ self-selected exposure to artificial light may drive the circadian pacemaker to a >24-h schedule. Affected patients are not able to maintain a stable phase relationship between the output of the pacemaker and the 24-h day. Such patients typically present with an incremental pattern of successive delays in sleep onsets and wake
times, progressing in and out of phase with local time. When the patient’s endogenous rhythms are out of phase with the local environment, insomnia coexists with excessive daytime sleepiness. Conversely, when the endogenous rhythms are in phase with the local environment, symptoms remit. The intervals between symptomatic periods may last several weeks to several months. Blind individuals unable to perceive light are particularly susceptible to this disorder. Nightly low-dose (0.5 mg) melatonin administration has been reported to improve sleep and, in some cases, even to induce synchronization of the circadian pacemaker.

**MEDICAL IMPLICATIONS OF CIRCADIAN RHYTHMICITY** Prominent circadian variations have been reported in the incidence of acute myocardial infarction, sudden cardiac death, and stroke, the leading causes of death in the United States. Platelet aggregability is increased after arising in the early morning hours, coincident with the peak incidence of these cardiovascular events. A better understanding of the possible role of circadian rhythmicity in the acute destabilization of a chronic condition such as atherosclerotic disease could improve the understanding of the pathophysiology.

**DISORDERS OF THE EYE**

**Jonathan C. Horton**

---

**THE HUMAN VISUAL SYSTEM**

The visual system provides a supremely efficient means for the rapid assimilation of information from the environment to aid in the guidance of behavior. The act of seeing begins with the capture of images focused on the cornea and lens upon a light-sensitive membrane in the back of the eye, called the retina. The retina is actually part of the brain, banished to the periphery to serve as a transducer for the conversion of patterns of light energy into neuronal signals. Light is absorbed by photopigment in two types of receptors: rods and cones. In the human retina there are 100 million rods and 5 million cones. The rods operate in dim (scotopic) illumination. The cones function under daylight (photopic) conditions. The cone system is specialized for color perception and high spatial resolution. The majority of cones are located within the macula, the portion of the retina serving the central 10° of vision. In the middle of the macula a small pit termed the fovea, packed exclusively with cones, provides best visual acuity.

Photoreceptors hyperpolarize in response to light, activating bipolar, amacrine, and horizontal cells in the inner nuclear layer. After processing of photoreceptor responses by this complex retinal circuit, the flow of sensory information ultimately converges upon a final common pathway: the ganglion cells. These cells translate the visual image impinging upon the retina into a continuously varying barrage of action potentials that propagates along the primary optic pathway to visual centers within the brain. There are a million ganglion cells in each retina, and hence a million fibers in each optic nerve.

Ganglion cell axons sweep along the inner surface of the retina in the nerve fiber layer, exit the eye at the optic disc, and travel through the optic nerve, optic chiasm, and optic tract to reach targets in the brain. The majority of fibers synapse upon cells in the lateral geniculate body, a thalamic relay station. Cells in the lateral geniculate body project in turn to the primary visual cortex. This massive afferent retinogeniculocortical sensory pathway provides the neural substrate for visual perception. Although the lateral geniculate body is the main target of the retina, separate classes of ganglion cells project to other subcortical visual nuclei involved in different functions. Ganglion cells that mediate pupillary constriction and circadian rhythms are light sensitive, owing to a novel visual pigment, melanopsin. Pupil responses are mediated by input to the pretectal olivary nuclei in the midbrain. The pretectal nuclei send their output to the Edinger-Westphal nuclei, which in turn provide parasympathetic innervation to the iris sphincter via an interneuron in the ciliary ganglion. Circadian rhythms are timed by a retinal projection to the suprachiasmatic nucleus. Visual orientation and eye movements are served by retinal input to the superior colliculus. Gaze stabilization and optokinetic reflexes are governed by a group of small retinal targets known collectively as the brainstem accessory optic system.

The eyes must be rotated constantly within their orbits to place and maintain targets of visual interest upon the fovea. This activity, called foveation, or looking, is governed by an elaborate efferent motor system. Each eye is moved by six extraocular muscles, supplied by cranial nerves from the oculomotor (III), trochlear (IV), and abducens (VI) nuclei. Activity in these ocular motor nuclei is coordinated by pontine and midbrain mechanisms for smooth pursuit, saccades, and gaze stabilization during head and body movements. Large regions of the frontal and parietooccipital cortex control these brainstem eye movement centers by providing descending supranuclear input.

**CLINICAL ASSESSMENT OF VISUAL FUNCTION**

**REFRACTIVE STATE** In approaching the patient with reduced vision, the first step is to decide whether refractive error is responsible. In emmetropia, parallel rays from infinity are focused perfectly upon the retina. Sadly, this condition is enjoyed by only a minority of the population. In myopia, the globe is too long, and light rays come to a focal point in front of the retina. Near objects can be seen clearly, but distant objects require a diverging lens in front of the eye. In hyperopia, the globe is too short, and hence a converging lens is used to supplement the refractive power of the eye. In astigmatism, the corneal surface is not perfectly spherical, necessitating a cylindrical corrective lens. In recent years it has become possible to correct refractive error with the excimer laser by performing LASIK (laser in situ keratomileusis) to alter the curvature of the cornea. With the onset of middle age, presbyopia develops as the lens within the eye becomes unable to increase its refractive power to accommodate upon near objects. To compensate for presbyopia, the em-
metropic patient must use reading glasses. The patient already wearing glasses for distance correction usually switches to bifocals. The only exception is the myopic patient, who may achieve clear vision at near simply by removing glasses containing the distance prescription.

Refractive errors usually develop slowly and remain stable after adolescence, except in unusual circumstances. For example, the acute onset of diabetes mellitus can produce sudden myopia because of lens edema induced by hyperglycemia. Testing vision through a pinhole aperture is a useful way to screen quickly for refractive error. If the visual acuity is better through a pinhole than with the unaided eye, the patient needs a refraction to obtain best corrected visual acuity.

**VISUAL ACUITY** The Snellen chart is used to test acuity at a distance of 6 m (20 ft). For convenience, a scale version of the Snellen chart, called the Rosenbaum card, is held at 36 cm (14 in) from the patient (Fig. 25-1). All subjects should be able to read the 6/6 m (20/20 ft) line with each eye using their refractive correction, if any. Patients who need reading glasses because of presbyopia must wear them for accurate testing with the Rosenbaum card. If 6/6 (20/20) acuity is not present in each eye, the deficiency in vision must be explained. If worse than 6/240 (20/800), acuity should be recorded in terms of counting fingers, hand motions, light perception, or no light perception. Legal blindness is defined by the Internal Revenue Service as a best corrected acuity of 6/60 (20/200) or less in the better eye, or a binocular visual field subtending 20° or less. For driving the laws vary by state, but most require a corrected acuity of 6/12 (20/40) in at least one eye. Patients with a homonymous hemianopia should not drive.

![Rosenbaum Pocket Vision Screener](image)

**FIGURE 25-1** The Rosenbaum card is a miniature, scale version of the Snellen chart for testing visual acuity at near. When the visual acuity is recorded, the Snellen distance equivalent should bear a notation indicating that vision was tested at near, not at 6 m (20 ft), or else the Jaeger number system should be used to report the acuity.

PUPILS The pupils should be tested individually in dim light with the patient fixating on a distant target. If they respond briskly to light, there is no need to check the near response, because isolated loss of constriction (miosis) to accommodation does not occur. For this reason, the ubiquitous abbreviation PERRLA (pupils equal, round, and reactive to light and accommodation) implies a wasted effort with the last step. However, it is important to test the near response if the light response is poor or absent. Light-near dissociation occurs with neurosyphilis (Argyll Robertson pupil), lesions of the dorsal midbrain (obstructive hydrocephalus, pineal region tumors), and after aberrant regeneration (oculomotor nerve palsy, Adie’s tonic pupil).

An eye with no light perception has no pupillary response to direct light stimulation. If the retina or optic nerve is only partially injured, the direct pupillary response will be weaker than the consensual pupillary response evoked by shining a light into the other eye. This *relative afferent pupillary defect* (Marcus Gunn pupil) can be elicited with the swinging flashlight test. It is an extremely useful sign in retrobulbar optic neuritis and other optic nerve diseases, where it may be the sole objective evidence for disease.

Subtle inequality in pupil size, up to 0.5 mm, is a fairly common finding in normal persons. The diagnosis of essential or physiologic anisocoria is secure as long as the relative pupil asymmetry remains constant as ambient lighting varies. Anisocoria that increases in dim light indicates a sympathetic paresis of the iris dilator muscle. The triad of miosis with ipsilateral ptosis and anhidrosis constitutes Horner’s syndrome, although anhidrosis is an inconstant feature. Brainstem stroke, carotid dissection, or neoplasm impinging upon the sympathetic chain are occasionally identified as the cause of Horner’s syndrome, but most cases are idiopathic.

Anisocoria that increases in bright light suggests a parasympathetic palsy. The first concern is an oculomotor nerve paresis. This possibility is excluded if the eye movements are full and the patient has no ptosis or diplopia. Acute pupillary dilation (mydriasis) can occur from damage to the ciliary ganglion in the orbit. Common mechanisms are infection (herpes zoster, influenza), trauma (blunt, penetrating, surgical), or ischemia (diabetes, temporal arteritis). After denervation of the iris sphincter the pupil does not respond well to light, but the response to near is often relatively intact. When the near stimulus is removed, the pupil redilates very slowly compared with the normal pupil, hence the term *tonic pupil*. In Adie’s syndrome, a tonic pupil occurs in conjunction with weak or absent tendon reflexes in the lower extremities. This benign disorder, which occurs predominantly in healthy young women, is assumed to represent a mild dysautonomia. Tonic pupils are also associated with Shy-Drager syndrome, segmental hypohidrosis, diabetes, and amyloidosis. Occasionally, a tonic pupil is discovered incidentally in an otherwise completely normal, asymptomatic individual. The diagnosis is confirmed by placing a drop of dilute (0.125%) pilocarpine into each eye. Denvration hypersensitivity produces pupillary constriction in a tonic pupil, whereas the normal pupil shows no response. Pharmacologic dilation from accidental or deliberate instillation of anticholinergic agents (atropine, scopolamine), Parasympathetic agents (pilocarpine, demecarium bromide) used to treat glaucoma produce miosis. In any patient with an unexplained pupillary abnormality, a slit-lamp examination is
helpful to exclude surgical trauma to the iris, an occult foreign body, perforating injury, intraocular inflammation, adhesions (synchiae), angle-closure glaucoma, and iris sphincter rupture from blunt trauma.

**EYE MOVEMENTS AND ALIGNMENT** Eye movements are tested by asking the patient with both eyes open to pursue a small target such as a penlight into the cardinal fields of gaze. Normal ocular versions are smooth, symmetric, full, and maintained in all directions without nystagmus. Saccades, or quick refixation eye movements, are assessed by having the patient look back and forth between two stationary targets. The eyes should move rapidly and accurately in a single jump to their target. Ocular alignment can be judged by holding a penlight directly in front of the patient at about 1 m. If the eyes are straight, the corneal light reflex will be centered in the middle of each pupil. To test eye alignment more precisely, the cover test is useful. The patient is instructed to gaze upon a small fixation target in the distance. One eye is covered suddenly while observing the second eye. If the second eye shifts to fixate upon the target, it was misaligned. If it does not move, the first eye is uncovered and the test is repeated on the second eye. If neither eye moves, the eyes are aligned orthotropically. If the eyes are orthotropically in primary gaze but the patient complains of diplopia, the cover test should be performed with the head tilted or turned in whatever direction elicits diplopia. With practice the examiner can detect an ocular deviation (heterotropia) as small as 1 to 2°.

Saccades, or quick refixation eye movements, are assessed by having the patient look back and forth between two stationary targets. The eyes should move rapidly and accurately in a single jump to their target. Ocular alignment can be judged by holding a penlight directly in front of the patient at about 1 m. If the eyes are straight, the corneal light reflex will be centered in the middle of each pupil. To test eye alignment more precisely, the cover test is useful. The patient is instructed to gaze upon a small fixation target in the distance. One eye is covered suddenly while observing the second eye. If the second eye shifts to fixate upon the target, it was misaligned. If it does not move, the first eye is uncovered and the test is repeated on the second eye. If neither eye moves, the eyes are aligned orthotropically. If the eyes are orthotropically in primary gaze but the patient complains of diplopia, the cover test should be performed with the head tilted or turned in whatever direction elicits diplopia. With practice the examiner can detect an ocular deviation (heterotropia) as small as 1 to 2° with the cover test. Deviations can be measured by placing prisms in front of the misaligned eye to determine the power required to neutralize the fixation shift evoked by covering the other eye.

**STEREOPTIC** Stereoeacuity is determined by presenting targets with retinal disparity separately to each eye using polarized images. The most popular office tests measure a range of thresholds from 800 to 40 seconds of arc. Normal stereoeacuity is 40 seconds of arc. If a patient achieves this level of stereoeacuity, one is assured that the eyes are aligned orthotropically and that vision is intact in each eye. Random dot stereograms have no monocular depth cues and provide an excellent screening test for strabismus and amblyopia in children.

**COLOR VISION** The retina contains three classes of cones, with visual pigments of differing peak spectral sensitivity: red (560 nm), green (530 nm), and blue (430 nm). The red and green cone pigments are encoded on the X chromosome; the blue cone pigment on chromosome 7. Mutations of the blue cone pigment are exceedingly rare. Mutations of the red and green pigments cause congenital X-linked color blindness in 8% of males. Affected individuals are not truly color blind; rather, they differ from normal subjects in how they perceive color and how they combine primary monochromatic lights to match a given color. Anomalous trichromats have three cone types, but a mutation in one cone pigment (usually red or green) causes a shift in peak spectral sensitivity, altering the proportion of primary colors required to achieve a color match. Dichromats have only two cone types and will therefore accept a color match based upon only two primary colors. Anomalous trichromats and dichromats have 6/6 (20/20) visual acuity, but their hue discrimination is impaired. Ishihara color plates can be used to detect red-green color blindness. The test plates contain a hidden number, visible only to subjects with color confusion from red-green color blindness. Because color blindness is almost exclusively X-linked, it is worth screening only male children.

The Ishihara plates are often used to detect acquired defects in color vision, although they are intended as a screening test for congenital color blindness. Acquired defects in color vision frequently result from disease of the macula or optic nerve. For example, patients with a history of optic neuritis often complain of color desaturation long after their visual acuity has returned to normal. Color blindness can also occur from bilateral strokes involving the ventral portion of the occipital lobe (cerebral achromatopsia). Such patients can perceive only shades of gray and may also have difficulty recognizing faces ( prosopagnosia). Infarcts of the dominant occipital lobe sometimes give rise to color anomia. Affected patients can discriminate colors, but they cannot name them.

**VISUAL FIELDS** Vision can be impaired by damage to the visual system anywhere from the eyes to the occipital lobes. One can localize the site of the lesion with considerable accuracy by mapping the visual field deficit by finger confrontation and then correlating it with the topographic anatomy of the visual pathway (Fig. 25-2). Quantitative visual field mapping is performed by computer-driven perimeters (Humphrey, Octopus) that present a target of variable intensity at fixed positions in the visual field (Fig. 25-2A). By generating an automated printout of light thresholds, these static perimeters provide a sensitive means of detecting scotomas in the visual field. They are exceedingly useful for serial assessment of visual function in chronic diseases such as glaucoma or pseudotumor cerebri.

The crux of visual field analysis is to decide whether a lesion is before, at, or behind the optic chiasm. If a scotoma is confined to one eye, it must be due to a lesion anterior to the chiasm, involving either the optic nerve or retina. Retinal lesions produce scotomas that correspond optically to their location in the fundus. For example, a superior-nasal retinal detachment results in an inferior-temporal field cut. Damage to the macula causes a central scotoma (Fig. 25-2B). Optic nerve disease produces characteristic patterns of visual field loss. Glaucoma selectively destroys axons that enter the superotemporal or inferotemporal poles of the optic disc, resulting in arcuate scotomas shaped like a Turkish scimitar, which emanate from the blind spot and curve around fixation to end flat against the horizontal meridian (Fig. 25-2C). This type of field defect mirrors the arrangement of the nerve fiber layer in the temporal retina. Arcuate or nerve fiber layer scotomas also occur from optic neuritis, ischemic optic neuropathy, optic disc drusen, and branch retinal artery or vein occlusion.

Damage to the entire upper or lower pole of the optic disc causes an altitudinal field cut that follows the horizontal meridian (Fig. 25-2D). This pattern of visual field loss is typical of ischemic optic neuropathy but also occurs from retinal vascular occlusion, advanced glaucoma, and optic neuritis.

About half the fibers in the optic nerve originate from ganglion cells serving the macula. Damage to papillomacular fibers causes a centrocecal scotoma encompassing the blind spot and macula (Fig. 25-2E). If the damage is irreversible, pallor eventually appears in the temporal portion of the optic disc. Temporal pallor from a centrocecal scotoma may develop in optic neuritis, nutritional optic neuropathy, toxic optic neuropathy, Leber's hereditary optic neuropathy, and compressive optic neuropathy. It is worth mentioning that the temporal side of the optic disc is slightly more pale than the nasal side in most normal individuals. Therefore, it can sometimes be difficult to decide whether the temporal pallor visible on fundus examination represents a pathologic change. Pallor of the nasal rim of the optic disc is a less equivocal sign of optic atrophy.

At the optic chiasm, fibers from nasal ganglion cells decussate into the contralateral optic tract. Crossed fibers are damaged more by compression than uncrossed fibers. As a result, mass lesions of the sellar region cause a temporal hemianopia in each eye. Tumors anterior to the optic chiasm, such as meningiomas of the tuberculum sella, produce a junctional scotoma characterized by an optic neuropathy in one eye and a superior temporal field cut in the other eye (Fig. 25-2G). More symmetric compression of the optic chiasm by a pituitary adenoma (Fig. 318-4), meningioma, craniopharyngioma, glioma, or aneurysm results in a bitemporal hemianopia (Fig. 25-2H). The insidious development of a bitemporal hemianopia often goes unnoticed by the patient and will escape detection by the physician unless each eye is tested separately.

It is difficult to localize a postchiasmal lesion accurately, because injury anywhere in the optic tract, lateral geniculate body, optic radiations, or visual cortex can produce a homonymous hemianopia, i.e., a temporonasal hemifield defect in the contralateral eye, and a temporopolar nasal hemifield defect in the ipsilateral eye (Fig. 25-2I). A unilateral postchiasmal lesion leaves the visual acuity in each eye unaffected.
although the patient may read the letters on only the left or right half of the eye chart. Lesions of the optic radiations tend to cause poorly matched or incongruous field defects in each eye. Damage to the optic radiations in the temporal lobe (Meyer’s loop) produces a superior quadrantic homonymous hemianopia (Fig. 25-2J), whereas injury to the optic radiations in the parietal lobe results in an inferior quadrantic homonymous hemianopia (Fig. 25-2K). Lesions of the primary visual cortex give rise to dense, congruous hemianopic field defects. Occlusion of the posterior cerebral artery supplying the occipital lobe is a frequent cause of total homonymous hemianopia. Some patients with hemianopia after occipital stroke have macular sparing, because the macular representation at the tip of the occipital lobe is supplied by collaterals from the middle cerebral artery (Fig. 25-2L). Destruction of both occipital lobes produces cortical blindness. This condition can be distinguished from bilateral prechiasmal visual loss by noting that the pupil responses and optic fundi remain normal.

## Red or Painful Eye

### Corneal Abrasions

These are seen best by placing a drop of fluorescein in the eye and looking with the slit lamp using a cobalt-blue light. A penlight with a blue filter will suffice if no slit lamp is available. Damage to the corneal epithelium is revealed by yellow fluorescence of the exposed basement membrane underlying the epithelium. It is important to check for foreign bodies. To search the conjunctival fornices, the lower lid should be pulled down and the upper lid everted. A foreign body can be removed with a moistened cotton-tipped applicator after placing a drop of topical anesthetic, such as proparacaine, in the eye. Alternatively, it may be possible to flush the foreign body from the eye by irrigating copiously with saline or artificial tears. If the corneal epithelium has been abraded, antibiotic ointment and a patch should be applied to the eye. A drop of an intermediate-acting cyclopelgic, such as cyclopentolate hydrochloride 1%, helps to reduce pain by relaxing the ciliary body. The eye should be reexamined the next day. Minor abrasions may not require patching and cycloplegia.

### Subconjunctival Hemorrhage

This results from rupture of small vessels bridging the potential space between the episclera and conjunctiva. Blood dissecting into this space can produce a spectacular red eye, but vision is not affected and the hemorrhage resolves without treatment. Subconjunctival hemorrhage is usually spontaneous but can occur from blunt trauma, eye rubbing, or vigorous coughing. Occasionally it is a clue to an underlying bleeding disorder.

### Pinguecula

This is a small, raised conjunctival nodule at the temporal or nasal limbus. In adults such lesions are extremely common and have little significance, unless they become inflamed (pingueculitis). A pingueculum resembles a pinguecula but has crossed the limbus to encroach upon the corneal surface. Removal is justified when symptoms of irritation or blurring develop, but recurrence is a common problem.

### Blepharitis

This refers to inflammation of the eyelids. The most common form occurs in association with acne rosacea or seborrheic dermatitis. The eyelid margins are usually colonized heavily by staphylococci. Upon close inspection, they appear greasy, ulcerated, and crusted with scaling debris that clings to the lashes. Treatment consists of warm compresses, strict eyelid hygiene, and topical antibiotics such as erythromycin. An external hordeolum (sty) is caused by staphylococcal infection of the superficial accessory glands of Zeis or Moll located in the eyelid margins. An internal hordeolum occurs after suppurative infection of the oil-secreting meibomian glands within the tarsal plate of the eyelid. Systemic antibiotics, usually tetracyclines, are sometimes necessary for treatment of meibomian gland inflammation (meibomitis) or chronic, severe blepharitis. A chalazion is a painless, granulomatous inflammation of a meibomian gland that produces a pealike nodule within the eyelid. It can be incised and drained,

---

**FIGURE 25-2** Ventral view of the brain, correlating patterns of visual field loss with the sites of lesions in the visual pathway. The visual fields overlap partially, creating a 120° monocular crescent on either side. The visual field maps in this figure were done with a computer-driven perimeter (Humphrey Instruments, Carl Zeiss, Inc.). It plots the retinal sensitivity to light in the central 30° using a gray scale format. Areas of visual field loss are shown in black. The examples of common monocular, prechiasmal field defects are all shown for the right eye. By convention, the visual fields are always recorded with the left eye’s field on the left, and the right eye’s field on the right, just as the patient sees the world.
or injected with glucocorticoids. Basal cell, squamous cell, or meibomian gland carcinoma should be suspected for any nonhealing, ulcerative lesion of the eyelids.

**Dacryocystitis** An inflammation of the lacrimal drainage system, this can produce epiphora (tearing) and ocular injection. Gentle pressure over the lacrimal sac evokes pain and reflux of mucus or pus from the tear puncta. Dacryocystitis usually occurs after obstruction of the lacrimal system. It is treated with topical and systemic antibiotics, followed by probing or surgery to reestablish patency. *Entropion* (inversion of the eyelid) or *ectropion* (sagging or eversion of the eyelid) can also lead to epiphora and ocular irritation.

**Conjunctivitis** This is the most common cause of a red, irritated eye. Pain is minimal, and the visual acuity is reduced only slightly. The most common viral etiology is adenovirus infection. It causes a watery discharge, mild foreign-body sensation, and photophobia. Bacterial infection tends to produce a more mucopurulent exudate. Mild cases of infectious conjunctivitis are usually treated empirically with broad-spectrum topical ocular antibiotics, such as sulfacetamide 10%, polymixin-bacitracin-neomycin, or trimethoprim-polymixin combination. Smears and cultures are usually reserved for severe, resistant, or recurrent cases of conjunctivitis. To prevent contagion, patients should be admonished to wash their hands frequently, not to touch their eyes, and to avoid direct contact with others.

**Allergic Conjunctivitis** This condition is extremely common and often mistaken for infectious conjunctivitis. Itching, redness, and epiphora are typical. The palpebral conjunctiva may become hypertrophic with giant excrescences called cobblestone papillae. Irritation from contact lenses or any chronic foreign body can also induce formation of cobblestone papillae. *Atopic conjunctivitis* occurs in subjects with atopic dermatitis or asthma. Symptoms caused by allergic conjunctivitis can be alleviated with cold compresses, topical vasoconstrictors, antihistamines, and mast-cell stabilizers such as cromolyn sodium. Topical glucocorticoid solutions provide dramatic relief of immune-mediated forms of conjunctivitis, but their long-term use is ill-advised because of the complications of glaucoma, cataract, and secondary infection. Topical nonsteroidal anti-inflammatory agents (NSAIDs) such as ketorolac tromethamine are a better alternative.

**Keratoconjunctivitis Sicca** Also known as dry eye, it produces a burning, foreign-body sensation, injection, and photophobia. In mild cases the eye appears surprisingly normal, but tear production measured by wetting of a filter paper (Schirmer strip) is deficient. A variety of systemic drugs, including antihistaminic, anticholinergic, and psychotropic medications, result in dry eye by reducing lacrimal secretion. Disorders that involve the lacrimal gland directly, such as sarcoidosis or Sjögren’s syndrome, also cause dry eye. Patients may develop dry eye after radiation therapy if the treatment field includes the orbits. Problems with ocular drying are also common after lesions affecting cranial nerves V or VII. Corneal anesthesia is particularly dangerous, because the absence of a normal blink reflex exposes the cornea to injury without out patient to warn the patient. Dry eye is managed by frequent and liberal application of artificial tears and ocular lubricants. In severe cases the tear puncta can be plugged or catherized to reduce lacrimal outflow.

**Keratitis** This is a threat to vision because of the risk of corneal clouding, scarring, and perforation. Worldwide, the two leading causes of blindness from keratitis are trachoma from chlamydial infection and vitamin A deficiency related to malnutrition. In the United States, contact lenses play a major role in corneal infection and ulceration. They should not be worn by anyone with an active eye infection. In evaluating the cornea, it is important to differentiate between a superficial infection (*keratoconjunctivitis*) and a deeper, more serious ulcerative process. The latter is accompanied by greater visual loss, pain, photophobia, redness, and discharge. Slit-lamp examination shows disruption of the corneal epithelium, a cloudy infiltrate or abscess in the stroma, and an inflammatory cellular reaction in the anterior chamber. In severe cases, pus settles at the bottom of the anterior chamber, giving rise to a hypopyon. Immediate empirical antibiotic therapy should be initiated after corneal scrapings are obtained for Gram’s stain, Giemsa stain, and cultures. Fortified topical antibiotics are most effective, supplemented with subconjunctival antibiotics as required. A fungal etiology should always be considered in the patient with keratitis. Fungal infection is common in warm humid climates, especially after penetration of the cornea by plant or vegetable material.

**Herpes Simplex** The *herpes viruses* are a major cause of blindness from keratitis. Most adults in the United States have serum antibodies to herpes simplex, indicating prior viral infection (Chap. 163). Primary ocular infection is generally caused by herpes simplex type 1, rather than type 2. It manifests as a unilateral follicular blepharoconjunctivitis, easily confused with adenoviral conjunctivitis unless telltale vesicles appear on the periorcular skin or conjunctiva. A dendritic pattern of corneal epithelial ulceration revealed by fluorescein staining is pathognomonic for herpes infection but is seen in only a minority of primary infections. Recurrent ocular infection arises from reactivation of the latent herpes virus. Viral eruption in the corneal epithelium may result in the characteristic herpes dendrite. Involvement of the corneal stroma produces edema, vascularization, and iridocyclitis. Herpes keratitis is treated with topical antiviral agents, cycloplegics, and oral acyclovir. Topical glucocorticoids are effective in mitigating corneal scarring but must be used with extreme caution because of the danger of corneal melting and perforation. Topical glucocorticoids also carry the risk of prolonging infection and inducing glaucoma.

**Herpes Zoster** Herpes zoster from reactivation of latent varicella (chickenpox) virus causes a dermatomal pattern of painful vesicular dermatitis. Ocular symptoms can occur after zoster eruption in any branch of the trigeminal nerve but are particularly common when vesicles form on the nose, reflecting nasociliary (V1) nerve involvement (Hutchinson’s sign). Herpes zoster ophthalmicus produces corneal dendrites, which can be difficult to distinguish from those seen in herpes simplex. Stromal keratitis, anterior uveitis, raised intraocular pressure, ocular motor nerve palsies, acute retinal necrosis, and post-herpetic scarring and neuralgia are other common sequelae. Herpes zoster ophthalmicus is treated with antiviral agents and cycloplegics. In severe cases, glucocorticoids may be added to prevent permanent visual loss from corneal scarring.

**Episcleritis** This is an inflammation of the episclera, a thin layer of connective tissue between the conjunctiva and sclera. Episcleritis resembles conjunctivitis but is a more localized process and discharge is absent. Most cases of episcleritis are idiopathic, but some occur in the setting of an autoimmune disease. *Scleritis* refers to a deeper, more severe inflammatory process, frequently associated with a connective tissue disease such as rheumatoid arthritis, lupus erythematosus, polyarteritis nodosa, Wegner’s granulomatosis, or relapsing polychondritis. The inflammation and thickening of the sclera can be diffuse or nodular. In anterior forms of scleritis, the globe assumes a violet hue due to blepharitis, blepharospasm, and inflammation of the anterior stroma, and an inflammatory cellular reaction in the anterior chamber. In severe cases, pus settles at the bottom of the anterior chamber, giving rise to a hypopyon. Immediate empirical antibiotic therapy should be initiated after corneal scrapings are obtained for Gram’s stain, Giemsa stain, and cultures. Fortified topical antibiotics are most effective, supplemented with subconjunctival antibiotics as required. A fungal etiology should always be considered in the patient with keratitis. Fungal infection is common in warm humid climates, especially after penetration of the cornea by plant or vegetable material.

**Uveitis** Involving the anterior structures of the eye, this is also called *iritis* or *iridocyclitis*. The diagnosis requires slit-lamp examination to identify inflammatory cells floating in the aqueous humor or deposited upon the corneal endothelium (keratic precipitates). Anterior uveitis develops in sarcoidosis, ankylosing spondylitis, juvenile rheumatoid arthritis, inflammatory bowel disease, psoriasis, Reiter’s syndrome, and Behçet’s disease. It is also associated with herpes infections, syphilis, Lyme disease, toxocariasis, tuberculosis, and leprosy. Although anterior uveitis can occur in conjunction with many diseases, no cause is found to explain the majority of cases. For this reason, laboratory
evaluation is usually reserved for patients with recurrent or severe anterior uveitis. Treatment is aimed at reducing inflammation and scarring by judicious use of topical glucocorticoids. Dilatation of the pupil reduces pain and prevents the formation of synchia.

**Posterior Uveitis** This is diagnosed by observing inflammation of the vitreous, retina, or choroid on fundus examination. It is more likely than anterior uveitis to be associated with an identifiable systemic disease. Some patients have panuveitis, or inflammation of both the anterior and posterior segments of the eye. Posterior uveitis is a manifestation of autoimmune diseases such as sarcoidosis, Behçet's disease, Vogt-Koyanagi-Harada syndrome, and inflammatory bowel disease (Fig. 25-3). It also accompanies diseases such as toxoplasmosis, ophthalmitis, coccidiodomycosis, toxocariasis, and histoplasmosis; infections caused by organisms such as Candida, Pneumocystis carinii, Cryptococcus, Aspergillus, herpes, and cytomegalovirus (see Fig. 166-1); and other diseases such as syphilis, Lyme disease, tuberculosis, cat-scratch disease, Whipple's disease, and brucellosis. In multiple sclerosis, chronic inflammatory changes can develop in the extreme periphery of the retina (pars planitis or intermediate uveitis).

**Acute Angle-Closure Glaucoma** This is a rare and frequently misdiagnosed cause of a red, painful eye. Susceptible eyes have a shallow anterior chamber, either because the eye has a short axial length (hypopria) or a lens enlarged by the gradual development of cataract. When the pupil becomes mid-dilated, the peripheral iris blocks aqueous outflow via the anterior chamber angle and the intraocular pressure rises abruptly, producing pain, injection, corneal edema, obscuration, and blurred vision. In some patients, ocular symptoms are overshadowed by nausea, vomiting, or headache, prompting a fruitless workup for abdominal or neurologic disease. The diagnosis is made by measuring the intraocular pressure during an acute attack or by observing a narrow chamber angle by means of a specially mirrored contact lens. Acute angle closure is treated with oral or intravenous acetazolamide, a narrow chamber angle by means of a specially mirrored contact lens. Suring the intraocular pressure during an acute attack or by observing for abdominal or neurologic disease. The diagnosis is made by measuring the intraocular pressure during an acute attack or by observing a narrow chamber angle by means of a specially mirrored contact lens. Acute angle closure after pharmacologic dilation rarely causes any permanent damage to the eye and serves as an inadvertent provocative test to identify patients with narrow angles who would benefit from prophylactic laser iridectomy.

**Endophthalmitis** This occurs from bacterial, viral, fungal, or parasitic infection of the internal structures of the eye. It is usually acquired by hematogenous seeding from a remote site. Chronically ill, diabetic, or immunosuppressed patients, especially those with a history of indwelling intravenous catheters or positive blood cultures, are at greatest risk for endogenous endophthalmitis. Although most patients have ocular pain and injection, visual loss is sometimes the only symptom. Septic emboli, from a diseased heart valve or a dental abscess, that lodge in the retinal circulation can give rise to endophthalmitis. White-centered retinal hemorrhages (Roth’s spots) are considered pathognomonic for subacute bacterial endocarditis, but they also appear in leukemia, diabetes, and many other conditions. Endophthalmitis also occurs as a complication of ocular surgery, occasionally months or even years after the operation. An occult penetrating foreign body or unrecognized trauma to the globe should be considered in any patient with unexplained intraocular infection or inflammation.

**TRANSIENT OR SUDDEN VISUAL LOSS**

**Amaurosis Fugax** This term refers to a transient ischemic attack of the retina (Chap. 349). Because neural tissue has a high rate of metabolism, interruption of blood flow to the retina for more than a few seconds results in *transient monocular blindness*, a term used interchangeably with amaurosis fugax. Patients describe a rapid fading of vision like a curtain descending, sometimes affecting only a portion of the visual field. Amaurosis fugax usually occurs from an embolus that becomes stuck within a retinal arteriole (Fig. 25-4). If the embolus breaks up or passes, flow is restored and vision returns quickly to normal without permanent damage. With prolonged interruption of blood flow, the inner retina suffers infarction. Ophthalmoscopy reveals zones of whitened, edematous retina following the distribution of the retinal arterioles. Complete occlusion of the central retinal artery produces arrest of blood flow in a milky retina with a cherry-red fovea (Fig. 25-5). Emboli are composed of either cholesterol (Hollenhorst plaque), calcium, or platelet-fibrin debris. The most common source is an atherosclerotic plaque in the carotid artery or aorta, although emboli can also arise from the heart, especially in patients with diseased valves, atrial fibrillation, or wall motion abnormalities.

In rare instances, amaurosis fugax occurs from low central retinal artery perfusion pressure in a patient with a critical stenosis of the ipsilateral carotid artery and poor collateral flow via the circle of Willis. In this situation, amaurosis fugax develops when there is a dip in systemic blood pressure or a slight worsening of the carotid stenosis. Sometimes there is contralateral motor or sensory loss, indicating concomitant hemispheric cerebral ischemia.

Retinal arterial occlusion also occurs rarely in association with retinal migraine, lupus erythematosus, anticoagulant antibodies (Fig. 25-5), anticoagulant deficiency states (protein S, protein C, and antithrombin III deficiency), pregnancy, intravenous drug abuse, blood dyscrasias, dysproteinemias, and temporal arteritis.
Marked systemic hypertension causes sclerosis of retinal arterioles, splinter hemorrhages, focal infarcts of the nerve fiber layer (cotton-wool spots), and leakage of lipid and fluid (hard exudate) into the macula (Fig. 25-6). In hypertensive crisis, sudden visual loss can result from vasospasm of retinal arterioles and retinal ischemia. In addition, acute hypertension may produce visual loss from ischemic swelling of the optic disc. Patients with acute hypertensive retinopathy should be treated by lowering the blood pressure. However, the blood pressure should not be reduced precipitously, because there is a danger of optic disc infarction from sudden hypoperfusion.

Impending branch or central retinal vein occlusion can produce prolonged visual obscurations that resemble those described by patients with amaurosis fugax. The veins appear engorged and phlebitic, with numerous retinal hemorrhages (Fig. 25-7). In some patients, venous blood flow recovers spontaneously, while others evolve a frank obstruction with extensive retinal bleeding (“blood and thunder” appearance), infarction, and visual loss. Venous occlusion of the retina is often idiopathic, but hypertension, diabetes, and glaucoma are prominent risk factors. Polycythemia, thrombocythemia, or other factors leading to an underlying hypercoagulable state should be corrected; aspirin treatment may be beneficial.

Anterior Ischemic Optic Neuropathy (AION) This is caused by insufficient blood flow through the posterior ciliary arteries supplying the optic disc. It produces painless, monocular visual loss that is usually sudden, although some patients have progressive worsening. The optic disc appears swollen and surrounded by nerve fiber layer splinter hemorrhages (Fig. 25-8). AION is divided into two forms: arteritic and nonarteritic. The nonarteritic form of AION is most common. No specific cause can be identified, although diabetes and hypertension are frequent risk factors. No treatment is available. About 5% of patients, especially those over age 60, develop the arteritic form of AION in conjunction with giant cell (temporal) arteritis (Chap. 306). It is urgent to recognize arteritic AION so that high doses of glucocorticoids can be instituted immediately to prevent blindness in the second eye. Symptoms of polymyalgia rheumatica may be present; the sedimentation rate and C-reactive protein level are usually elevated. In a patient with visual loss from suspected arteritic AION, temporal artery biopsy is mandatory to confirm the diagnosis. Glucocorticoids should be started immediately, without waiting for the biopsy to be completed. The diagnosis of arteritic AION is difficult to sustain in the face of a negative temporal artery biopsy, but such cases do occur.

Posterior Ischemic Optic Neuropathy This is an infrequent cause of acute visual loss, induced by the combination of severe anemia and hypotension. Cases have been reported after major blood loss during surgery, exsanguinating trauma, gastrointestinal bleeding, and renal dialysis. The fundus usually appears normal, although optic disc swelling develops if the process extends far enough anteriorly. Vision can be salvaged in some patients by prompt blood transfusion and reversal of hypotension.

Optic Neuritis This is a common inflammatory disease of the optic nerve. In the Optic Neuritis Treatment Trial (ONTT), the mean age of patients was 32 years, 77% were female, 92% had ocular pain (especially with eye movements), and 35% had optic disc swelling. In most patients, the demyelinating event was retrobulbar and the ocular fun-
B12, and folic acid levels should be checked in any patient with unex-
pected oral or alcoholism, can lead to insidious visual loss. Thiamine, vitamin
FMN, and folic acid. Deficiency states, induced either by starvation, malabsorp-
tion, or alcoholism, can retard the development of more lesions. In summary, an MR scan
is recommended in every patient with a first attack of optic neuritis. When visual loss is severe (worse than 20/100), treatment with intra-
venous followed by oral glucocorticoids hastens recovery. If multiple
lesions are present on the MR scan, treatment with interferon beta-1a
should be broached with the patient.

**Leber’s Hereditary Optic Neuropathy** This is a disease of young men, char-
acterized by gradual painless, severe, central visual loss in one eye,
followed weeks or months later by the same process in the other eye. Acutely, the optic disc appears mildly plethoric with surface capillary
telangiectases, but no vascular leakage on fluorescein angiography. Eventually optic atrophy ensues. Leber’s optic neuropathy is caused by a point mutation at codon 11778 in the mitochondrial gene encoding
nicotinamide adenine dinucleotide dehydrogenase (NADH) sub-
unit 4. Additional mutations responsible for the disease have been identified, most in mitochondrial genes encoding proteins involved in
electron transport. Mitochondrial mutations causing Leber’s neuropathy are inherited from the mother by all her children, but usually only
sons develop symptoms. There is no treatment.

**Toxic Optic Neuropathy** This can result in acute visual loss with bilateral
optic disc swelling and central or cecocentral scotomas. Such cases have been reported to result from exposure to ethambutol, methyl al-
cohol (moonshine), ethylene glycol (antifreeze), or carbon monoxide.
In toxic optic neuropathy, visual loss can also develop gradually and
produce optic atrophy (Fig. 25-10) without a phase of acute optic disc
edema. Many agents have been implicated as a cause of toxic optic
neuropathy, but the evidence supporting the association for many is
weak. The following is a partial list of potential offending drugs or
toxins: disulfiram, ethchlorvynol, chloramphenicol, amiodarone,
monoclonal anti-CD3 antibody, ciprofloxacin, digitalis, streptomyacin,
lead, arsenic, thallium, D-penicillamine, isoniazid, emetine, and sul-
fonamides. Deficiency states, induced either by starvation, malabsorp-
tion, or alcoholism, can lead to insidious visual loss. Thiamine, vitamin
B12, and folic acid levels should be checked in any patient with unex-
plained, bilateral central scotomas and optic pallor.

**Papilledema** This connotes bilateral optic disc swelling from raised intracranial pressure (Fig. 25-11). Headache is a frequent, but not in-
variable, accompaniment. All other forms of optic disc swelling, e.g.,
from optic neuritis or ischemic optic neuropathy, should be called “optic disc edema.” This convention is arbitrary but serves to avoid confusion. Often it is difficult to differentiate papilledema from other
forms of optic disc edema by fundus examination alone. Transient visual obscurations are a classic symptom of papilledema. They can
occur in only one eye or simultaneously in both eyes. They usually
last seconds but can persist longer if the papilledema is fulminant. Obscurations follow abrupt shifts in posture or happen spontaneously.
When obscurations are prolonged or spontaneous, the papilledema is more threatening. Visual acuity is not affected by papilledema unless the papilledema is severe, long-standing, or accompanied by macular
edema and hemorrhage. Visual field testing shows enlarged blind spots
and peripheral constriction (Fig. 25-2F). With unremitting papil-
ledema, peripheral visual field loss progresses in an insidious fashion
while the optic nerve develops atrophy. In this setting, reduction of
toxic optic swelling is an ominous sign of a dying nerve rather than an
encouraging indication of resolving papilledema.

**Papilledema** is defined as a puffed out optic disc. 

**Optic Disc Edema** is defined as a puffed out optic disc with a difference in final acuity (measured 6 months after the attack), but the recovery of visual function occurs more rapidly.

For some patients, optic neuritis remains an isolated event. How-
ever, the ONTT showed that the 5-year cumulative probability of de-
veloping clinically definite multiple sclerosis following optic neuritis is 30% in patients with two or more demyelinating plaques on brain
magnetic resonance (MR) imaging, treatment with interferon beta-1a can
retard the development of more lesions. In summary, an MR scan
is recommended in every patient with a first attack of optic neuritis.
When visual loss is severe (worse than 20/100), treatment with intra-
venous followed by oral glucocorticoids hastens recovery. If multiple
lesions are present on the MR scan, treatment with interferon beta-1a
should be broached with the patient.

**Leber’s Hereditary Optic Neuropathy** This is a disease of young men, char-
acterized by gradual painless, severe, central visual loss in one eye,
followed weeks or months later by the same process in the other eye. Acutely, the optic disc appears mildly plethoric with surface capillary
telangiectases, but no vascular leakage on fluorescein angiography. Eventually optic atrophy ensues. Leber’s optic neuropathy is caused by a point mutation at codon 11778 in the mitochondrial gene encoding
nicotinamide adenine dinucleotide dehydrogenase (NADH) sub-
unit 4. Additional mutations responsible for the disease have been identified, most in mitochondrial genes encoding proteins involved in
electron transport. Mitochondrial mutations causing Leber’s neuropathy are inherited from the mother by all her children, but usually only
sons develop symptoms. There is no treatment.

**Toxic Optic Neuropathy** This can result in acute visual loss with bilateral
optic disc swelling and central or cecocentral scotomas. Such cases have been reported to result from exposure to ethambutol, methyl al-
cohol (moonshine), ethylene glycol (antifreeze), or carbon monoxide.
In toxic optic neuropathy, visual loss can also develop gradually and
produce optic atrophy (Fig. 25-10) without a phase of acute optic disc
edema. Many agents have been implicated as a cause of toxic optic
neuropathy, but the evidence supporting the association for many is
weak. The following is a partial list of potential offending drugs or
toxins: disulfiram, ethchlorvynol, chloramphenicol, amiodarone,
monoclonal anti-CD3 antibody, ciprofloxacin, digitalis, streptomyacin,
lead, arsenic, thallium, D-penicillamine, isoniazid, emetine, and sul-
fonamides. Deficiency states, induced either by starvation, malabsorp-
tion, or alcoholism, can lead to insidious visual loss. Thiamine, vitamin
B12, and folic acid levels should be checked in any patient with unex-
plained, bilateral central scotomas and optic pallor.

**Papilledema** This connotes bilateral optic disc swelling from raised intracranial pressure (Fig. 25-11). Headache is a frequent, but not in-
variable, accompaniment. All other forms of optic disc swelling, e.g.,
from optic neuritis or ischemic optic neuropathy, should be called “optic disc edema.” This convention is arbitrary but serves to avoid confusion. Often it is difficult to differentiate papilledema from other
forms of optic disc edema by fundus examination alone. Transient visual obscurations are a classic symptom of papilledema. They can
occur in only one eye or simultaneously in both eyes. They usually
last seconds but can persist longer if the papilledema is fulminant. Obscurations follow abrupt shifts in posture or happen spontaneously.
When obscurations are prolonged or spontaneous, the papilledema is more threatening. Visual acuity is not affected by papilledema unless the papilledema is severe, long-standing, or accompanied by macular
edema and hemorrhage. Visual field testing shows enlarged blind spots
and peripheral constriction (Fig. 25-2F). With unremitting papil-
ledema, peripheral visual field loss progresses in an insidious fashion
while the optic nerve develops atrophy. In this setting, reduction of
toxic optic swelling is an ominous sign of a dying nerve rather than an
encouraging indication of resolving papilledema.

Evaluation of papilledema requires neuroimaging to exclude an intracranial lesion. MR angiography is appropriate in selected cases to
search for a dural venous sinus occlusion or an arteriovenous shunt.
If neuroradiologic studies are negative, the subarachnoid opening pres-
sure should be measured by lumbar puncture. An elevated pressure,
with normal cerebrospinal fluid, points by exclusion to the diagnosis of pseudotumor cerebri (idiopathic intracranial hypertension). The ma-
jority of patients are young, female, and obese. Treatment with a car-
bonic anhydrase inhibitor such as acetazolamide lowers intracranial
pressure by reducing the production of cerebrospinal fluid. Weight
reduction is vital but often unsuccessful. If acetazolamide and weight
loss fail, and visual field loss is progressive, a shunt should be per-
formed without delay to prevent blindness. Occasionally, emergency

**FIGURE 25-9** Retrobulbar optic neuritis is characterized by a normal fundus exami-
nation initially, hence the rubric, “the doctor sees noth-
ing, and the patient sees nothing.” Optic atrophy de-
velops after severe or re-
peated attacks.

**FIGURE 25-10** Optic atrophy is not a specific diagnosis, but refers to the combination
of optic disc pallor, arteriolar narrowing, and nerve fiber layer destruction produced by
a host of eye diseases, especially optic neuropathies.

**FIGURE 25-11** Papil-
ledema means optic disc
edema from raised intracra-
nial pressure. This obese
young women with pseudo-
tumor cerebri was misdiag-
nosed as a migraineur until
fundus examination was per-
formed, showing optic disc
elevation, hemorrhages, and
cotton wool spots.
surgery is required for sudden blindness caused by fulminant papilledema.

**Optic Disc Drusen**  These are refractile deposits within the substance of the optic nerve head (Fig. 25-12). They are unrelated to drusen of the retina, which occur in age-related macular degeneration. Optic disc drusen are most common in people of northern European descent. Their diagnosis is obvious when they are visible as glittering particles upon the surface of the optic disc. However, in many patients they are hidden beneath the surface, producing pseudo-papilledema. It is important to recognize optic disc drusen to avoid an unnecessary evaluation for papilledema. Ultrasound or computed tomography (CT) scanning is sensitive for detection of buried optic disc drusen because they contain calcium. In most patients, optic disc drusen are an incidental, innocuous finding, but they can produce visual obscurations. On perimetry they give rise to enlarged blind spots and arcuate scotomas from damage to the optic disc. With increasing age, drusen tend to become more exposed on the disc surface as optic atrophy develops. Hemorrhage, choroidal neovascular membrane, and AION are more likely to occur in patients with optic disc drusen. No treatment is available.

**Vitreous Degeneration**  This occurs in all individuals with advancing age, leading to visual symptoms. Opacities develop in the vitreous, casting annoying shadows upon the retina. As the eye moves, these distracting “floaters” move synchronously, with a slight lag caused by inertia of the vitreous gel. Vitreous traction upon the retina causes mechanical stimulation, resulting in perception of flashing lights. This photopsia is brief and confined to one eye, in contrast to the bilateral, prolonged scintillations of cortical migraine. Contraction of the vitreous can result in sudden separation from the retina, heralded by an alarming shower of floaters and photopsia. This process, known as *vitreous detachment*, is a frequent involutional event in the elderly. It is not harmful unless it damages the retina. A careful examination of the dilated fundus is important in any patient complaining of floaters or photopsia to search for peripheral tears or holes. If such a lesion is found, laser application or cryotherapy can forestall a retinal detachment. Occasionally a tear ruptures a retinal blood vessel, causing vitreous hemorrhage and sudden loss of vision. On attempted ophtalmoscopy the fundus is hidden by a dark red haze of blood. Ultrasound is required to examine the interior of the eye for a retinal tear or detachment. If the hemorrhage does not resolve spontaneously, the vitreous can be removed surgically. Vitreous hemorrhage also occurs from the fragile neovascular vessels that proliferate on the surface of the retina in diabetes, sickle cell anemia, and other ischemic ocular diseases.

**Retinal Detachment**  This produces symptoms of floaters, flashing lights, and a scotoma in the peripheral visual field corresponding to the detachment (Fig. 25-13). If the detachment includes the fovea, there is an afferent pupil defect and the visual acuity is reduced. In most eyes, retinal detachment starts with a hole, flap, or tear in the peripheral retina (rhegmatogenous retinal detachment). Patients with peripheral retinal thinning (lattice degeneration) are particularly vulnerable to this process. Once a break has developed in the retina, liquefied vitreous is free to enter the subretinal space, separating the retina from the pigment epithelium. The combination of vitreous traction upon the retinal surface and passage of fluid behind the retina leads inexorably to detachment. Patients with a history of myopia, trauma, or prior cataract extraction are at greatest risk for retinal detachment. The diagnosis is confirmed by ophtalmosscopic examination of the dilated eye.

**Classic Migraine** (See also Chap. 14)  This usually occurs with a visual aura lasting about 20 min. In a typical attack, a small central disturbance in the field of vision marches toward the periphery, leaving a transient scotoma in its wake. The expanding border of migraine scotoma has a scintillating, dancing, or zig-zag edge, resembling the bastions of a fortified city, hence the term *fortification spectra*. Patients’ descriptions of fortification spectra vary widely and can be confused with amaurosis fugax. Migraine patterns usually last longer and are perceived in both eyes, whereas amaurosis fugax is brief and occurs in only one eye. Migraine phenomena also remain visible in the dark or with the eyes closed. Generally they are confined to either the right or left visual hemifield, but sometimes both fields are involved simultaneously. Patients often have a long history of stereotypic attacks. After the visual symptoms recede, headache develops in most patients.

**Transient Ischemic Attacks**  Vertebrobasilar insufficiency may result in acute homonymous visual symptoms. Many patients mistakenly describe symptoms in their left or right eye, when in fact they are occurring in the left or right hemifield of both eyes. Interruption of blood supply to the visual cortex causes a sudden fogging or graying of vision, occasionally with flashing lights or other positive phenomena that mimic migraine. Cortical ischemic attacks are briefer in duration than migraine, occur in older patients, and are not followed by headache. There may be associated signs of brainstem ischemia, such as diplopia, vertigo, numbness, weakness, or dysarthria.

**Stroke**  This occurs when interruption of blood supply from the posterior cerebral artery to the visual cortex is prolonged. The only finding on examination is a homonymous visual field defect that stops abruptly at the vertical meridian. Occipital lobe stroke is usually due to thrombotic occlusion of the vertebrobasilar system, embolus, or dissection. Lobar hemorrhage, tumor, abscess, and arteriovenous malformation are other common causes of hemianopic cortical visual loss.

**Factitious (Functional, Nonorganic) Visual Loss**  This is claimed by hysterics or malingerers. The latter comprise the vast majority, seeking sym-
pathy, special treatment, or financial gain by feigning loss of sight. The diagnosis is suspected when the history is atypical, physical findings are lacking or contradictory, inconsistencies emerge on testing, and a secondary motive can be identified. In our litigious society, the fraudulent pursuit of recompense has spawned an epidemic of factitious visual loss.

**CHRONIC VISUAL LOSS**

**Cataract** This is a clouding of the lens sufficient to reduce vision. Most cataracts develop slowly as a result of aging, leading to gradual impairment of vision. The formation of cataract occurs more rapidly in patients with a history of ocular trauma, uveitis, or diabetes mellitus. Cataracts are acquired in a variety of genetic diseases, such as myotonic dystrophy, neurofibromatosis type 2, and galactosemia. Radiation therapy and glucocorticoid treatment can induce cataract as a side effect. The cataracts associated with radiation or glucocorticoids have a typical posterior subcapsular location. Cataract can be detected by noting an impaired red reflex when viewing light reflected from the fundus with an ophthalmoscope or by examining the dilated eye using the slit lamp.

The only treatment for cataract is surgical extraction of the opacified lens. Over a million cataract operations are performed each year in the United States. The operation is generally done under local anesthesia on an outpatient basis. A plastic or silicone intraocular lens is placed within the empty lens capsule in the posterior chamber, substituting for the natural lens and leading to rapid recovery of sight. More than 95% of patients who undergo cataract extraction can expect an improvement in vision. In many patients, the lens capsule remaining in the eye after cataract extraction eventually turns cloudy, causing a secondary loss of vision. A small opening is made in the lens capsule with a laser to restore clarity.

**Glaucoma** This is a slowly progressive, insidious optic neuropathy, usually associated with chronic elevation of intraocular pressure. In Americans of African descent it is the leading cause of blindness. The mechanism whereby raised intraocular pressure injures the optic nerve is not understood. Axons entering the inferotemporal and superotemporal aspects of the optic disc are damaged first, producing typical nerve fiber bundle or arcuate scotomas on perimetric testing. As fibers are destroyed, the neural rim of the optic disc shrinks and the physiologic cup within the optic disc enlarges (Fig. 25-14). This process is referred to as pathologic “cupping.” The cup-to-disc diameter is expressed as a ratio, e.g., 0.2/1. The cup-to-disc ratio ranges widely in normal individuals, making it difficult to diagnose glaucoma reliably simply by observing an unusually large or deep optic cup. Careful documentation of serial examinations is helpful. In the patient with physiologic cupping, the large cup remains stable, whereas in the patient with glaucoma it expands relentlessly over the years. Detection of visual field loss by computerized perimetry also contributes to the diagnosis. Finally, most patients with glaucoma have raised intraocular pressure. However, many patients with typical glaucomatous cupping and visual field loss have intraocular pressures that apparently never exceed the normal limit of 20 mmHg (so-called low-tension glaucoma).

In acute angle-closure glaucoma, the eye is red and painful due to abrupt, severe elevation of intraocular pressure. Such cases account for only a handful of patients with glaucoma. Most patients with glaucoma have open, anterior chamber angles. The cause of raised intraocular pressure in open angle glaucoma is unknown but is associated with gene mutations in the heritable forms.

Glaucoma is usually painless (except in angle-closure glaucoma). Pfoveal acuity is spared until end-stage disease is reached. For these reasons, severe and irreversible damage can occur before either the patient or physician recognizes the diagnosis. Screening of patients for glaucoma by noting the cup-to-disc ratio on ophthalmoscopy and by measuring intraocular pressure is vital. Glaucoma is treated with topical adrenergic agonists, cholinergic agonists, beta blockers, and prostaglandin analogues. Occasionally, systemic absorption of beta blocker from eye drops can be sufficient to cause side effects of bradycardia, hypotension, heart block, bronchospasm, or depression. Topical or oral carbonic anhydrase inhibitors are used to lower intraocular pressure by reducing aqueous production. Laser treatment of the trabecular meshwork in the anterior chamber angle improves aqueous outflow from the eye. If medical or laser treatments fail to halt optic nerve damage from glaucoma, a filter must be constructed surgically (trabeculectomy) to release aqueous from the eye in a controlled fashion.

**Macular Degeneration** This is a major cause of gradual, painless, bilateral central visual loss in the elderly. The old term, “senile macular degeneration,” misinterpreted by many patients as an unflattering reference, has been replaced with “age-related macular degeneration.” It occurs in a nonexudative (dry) form and an exudative (wet) form. The nonexudative process begins with the accumulation of extracellular deposits, called drusen, underneath the retinal pigment epithelium. On ophthalmoscopy, they are pleomorphic but generally appear as small discrete yellow lesions clustered in the macula (Fig. 25-15). With time they become larger, more numerous, and confluent. The retinal pigment epithelium becomes focally detached and atrophic, causing visual loss by interfering with photoreceptor function. Treatment with vitamins C and E, beta carotene, and zinc may retard dry macular degeneration.

Exudative macular degeneration, which develops in only a minority of patients, occurs when neovascular vessels from the choroid grow through defects in Bruch’s membrane into the potential space beneath the retinal pigment epithelium. Leakage from these vessels produces elevation of the retina and pigment epithelium, with distortion (metamorphopsia) and blurring of vision. Although onset of these symptoms is usually gradual, bleeding from subretinal choroidal neovascular membranes sometimes causes acute visual loss. The neovascular membranes can be difficult to see on fundus examination because they are beneath the retina. Fluorescein or indocyanine green angiography is extremely useful for their detection. In some patients, prompt laser ablation of choroidal neovascular membranes seen on fluorescein angiography can halt the exudative process. However, the neovascular membranes frequently recur, requiring constant vigilance and repeated photocoagulation.
Major or repeated hemorrhage under the retina from neovascular membranes results in fibrosis, development of a round (disciform) macular scar, and permanent loss of central vision. Surgical attempts to remove subretinal membranes in age-related macular degeneration have not improved vision in most patients. However, outcomes have been more encouraging for patients with choroidal neovascular membranes from ocular histoplasmosis syndrome.

**Central Serous Chorioretinopathy** This primarily affects males between the ages of 20 and 50. Leakage of serous fluid from the choroid causes small, localized detachment of the retinal pigment epithelium and the neurosensory retina. These detachments produce acute or chronic symptoms of metamorphopsia and blurred vision when the macula is involved. They are difficult to visualize with a direct ophthalmoscope because the detached retina is transparent and only slightly elevated. Diagnosis of central serous chorioretinopathy is made easily by fluorescein angiography, which shows dye streaming into the subretinal space. The cause of central serous chorioretinopathy is unknown. Symptoms may resolve spontaneously if the retina reattaches, but recurrent detachment is common. Laser photocoagulation has benefited some patients with this condition.

**Diabetic Retinopathy** A rare disease until 1921, when the discovery of insulin resulted in a dramatic improvement in life expectancy for patients with diabetes mellitus, it is now a leading cause of blindness in the United States. The retinopathy of diabetes takes years to develop but eventually appears in nearly all cases. Regular surveillance of the dilated fundus is crucial for any patient with diabetes. In advanced diabetic retinopathy, the proliferation of neovascular vessels leads to blindness from vitreous hemorrhage, retinal detachment, and glaucoma (see Fig. 323-9). These complications can be avoided in most patients by administration of panretinal laser photocoagulation at the appropriate point in the evolution of the disease. →*For further discussion of the manifestations and management of diabetic retinopathy, see Chap. 323.*

**Retinitis Pigmentosa** This is a general term for a disparate group of rod and cone dystrophies characterized by progressive night blindness, visual field constriction with a ring scotoma, loss of acuity, and an abnormal electroretinogram (ERG). It occurs sporadically or in an autosomal recessive, dominant, or X-linked pattern. Irregular black deposits of clumped pigment in the peripheral retina, called *bone spicules* because of their vague resemblance to the spicules of cancellous bone, give the disease its name (Fig. 25-16). The name is actually a misnomer because retinitis pigmentosa is not an inflammatory process. Most cases are due to a mutation in the gene for rhodopsin, the rod photopigment, or in the gene for peripherin, a glycoprotein located in photoreceptor outer segments. Vitamin A (15,000 IU/day) slightly retards the deterioration of the ERG in patients with retinitis pigmentosa but has no beneficial effect on visual acuity or fields. Some forms of retinitis pigmentosa occur in association with rare, hereditary systemic diseases (olivopontocerebellar degeneration, Bassen-Kornzweig disease, Kearn-Sayre syndrome, Refsum’s disease). Chronic treatment with chloroquine, hydroxychloroquine, and phenothiazines (especially thioridazine) can produce visual loss from a toxic retinopathy that resembles retinitis pigmentosa.

**Epiretinal Membrane** This is a fibrocellular tissue that grows across the inner surface of the retina, causing metamorphopsia and reduced visual acuity from distortion of the macula. A crinkled, cellophane-like membrane is visible on the retinal examination. Epiretinal membrane is most common in patients over 50 years of age and is usually unilateral. Most cases are idiopathic, but some occur as a result of hypertensive retinopathy, diabetes, retinal detachment, or trauma. When visual acuity is reduced to the level of about 6/24 (20/80), vitrectomy and surgical peeling of the membrane to relieve macular puckerings are recommended. Contraction of an epiretinal membrane sometimes gives rise to a macular hole. Most macular holes, however, are caused by local vitreous traction within the fovea. Vitrectomy can improve acuity in selected cases.

**Melanoma and Other Tumors** Melanoma is the most common primary tumor of the eye (Fig. 25-17). It causes photopsia, an enlarging scotoma, and loss of vision. A small melanoma is often difficult to differentiate from a benign choroidal nevus. Serial examinations are required to document a malignant pattern of growth. Treatment of melanoma is controversial. Options include enucleation, local resection, and irradiation. *Metastatic tumors* to the eye outnumber primary tumors. Breast and lung carcinoma have a special propensity to spread to the choroid or iris. Leukemia and lymphoma also commonly invade ocular tissues. Sometimes their only sign on eye examination is cellular debris in the vitreous, which can masquerade as a chronic posterior uveitis. *Retrobulbar tumor* of the optic nerve (meningioma, glioma) or chiasmal tumor (pituitary adenoma, meningioma) produces gradual visual loss with few objective findings, except for optic disc pallor. Rarely, sudden expansion of a pituitary adenoma from infarction and bleeding (*pituitary apoplexy*) causes acute retrobulbar visual loss, with headache, nausea, and ocular motor nerve palsies. In any patient with visual field loss or optic atrophy, CT or MR scanning should be considered if the cause remains unknown after careful review of the history and thorough examination of the eye.

**PROPTOSIS**

When the globes appear asymmetric, the clinician must first decide which eye is abnormal. Is one eye recessed within the orbit (*enophthalmos*) or is the other eye protuberant (*proptosis*)? A small globe or a Horner’s syndrome can give the appearance of enophthalmos. True enophthalmos occurs commonly after trauma, from atrophy of retrobulbar fat, or fracture of the orbital floor. The position of the eyes within the orbits is measured using a Hertel exophthalmometer, a hand-held instrument that records the position of the anterior corneal surface relative to the lateral orbital rim. If this instrument is not available, relative eye position can be judged by...
bending the patient’s head forward and looking down upon the orbits. A proptosis of only 2 mm in one eye is detectable from this perspective. The development of proptosis implies a space-occupying lesion in the orbit, and usually warrants CT or MR imaging.

**Graves’ Ophthalmopathy** This is the leading cause of proptosis in adults (Chap. 320). The proptosis is often asymmetric and can even appear to be unilateral. Orbital inflammation and engorgement of the extraocular muscles, particularly the medial rectus and the inferior rectus, account for the protrusion of the globe. Corneal exposure, lid retraction, conjunctival injection, restriction of gaze, diplopia, and visual loss from optic nerve compression are cardinal symptoms. Graves’ ophthalmopathy is treated with oral prednisone (60 mg/d) for 1 month, followed by a taper over several months, topical lubricants, eyelid surgery, eye muscle surgery, or orbital decompression. Radiation therapy is not effective.

**Orbital Pseudotumor** This is an idiopathic, inflammatory orbital syndrome, frequently confused with Graves’ ophthalmopathy. Symptoms are pain, limited eye movements, proptosis, and congestion. Evaluation for sarcoidosis, Wegener’s granulomatosis, and other types of orbital vasculitis or collagen-vascular disease is negative. Imaging often shows swollen eye muscles (orbital myositis) with enlarged tendons. By contrast, in Graves’ ophthalmopathy the tendons of the eye muscles are usually spared. The Tolosa-Hunt syndrome may be regarded as an extension of orbital pseudotumor through the superior orbital fissure into the cavernous sinus. The diagnosis of orbital pseudotumor is difficult. Biopsy of the orbit frequently yields nonspecific evidence of fat infiltration by lymphocytes, plasma cells, and eosinophils. A dramatic response to a therapeutic trial of systemic glucocorticoids indirectly provides the best confirmation of the diagnosis.

**Orbital Cellulitis** This causes pain, lid erythema, proptosis, conjunctival chemosis, restricted motility, decreased acuity, afferent papillary defect, fever, and leukocytosis. It often arises from the paranasal sinuses, especially by contiguous spread of infection from the ethmoid sinus through the lamina papyracea of the medial orbit. A history of recent upper respiratory tract infection, chronic sinusitis, thick mucous secretions, or dental disease is significant in any patient with suspected orbital cellulitis. Blood cultures should be obtained, but they are usually negative. Most patients respond to empirical therapy with broad-spectrum intravenous antibiotics. Occasionally, orbital cellulitis follows an overwhelming course, with massive proptosis, blindness, septic cavernous sinus thrombosis, and meningitis. To avert this disaster, orbital cellulitis should be managed aggressively in the early stages, with immediate antibiotic therapy and imaging of the orbits. Prompt surgical drainage of an orbital abscess or paranasal sinusitis is indicated if optic nerve function deteriorates despite antibiotics.

**Tumors** Tumors of the orbit cause painless, progressive proptosis. The most common primary tumors are hemangioma, lymphangioma, neurofibroma, dermoid cyst, adenoid cystic carcinoma, optic nerve glioma, optic nerve meningioma, and benign mixed tumor of the lacrimal gland. Metastatic tumor to the orbit occurs frequently in breast carcinoma, lung carcinoma, and lymphoma. Diagnosis by fine-needle aspiration followed by urgent radiation therapy can sometimes preserve vision.

**Carotid Cavernous Fistulas** With anterior drainage through the orbit these produce proptosis, diplopia, glaucoma, and corkscrew, arterialized conjunctival vessels. Direct fistulas usually result from trauma. They are easily diagnosed because of the prominent signs produced by high-flow, high-pressure shunting. Indirect fistulas, or dural arteriovenous malformations, are more likely to occur spontaneously, especially in older women. The signs are more subtle and the diagnosis is frequently missed. The combination of slight proptosis, diplopia, enlarged muscles, and an injected eye is often mistaken for thyroid ophthalmopathy. A bruit heard upon auscultation of the head, or reported by the patient, is a valuable diagnostic clue. Imaging shows an enlarged superior ophthalmic vein in the orbits. Carotid cavernous shunts can be eliminated by intravascular embolization.

**PTOSIS**

**Blepharoptosis** This is an abnormal drooping of the eyelid. Unilateral or bilateral ptosis can be congenital, from dysgenesis of the levator palpebrae superioris, or from abnormal insertion of its aponeurosis into the eyelid. Acquired ptosis can develop so gradually that the patient is unaware of the problem. Inspection of old photographs is helpful in dating the onset. A history of prior trauma, eye surgery, contact lens use, diplopia, systemic symptoms (e.g., dysphagia or peripheral muscle weakness), or a family history of ptosis should be sought. Fluctuating ptosis that worsens late in the day is typical of myasthenia gravis. Examination should focus upon evidence for proptosis, eyelid masses or deformities, inflammation, pupil inequality, or limitation of motility. The width of the palpebral fissures is measured in primary gaze to quantitate the degree of ptosis. The ptosis will be underestimated if the patient compensates by lifting the brow with the frontalis muscle.

**Mechanical Ptosis** This occurs in many elderly patients from stretching and redundancy of eyelid skin and subcutaneous fat (dermatochalasis). The extra weight of these sagging tissues causes the lid to droop. Enlargement or deformation of the eyelid from infection, tumor, trauma, or inflammation also results in ptosis on a purely mechanical basis.

**Aponeurotic Ptosis** This is an acquired dehiscence or stretching of the aponeurotic tendon, which connects the levator muscle to the tarsal plate of the eyelid. It occurs commonly in older patients, presumably from loss of connective tissue elasticity. Aponeurotic ptosis is also a frequent sequela of eyelid swelling from infection or blunt trauma to the orbit, cantharact surgery, or hard contact lens usage.

**Myogenic Ptosis** The causes of myogenic ptosis include myasthenia gravis (Chap. 366) and a number of rare myopathies that manifest with ptosis. The term chronic progressive external ophthalmoplegia refers to a spectrum of systemic diseases caused by mutations of mitochondrial DNA. As the name implies, the most prominent findings are symmetric, slowly progressive ptosis and limitation of eye movements. In general, diplopia is a late symptom because all eye movements are reduced equally. In the Kearns-Sayre variant, retinal pigmentary changes and abnormalities of cardiac conduction develop. Peripheral muscle biopsy shows characteristic “ragged-red fibers.” Oculopharyngeal dystrophy is a distinct autosomal dominant disease with onset in middle age, characterized by ptosis, limited eye movements, and trouble swallowing. Myotonic dystrophy, another autosomal dominant disorder, causes ptosis, ophthalmoplegia, cataract, and pigmentary retinopathy. Patients have muscle wasting, myotonia, frontal balding, and cardiac abnormalities.

**Neurogenic Ptosis** This results from a lesion affecting the innervation to either of the two muscles that open the eyelid: Müller’s muscle or the levator palpebrae superioris. Examination of the pupil helps to distinguish between these two possibilities. In Horner’s syndrome, the eye with ptosis has a smaller pupil and the eye movements are full. In an oculomotor nerve palsy, the eye with the ptosis has a larger, or a normal, pupil. If the pupil is normal but there is limitation of adduction, elevation, and depression, a pupil-sparing oculomotor nerve palsy is likely (see next section). Rarely, a lesion affecting the small, central subnucleus of the oculomotor complex will cause bilateral ptosis with normal eye movements and pupils.

**DOUBLE VISION**

The first point to clarify is whether diplopia persists in either eye after covering the fellow eye. If it does, the diagnosis is monocular diplopia. The cause is usually intrinsic to the eye and therefore has no dire implications for the patient. Corneal aberrations (e.g., keratoconus, pterygium), uncorrected refractive error, cataract, or foveal traction may give rise to monocular diplopia. Occasionally it is a symptom of malingering or psychiatric disease. Diplopia alleviated by covering
one eye is binocular diplopia and is caused by disruption of ocular alignment. Inquiry should be made into the nature of the double vision (purely side-by-side versus partial vertical displacement of images), mode of onset, duration, intermittency, diurnal variation, and associated neurologic or systemic symptoms. If the patient has diplopia while being examined, motility testing should reveal a deficiency corresponding to the patient’s symptoms. However, subtle limitation of ocular excursions is often difficult to detect. For example, a patient with a slight left abducens nerve paresis may appear to have full eye movements, despite a complaint of horizontal diplopia upon looking to the left. In this situation, the cover test provides a more sensitive method for demonstrating the ocular misalignment. It should be conducted in primary gaze, and then with the head turned and tilted in each direction. In the above example, a cover test with the head turned to the right will maximize the fixation shift evoked by the cover test.

Occasionally, a cover test performed in an asymptomatic patient during a routine examination will reveal an ocular deviation. If the eye movements are full and the ocular misalignment is equal in all directions of gaze (concomitant deviation), the diagnosis is strabismus. In this condition, which affects about 1% of the population, fusion is disrupted in infancy or early childhood. To avoid diplopia, vision is suppressed from the nonfixating eye. In some children, this leads to impaired vision (amblyopia, or “lazy” eye) in the deviated eye.

Binocular diplopia occurs from a wide range of processes: infectious, neoplastic, metabolic, degenerative, inflammatory, and vascular. One must decide if the diplopia is neurogenic in origin or due to restriction of globe rotation by local disease in the orbit. Orbital pseudotumor, myositis, infection, tumor, thyroid disease, and muscle entrapment (e.g., from a blowout fracture) cause restrictive diplopia. The diagnosis of restriction is usually made by recognizing other associated signs and symptoms of local orbital disease in conjunction with imaging.

**Myasthenia Gravis** (See also Chap. 366) This is a major cause of diplopia. The diplopia is often intermittent, variable, and not confined to any single ocular motor nerve distribution. The pupils are always normal. Fluctuating ptosis may be present. Many patients have a purely ocular form of the disease, with no evidence of systemic muscular weakness. The diagnosis can be confirmed by an intravenous edrophonium injection or by an assay for antiacetylcholine receptor antibodies. Negative results from these tests do not exclude the diagnosis. Botulism from food or wound poisoning can mimic ocular myasthenia.

After restrictive orbital disease and myasthenia gravis are excluded, a lesion of a cranial nerve supplying innervation to the extraocular muscles is the most likely cause of binocular diplopia.

**Oculomotor Nerve** The third cranial nerve innervates the medial, inferior, and superior recti; inferior oblique; levator palpebrae superioris; and the iris sphincter. Total palsy of the oculomotor nerve causes ptosis, a dilated pupil, and leaves the eye “down and out” because of the unopposed action of the lateral rectus and superior oblique. This combination of findings is obvious. More challenging is the diagnosis of an early or partial oculomotor nerve palsy. In this setting, any combination of ptosis, pupil dilation, and weakness of the eye muscles supplied by the oculomotor nerve may be encountered. Frequent serial examinations during the evolving phase of the palsy and a high index of suspicion help ensure that the diagnosis is not missed. The advent of an oculomotor nerve palsy with any degree of pupil involvement in an otherwise healthy patient, especially when accompanied by pain, raises the specter of a circle of Willis aneurysm. If an MR imaging shows no compressive lesion, an arteriogram must be considered to rule out an aneurysm of either the posterior communicating artery or the basilar artery. If the pupil is entirely normal, with all other components of an oculomotor palsy present, aneurysm is so rare that an angiogram is seldom indicated.

A lesion of the oculomotor nucleus in the rostral midbrain produces signs that differ from those caused by a lesion of the nerve itself. There is bilateral ptosis because the levator muscle is innervated by a single central subnucleus. There is also weakness of the contralateral superior rectus, because it is supplied by the oculomotor nucleus on the other side. Occasionally both superior recti are weak. Isolated nuclear oculomotor palsy is rare. Usually neurologic examination reveals additional signs to suggest brainstem damage from infarction, hemorrhage, tumor, or infection.

Injury to structures surrounding fascicles of the oculomotor nerve descending through the midbrain has given rise to a number of classic eponymic designations. In Nott’s syndrome, injury to the superior cerebellar peduncle causes ipsilateral oculomotor palsy and contralateral cerebellar ataxia. In Benedikt’s syndrome, injury to the red nucleus results in ipsilateral oculomotor palsy and contralateral tremor, chorea, and athetosis. Claude’s syndrome incorporates features of both the aforementioned syndromes, by injury to both the red nucleus and the superior cerebellar peduncle. Finally, in Weber’s syndrome, injury to the cerebral peduncle causes ipsilateral oculomotor palsy with contralateral hemiparesis.

In the subarachnoid space the oculomotor nerve is vulnerable to aneurysm, meningitis, tumor, infarction, and compression. In cerebellar herniation the nerve becomes trapped between the edge of the tentorium and the uncus of the temporal lobe. Oculomotor palsy can also occur from midbrain torsion and hemorrhages during herniation. In the cavernous sinus, oculomotor palsy arises from carotid aneurysm, carotid cavernous fistula, cavernous sinus thrombosis, tumor (papillary adenoma, meningioma, metastasis), herpes zoster infection, and the Tolosa-Hunt syndrome.

The etiology of an isolated, pupil-sparing oculomotor palsy often remains an enigma, even after neuroimaging and extensive laboratory testing. Most cases are thought to result from microvascular infarction of the nerve, somewhere along its course from the brainstem to the orbit. Usually the patient complains of pain. Diabetes, hypertension, and vascular disease are major risk factors. Spontaneous recovery over a period of months is the rule. If this fails to occur, or if new findings develop, the diagnosis of microvascular oculomotor nerve palsy should be reconsidered. Aberrant regeneration is common when the oculomotor nerve is injured by trauma or compression (tumor, aneurysm). Miswiring of sprouting fibers to the levator muscle and the rectus muscles results in elevation of the eyelid upon downgaze or adduction. The pupil also constricts upon attempted adduction, elevation, or depression of the globe. Aberrant regeneration is not seen after oculomotor palsy from microvascular infarct and hence vitiates that diagnosis.

**Troclear Nerve** The fourth cranial nerve originates in the midbrain, just caudal to the oculomotor nerve complex. Fibers exit the brainstem dorsally and cross to innervate the contralateral superior oblique. The principal actions of this muscle are to depress and to intort the globe. A palsy therefore results in hypertropia and exocytorsion. The cyclotorsion is seldom noticed by patients. Instead, they complain of vertical diplopia, especially upon reading or looking down. The vertical diplopia is also exacerbated by tilting the head toward the side with the muscle palsy, and alleviated by tilting it away. This “head tilt” test is a cardinal diagnostic feature.

Isolated trochlear nerve palsy occurs from all the causes listed above for the oculomotor nerve, except aneurysm. The trochlear nerve is particularly apt to suffer injury after closed head trauma. The free edge of the tentorium is thought to impinge upon the nerve during a concussive blow. Most isolated trochlear nerve palsies are idiopathic and hence diagnosed by exclusion as “microvascular.” Spontaneous improvement occurs over a period of months in most patients. A base-down prism (conveniently applied to the patient’s glasses as a stick-on Fresnel lens) may serve as a temporary measure to alleviate diplopia. If the palsy does not resolve, the eyes can be realigned by weakening the inferior oblique muscle.

**Abducens Nerve** The sixth cranial nerve innervates the lateral rectus muscle. A palsy produces horizontal diplopia, worse on gaze to the
side of the lesion. A nuclear lesion has different consequences, because the abducens nucleus contains interneurons that project via the medial longitudinal fasciculus to the medial rectus subnucleus of the contralateral oculomotor complex. Therefore, an abducens nuclear lesion produces a complete lateral gaze palsy, from weakness of both the ipsilateral lateral rectus and the contralateral medial rectus. Foville’s syndrome following dorsal pontine injury includes lateral gaze palsy, ipsilateral facial palsy, and contralateral hemiparesis incurred by damage to descending corticospinal fibers. Millard-Gubler syndrome from ventral pontine injury is similar, except for the eye findings. There is lateral rectus weakness only, instead of gaze palsy, because the abducens fascicle is injured rather than the nucleus. Infarct, tumor, hemorrhage, vascular malformation, and multiple sclerosis are the most common etiologies of brainstem abducens palsy.

After leaving the ventral pons, the abducens nerve runs forward along the clivus to pierce the dura at the petrous apex, where it enters the cavernous sinus. Along its subarachnoid course it is susceptible to meningitis, tumor (meningioma, chordoma, carcinomatous meningiitis), subarachnoid hemorrhage, trauma, and compression by aneurysm or dolichoectatic vessels. At the petrous apex, mastoiditis can produce deafness, pain, and ipsilateral abducens palsy (Gradeningo’s syndrome). In the cavernous sinus, the nerve can be affected by carotid aneurysm, carotid cavernous fistula, tumor (pituitary adenoma, meningioma, nasopharyngeal carcinoma), herpes infection, and Tolosa-Hunt syndrome.

Unilateral or bilateral abducens palsy is a classic sign of raised intracranial pressure. The diagnosis can be confirmed if papilledema is observed on fundus examination. The mechanism is still debated but is probably related to rostral-caudal displacement of the brainstem. The same phenomenon accounts for abducens palsy from low intracranial pressure (e.g., after lumbar puncture, spinal anesthesia, or spontaneous dural cerebrospinal fluid leak).

Treatment of abducens palsy is aimed at prompt correction of the underlying cause. However, the cause remains obscure in many instances, despite diligent evaluation. As mentioned above for isolated trochlear or oculomotor palsy, most cases are assumed to represent microvascular infarcts because they often occur in the setting of diabetes or other vascular risk factors. Some cases may develop as a postinfectious mononeuritis (e.g., following a viral flu). Patching one eye or applying a temporary prism will provide relief of diplopia until the palsy resolves. If recovery is incomplete, eye muscle surgery can nearly always realign the eyes, at least in primary position. A patient with an abducens palsy that fails to improve should be reevaluated for an occult etiology (e.g., chordoma, carcinomatous meningitis, carotid cavernous fistula, myasthenia gravis).

Multiple Ocular Motor Nerve Palsies These should not be attributed to spontaneous microvascular events affecting more than one cranial nerve at a time. This remarkable coincidence does occur, especially in diabetic patients, but the diagnosis is made only in retrospect after exhausting all other diagnostic alternatives. Neuroimaging should focus on the cavernous sinus, superior orbital fissure, and orbital apex, where all three ocular motor nerves are in close proximity. In the diabetic compromised host, fungal infection (e.g., Aspergillus, Cryptococcus) is a frequent cause of multiple nerve palsies. In the patient with systemic malignancy, carcinomatous meningitis is a likely diagnosis. Cytologic examination may be negative despite repeated sampling of the cerebrospinal fluid. The cancer-associated Lambert-Eaton myasthenic syndrome can also produce ophthalmoplegia. Giant cell (temporal) arteritis occasionally manifests as diplopia from ischemic palsies of extracranial muscles. Fisher syndrome, an ocular variant of Guillain-Barré, can produce ophthalmoplegia with areflexia and ataxia. Often the ataxia is mild, and the areflexia is overlooked because the physician’s attention is focused upon the eyes. Antiganglioside antibodies (GQ1b) can be detected in about 50% of cases.

Supranuclear Disorders of Gaze These are often mistaken for multiple ocular motor nerve palsies. For example, Wernicke’s encephalopathy can produce nystagmus and a partial deficit of horizontal and vertical gaze that mimics a combined abducens and oculomotor nerve palsy. The disorder occurs in malnourished or alcoholic patients and can be reversed by thiamine. Infarct, hemorrhage, tumor, multiple sclerosis, encephalitis, vasculitis, and Whipple’s disease are other important causes of supranuclear gaze palsy. Disorders of vertical gaze, especially downwards saccades, are an early feature of progressive supranuclear palsy. Smooth pursuit is affected later in the course of the disease. Parkinson’s disease, Huntington’s chorea, and olivopontocerebellar degeneration can also affect vertical gaze.

The frontal eye field of the cerebral cortex is involved in generation of saccades to the contralateral side. After hemispheric stroke, the eyes usually deviate towards the lesioned side because of the unopposed action of the frontal eye field in the normal hemisphere. With time, this deficit resolves. Seizures generally have the opposite effect: the eyes deviate conjugately away from the irritative focus. Parietal lesions disrupt smooth pursuit of targets moving toward the side of the lesion. Bilateral parietal lesions produce Balint’s syndrome, characterized by impaired eye-hand coordination (optic ataxia), difficulty initiating voluntary eye movements (ocular apraxia), and visuospatial disorientation (simultanagnosia).

Horizontal Gaze Descending cortical inputs mediating horizontal gaze ultimately converge at the level of the pons. Neurons in the paramedian pontine reticular formation are responsible for controlling conjugate gaze toward the same side. They project directly to the ipsilateral abducens nucleus. A lesion of either the paramedian pontine reticular formation or the abducens nucleus causes an ipsilateral conjugate gaze palsy. Lesions at either locus produce nearly identical clinical syndromes, with the following exception: vestibular stimulation (oculocerebral maneuver or caloric irrigation) will succeed in driving the eyes conjugately to the side in a patient with a lesion of the paramedian pontine reticular formation, but not in a patient with a lesion of the abducens nucleus.

Internuclear Ophthalmoplegia This results from damage to the medial longitudinal fasciculus ascending from the abducens nucleus in the pons to the oculomotor nucleus in the midbrain (hence, “internuclear”). Damage to fibers carrying the conjugate signal from abducens interneurons to the contralateral medial rectus motoneurons results in a failure of adduction on attempted lateral gaze. For example, a patient with a left internuclear ophthalmoplegia will have slowed or absent adducting movements of the left eye. A patient with bilateral injury to the medial longitudinal fasciculus will have bilateral internuclear ophthalmoplegia. Multiple sclerosis is the most common cause, although tumor, stroke, trauma, or any brainstem process may be responsible. One-and-a-half syndrome is due to a combined lesion of the medial longitudinal fasciculus and the abducens nucleus on the same side. The patient’s only horizontal eye movement is abduction of the eye on the other side.

Vertical Gaze This is controlled at the level of the midbrain. The neuronal circuits affected in disorders of vertical gaze are not fully elucidated, but lesions of the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal cause supranuclear paresis of upgaze, downgaze, or all vertical eye movements. Distal basilar artery ischemia is the most common etiology. Skew deviation refers to a vertical misalignment of the eyes, usually constant in all positions of gaze. The finding has poor localizing value because skew deviation has been reported after lesions in widespread regions of the brainstem and cerebellum.

Parinaud’s Syndrome Also known as dorsal midbrain syndrome, this is a distinct supranuclear vertical gaze disorder from damage to the posterior commissure. It is a classic sign of hydrocephalus from aqueductal stenosis. Pineal region tumors can cause a similar syndrome. When caused by a stroke also cause Parinaud’s syndrome. Features include loss of upgaze (and sometimes downgaze), convergence-retraction nystagmus on at-
tempted upgaze, downwards ocular deviation (“setting sun” sign), lid retraction (Collier’s sign), skew deviation, pseudoabducens palsy, and light-near dissociation of the pupils.

**Nystagmus** This is a rhythmic oscillation of the eyes, occurring physiologically from vestibular and optokinetic stimulation or pathologically in a wide variety of diseases (Chap. 20). Abnormalities of the eyes or optic nerves, present at birth or acquired in childhood, can produce a complex, searching nystagmus with irregular pendular (sinusoidal) and jerk features. This nystagmus is commonly referred to as congenital sensory nystagmus. It is a poor term, because even in children with congenital lesions, the nystagmus does not appear until several months of age. Congenital motor nystagmus, which looks similar to congenital sensory nystagmus, develops in the absence of any abnormality of the sensory visual system. Visual acuity is also reduced in congenital motor nystagmus, probably by the nystagmus itself, but seldom below a level of 20/200.

**Jerk Nystagmus** This is characterized by a slow drift off the target, followed by a fast corrective saccade. By convention, the nystagmus is named after the quick phase. Jerk nystagmus can be downbeat, upbeat, horizontal (left or right), and torsional. The pattern of nystagmus may vary with gaze position. Some patients will be oblivious to their nystagmus. Others will complain of blurred vision, or a subjective, to-and-fro movement of the environment (oscillopsia) corresponding to their nystagmus. Fine nystagmus may be difficult to see upon gross examination of the eyes. Observation of nystagmoid movements of the optic disc on opthalmoscopy is a sensitive way to detect subtle nystagmus.

**Gaze-Evoked Nystagmus** This is the most common form of jerk nystagmus. When the eyes are held eccentrically in the orbits, they have a natural tendency to drift back to primary position. The subject compensates by making a corrective saccade to maintain the deviated eye position. Many normal patients have mild gaze-evoked nystagmus. Exaggerated gaze-evoked nystagmus can be induced by drugs (sedatives, anticonvulsants, alcohol); muscle paresis; myasthenia gravis; demyelinating disease; and cerebellopontine angle, brainstem, and cerebellar lesions.

**VESTIBULAR NYSTAGMUS** Vestibular nystagmus results from dysfunction of the labyrinth (Ménière’s disease), vestibular nerve, or vestibular nucleus in the brainstem. Peripheral vestibular nystagmus often occurs in discrete attacks, with symptoms of nausea and vertigo. There may be associated tinnitus and hearing loss. Sudden shifts in head position may provoke or exacerbate symptoms.

**Downbeat Nystagmus** Downbeat nystagmus occurs from lesions near the craniocervical junction (Chiari malformation, basilar invagination). It has also been reported in brainstem or cerebellar stroke, lithium or anticonvulsant intoxication, alcoholism, and multiple sclerosis. Upbeat nystagmus is associated with damage to the pontine tegmentum, from stroke, demyelination, or tumor.

**Opsoclonus** This rare, dramatic disorder of eye movements consists of bursts of consecutive saccades (saccadomania). When the saccades are confined to the horizontal plane, the term ocular flutter is preferred. It can occur from viral encephalitis, trauma, or a paraneoplastic effect of neuroblastoma, breast carcinoma, and other malignancies. It has also been reported as a benign, transient phenomenon in otherwise healthy patients.

**SMELL**

The sense of smell determines the flavor and palatability of food and drink. It serves, along with the trigeminal system, as a monitor of inhaled chemicals, including dangerous substances such as natural gas, smoke, and air pollutants. Olfactory dysfunction affects ~1% of people under age 60 and more than half of the population beyond this age.

**DEFINITIONS** Smell is the perception of odor by the nose. Taste is the perception of salty, sweet, sour, or bitter by the tongue. Related sensations during eating such as somatic sensations of coolness, warmth, and irritation are mediated through the trigeminal, glossopharyngeal, and vagal afferents in the nose, oral cavity, tongue, pharynx, and larynx. Flavor is the complex interaction of taste, smell, and somatic sensation. Terms relating to disorders of smell include anosmia, an absence of the ability to smell; hyposmia, a decreased ability to smell; hyperosmia, an increased sensitivity to an odorant; dysosmia, distortion in the perception of an odor; phantosmia, perception of an odorant where none is present; and agnosia, inability to classify, contrast, or identify odor sensations verbally, even though the ability to distinguish between odorants or to recognize them may be normal. An odor stimulus is referred to as an odorant. Each category of smell dysfunction can be further subclassified as total (applying to all odorants) or partial (dysfunction of only select odorants).

**PHYSIOLOGY OF SMELL** The olfactory neuroepithelium is located in the superior part of the nasal cavities. It contains an orderly arrangement of bipolar olfactory receptor cells, microvillus cells, sustentacular cells, and basal cells. The dendritic process of the bipolar cell has a bulb-shaped vesicle that projects into the mucous layer and bears six to eight cilia containing the odorant. Each bipolar cell contains 56 cm² (9 in²) of surface area to receive olfactory stimuli.

Microvillus cells are located adjacent to the receptor cells on the surface of the neuroepithelium. Sustentacular cells, unlike their counterparts in the respiratory epithelium, are not specialized to secrete mucus. Although they form a tight barrier separating neurons from the outside environment, their complete function is unknown. The basal cells are progenitors of other cell types in the olfactory neuroepithelium, including the bipolar receptor cells. There is a regular turnover of bipolar receptor cells, which function as the primary sensory neurons. In addition, with injury to the cell body or its axon, the receptor cell is replaced by a differentiated basal cell, which reestablishes a central neural connection. These primary sensory neurons are unique among sensory systems in that they are regularly replaced and regenerate after injury.

The unmyelinated axons of receptor cells form the fila of the olfactory nerve, pass through the cribriform plate, and terminate within spherical masses of neuropil, termed glomeruli, in the olfactory bulb. The glomeruli are the focus of a high degree of convergence of information, since many more fibers enter than leave them. The main second-order neurons are mitral cells. The primary dendrite of each mitral cell extends into a single glomerulus. Axons of the mitral cells project...
along with the axons of adjacent tufted cells to the limbic system, including the anterior olfactory nucleus and the amygdala. Cognitive awareness of smell requires stimulation of the prepiriform cortex or amygdaloid nuclei.

A secondary site of olfactory chemosensation is located in the epithelium of the vomeronasal organ, a tubular structure that opens on the ventral aspect of the nasal septum. Sensory neurons located in the vomeronasal organ detect pheromones, nonvolatile chemical signals that in lower mammals trigger innate and stereotypic reproductive and social behaviors, as well as neuroendocrine changes. Neurons from the organ project to the accessory olfactory bulbs and not the main olfactory bulb, as does the olfactory neuroepithelium. Whether humans use the vomeronasal organ to detect and respond to chemical signals from others remains controversial. Development of the olfactory and vomeronasal system appears to be required for normal sexual maturation.

The sensation of smell begins with introduction of an odorant to the cilia of the bipolar neuron. Most odors are hydrophobic; as they move from the air phase of the nasal cavity to the aqueous phase of the olfactory mucous, they are transported toward the cilia by small water-soluble proteins called odorant-binding proteins and reversibly bind to receptors on the cilia surface. Binding leads to conformational changes in the receptor protein, activation of G protein–coupled second messengers, and generation of action potentials in the primary neurons. Intensity appears to be coded by the amount of firing in the afferent neurons.

Olfactory receptor proteins belong to the large family of G protein–coupled receptors that also includes rhodopsins; α- and β-adrenergic receptors; muscarinic acetylcholine receptors; and neurotransmitter receptors for dopamine, serotonin, and substance P. In humans, there are 300 to 1000 olfactory receptor genes belonging to 20 different families located in clusters at more than 25 different chromosomal locations. Each olfactory neuron seems to express only one or, at most, a few receptor genes, thus providing the molecular basis of odor discrimination. Bipolar cells that express similar receptors appear to be scattered across discrete spatial zones. These similar cells converge on a select few glomeruli in the olfactory bulb. The result is a potential spatial map of how we receive odor stimuli, much like the tonotopic organization of how we perceive sound.

**DISORDERS OF THE SENSE OF SMELL**

These are caused by conditions that interfere with the access of the odorant to the olfactory neuroepithelium (transport loss), injure the receptor region (sensory loss), or damage central olfactory pathways (neural loss). Currently no clinical tests exist to differentiate these different types of olfactory losses. Fortunately, the history of the disease provides important clues to the cause. The leading causes of olfactory disorders are summarized in Table 26-1; the most common etiologies are head trauma in children and young adults, and viral infections in older adults.

Head trauma is followed by unilateral or bilateral impairment of smell in up to 15% of cases; anosmia is more common than hyposmia. Olfactory dysfunction is more common when trauma is associated with loss of consciousness, moderately severe head injury (grades II to V), and skull fracture. Frontal injuries and fractures disrupt the cribiform plate and olfactory axons that perforate it. Sometimes there is an associated cerebrospinal fluid (CSF) rhinorrhea resulting from a tearing of the dura overlying the cribiform plate and paranasal sinuses. Anosmia may also follow blows to the occiput. Once traumatic anosmia develops, it is usually permanent; only 10% of patients ever improve or recover. Perversion of the sense of smell may occur as a transient phase in the recovery process.

Viral infections destroy the olfactory neuroepithelium, which is replaced by respiratory epithelium. Parainfluenza virus type 3 appears to be especially detrimental to human olfaction. HIV infection is associated with subjective distortion of taste and smell, which may become more severe as the disease progresses. The loss of taste and smell may play an important role in the development and progression of HIV-associated wasting. Congenital anosmias are rare but important. Kallmann syndrome is an X-linked disorder characterized by congenital anosmia and hypogonadotropic hypogonadism resulting from a failure of migration from the olfactory placode of olfactory receptor neurons and neurons synthesizing gonadotropin-releasing hormone (Chap. 325). Anosmia can also occur in albinos. The receptor cells are present but are hypoplastic, lack cilia, and do not project above the supporting cells.

Meningiomas of the inferior frontal region are the most frequent neoplastic cause of anosmia; loss of smell may be the only neurologic abnormality. Rarely, anosmia can occur with gliomas of the frontal lobe. Occasionally, pituitary adenomas, craniopharyngiomas, suprasellar meningiomas, and aneurysms of the anterior part of the circle of Willis extend forward and damage olfactory structures. These tumors and hamartomas may also induce seizures with olfactory hallucinations, indicating involvement of the uncus of the temporal lobe.

Dysosmia, subjective distortions of olfactory perception, may occur with intranasal diseases that partially impair smell or may represent a phase in the recovery from a neurogenic anosmia. Most dysosmic disorders consist of disagreeable odors, sometimes accompanied by distortions of taste. Dysosmia also can occur with depression.

### APPROACH TO THE PATIENT

Unilateral anosmia is rarely a complaint and is only recognized by separate testing of smell in each nasal cavity. Bilateral anosmia, on the other hand, brings patients to medical attention. Anosmic patients usually complain of a loss of the sense of taste even though their taste thresholds may be within normal limits. In actuality, they are complaining of a loss of flavor detection, which is mainly an olfactory function. The physical examination should include a thorough inspection of the ears, upper respiratory tract, and head and neck. A neurologic examination emphasizing the cranial nerves and cerebellar and sensorimotor function is essential. Any signs of depression should be noted.

Sensory olfactory function can be assessed by any of several methods. The Odor Stix test uses a commercially available odor-producing magic marker—like pen held approximately 8 to 15 cm (3 to 6 in.) from the patient’s nose. The 30-cm alcohol test uses a freshly opened isopropyl alcohol packet held approximately 30 cm (12 in.) from the patient’s nose. There is a commercially available scratch-and-sniff card containing three odors available for testing olfaction grossly. A superior test is the University of Pennsylvania Smell Identification Test (UPSIT). This consists of a 40-item, forced choice, microencapsulated odor, scratch-and-sniff paradigm. For example, one of the items reads, “This odor smells most like (a) chocolate, (b) banana, (c) onion, or (d) fruit punch.” The test is highly reliable, is sensitive to age and sex differences, and provides an accurate quantitative determination of the olfactory deficit. The average score for total anosmics is slightly higher than that ex-
The qualities of sweet, salt, bitter, or sour;

**total agnosia**

Loss of the sense of taste, usually with normal detection thresholds for sucrose-best, salt-best, and quinine-best neurons. A with olfaction and gustation is needed for discriminating chemicals within qualities. For example, sweetness may be carried by sucrose-best neurons, but the differentiation of sucrose and fructose may require a comparison of the relative activity among sucrose-best, salt-best, and quinine-best neurons. As with olfaction and other sensory systems, intensity appears to be encoded by the quantity of neural activity.

**TASTE**

Compared with disorders of smell, gustatory disorders are uncommon. Loss of olfactory sensitivity is often accompanied by complaints of loss of the sense of taste, usually with normal detection thresholds for taste.

**DEFINITIONS**

Disturbances of the sense of taste may be categorized as **total ageusia**, total absence of gustatory function or inability to detect the qualities of sweet, salt, bitter, or sour; **partial ageusia**, ability to detect some of but not all the qualitative gustatory sensations; **specific ageusia**, inability to detect the taste quality of certain substances; **total hypogeusia**, decreased sensitivity to all tastants; **partial hypogeusia**, decreased sensitivity to some tastants; and **dysgeusia or phantogeusia**, distortion in the perception of a tastant, i.e., the perception of the wrong quality when a tastant is presented or the perception of a taste when there has been no tastant ingested. Confusions between sour and bitter, and less commonly between salty and bitter, may represent semantic misunderstandings or have true pathophysiological bases. It may be possible to differentiate between the loss of flavor recognition in patients with olfactory losses who complain of a loss of taste as well as smell by asking if they are able to taste sweetness in sodas, saltiness in potato chips, etc.

**DISORDERS OF THE SENSE OF TASTE**

Disorders of the sense of taste are caused by conditions that interfere with the access of the tastant to the receptor cells in the taste bud (transport loss), injure receptor cells (sensory loss), or damage gustatory afferent nerves and central gustatory pathways (neural loss) (Table 26-2). **Transport gustatory losses** result from xerostomia due to many causes, including Sjögren’s syndrome, radiation therapy, heavy-metal intoxication, and bacterial col-

Onization of the taste pore. *Sensory gustatory losses* are caused by inflammatory and degenerative diseases in the oral cavity; a vast number of drugs, particularly those that interfere with cell turnover such as antithyroid and antineoplastic agents; radiation therapy to the oral cavity and pharynx; viral infections; endocrine disorders; neoplasms; and aging. *Neural gustatory losses* occur with neoplasms, trauma, and surgical procedures in which the gustatory afferents are injured. Taste buds degenerate when their gustatory afferents are transected but remain when their somatosensory afferents are severed. Patients with renal disease have increased thresholds for sweet and sour tastes, which resolves with dialysis.

A side effect of medication is the single most common cause of taste dysfunction in clinical practice. Xerostomia, regardless of the etiology, can be associated with taste dysfunction. It is associated with poor oral clearance and poor dental hygiene, and can adversely affect the oral mucosa, all leading to dysgeusia. However, severe salivary gland failure does not necessarily lead to taste complaints. Xerostomia, the use of antibiotics or glucocorticoids, or immunodeficiency can lead to overgrowth of *Candida*; overgrowth alone, without thrush or overt signs of infection, can be associated with bad taste or hypoguesia. When taste dysfunction occurs in a patient at risk for fungal overgrowth, a trial of nystatin or other antifungal medication is warranted.

Upper respiratory infections and head trauma can lead to both smell and taste dysfunction; taste is more likely to improve than smell. The mechanism of taste disturbance in these situations is not well understood. Trauma to the chorda tympani branch of the facial nerve during middle ear surgery or third molar extractions is relatively common and can cause dysgeusia. Bilateral chorda tympani injuries are usually associated with hypoguesia, whereas unilateral lesions produce only limited symptoms.

Finally, aging itself may be associated with reduced taste sensitivity. The taste dysfunction may be limited to a single compound and may be mild.

**APPROACH TO THE PATIENT**

Patients who complain of loss of taste should be evaluated for both gustatory and olfactory function. Clinical assessment of taste is not as well developed or standardized as that of smell. The first step is to perform suprathreshold whole-mouth taste testing for quality, intensity, and pleasantness perception of four taste qualities: sweet, salty, sour, and bitter. Most commonly used reagents for taste testing are sucrose, citric acid or hydrochloric acid, caffeine or quinine (sulfate or hydrochloride), and sodium chloride. The taste stimuli should be freshly prepared. For quantification, detection thresholds are obtained by applying graduated dilutions to the tongue quadrants or by whole-mouth sips. Electric taste testing (*electrogustometry*) is used clinically to identify taste deficits in specific quadrants of the tongue. Regional gustatory testing may also be performed to assess for the possibility of loss localized to one or more receptor fields as a result of a peripheral or central lesion. The history of the disease and localization studies provide important clues to the reason for taste disturbance. For example, absence of taste on the anterior two-thirds of the tongue associated with a facial paralysis indicates that the lesion is proximal to the juncture of the chorda tympani branch with the facial nerve in the mastoid.

**TREATMENT**

Treatment of gustatory disorders is limited. No effective therapies exist for the sensorineural disorders of taste. Altered taste due to surgical stretch injury of chorda tympani nerve usually improves within 3 to 4 months, while dysfunction is usually permanent with transection of the nerve. Taste dysfunction following trauma may resolve spontaneously without intervention and is more likely to do so than post-traumatic smell dysfunction. Idiopathic alterations of taste sensitivity usually remain stable or worsen; zinc and vitamin therapy are of unproven value. Directed therapy to address factors that affect taste perception can be of value. Xerostomia can be treated with artificial saliva, providing some benefits to patients with a disturbed salivary milieu. Oral pilocarpine may be beneficial for a variety of forms of xerostomia. Appropriate treatment of bacterial and fungal infections of the oral cavity can be of great help in improving taste function. Taste disturbance related to drugs can often be resolved by changing the prescribed medication.

**HEARING**

Hearing loss is one of the most common sensory disorders in humans and can present at any age. Nearly 10% of the adult population has some hearing loss, and one-third of individuals over the age of 65 have a hearing loss of sufficient magnitude to require a hearing aid.

**PHYSIOLOGY OF HEARING** (Fig. 26-1) The function of the external and middle ear is to amplify sound to facilitate mechanotransduction by hair cells in the inner ear. Sound waves enter the external auditory canal and set the tympanic membrane in motion, which in turn moves the malleus, incus, and stapes of the middle ear. Movement of the footplate of the stapes causes pressure changes in the fluid-filled inner ear eliciting a traveling wave in the basilar membrane of the cochlea. The tympanic membrane and the ossicular chain in the middle ear serve as an impedance-matching mechanism, improving the efficiency of energy transfer from air to the fluid-filled inner ear.

Stereocilia of the hair cells of the organ of Corti, which rests on the basilar membrane, are in contact with the tectorial membrane and are deformed by the traveling wave. A point of maximal displacement of the basilar membrane is determined by the frequency of the stimulating tone. High-frequency tones cause maximal displacement of the basilar membrane near the base of the cochlea. As the frequency of the stimulating tone decreases, the point of maximal displacement moves toward the apex of the cochlea.

The inner and outer hair cells of the organ of Corti have different innervation patterns, but both are mechanoreceptors. The afferent innervation relates principally to the inner hair cells, and the efferent innervation relates principally to outer hair cells. The motility of the outer hair cells alters the micromechanics of the inner hair cells creating a cochlear amplifier, which explains the exquisite sensitivity and frequency selectivity of the cochlea.

The current concept of cochlear transduction is that displacement of the tips of the stereocilia allows potassium to flow into the cell, resulting in its depolarization. The potassium influx opens calcium channels near the base of the cell, stimulating transmitter release. The neurotransmitter at the hair cell and cochlear nerve dendrite interface is thought to be glutamate. Each of the cochlear nerve neurons can be activated at a frequency and intensity specific for that cell. This specificity is maintained at each point of the central auditory pathway: dorsal and ventral cochlear nuclei, trapezoid body, superior olivary...
complex, lateral lemniscus, inferior colliculus, medial geniculate body, and auditory cortex. At low frequencies, individual auditory nerve fibers can respond more or less synchronously with the stimulating tone. At higher frequencies, phase-locking occurs so that neurons alternate in response to particular phases of the cycle of the sound wave. Intensity is encoded by the amount of neural activity in individual neurons, the number of neurons that are active, and the specific neurons that are activated.

**GENETIC CAUSES OF HEARING LOSS** More than half of childhood hearing impairment is thought to be hereditary; hereditary hearing impairment (HHI) can also manifest later in life. HHI may be classified as either nonsyndromic, when hearing loss is the only clinical abnormality, or syndromic, when hearing loss is associated with anomalies in other organ systems. Nearly two-thirds of HHIs are nonsyndromic, and the remaining one-third are syndromic. Between 70 and 80% of nonsyndromic HHI is inherited in an autosomal recessive manner; another 15 to 20% is autosomal dominant. Less than 5% is X-linked or maternally inherited via the mitochondria.

Over 60 loci harboring genes for nonsyndromic HHI have been mapped, with equal numbers of dominant and recessive modes of inheritance; numerous genes have now been cloned (Table 26-3). The hearing genes fall into the categories of structural proteins (MYO7A, MYO15, TECTA, DIAPH1), transcription factors (POU3F4, POU4F3), ion channels (KCNQ4, PDS), and gap junction proteins (Cx26, Cx30, Cx31). Several of these genes, including connexin 26 (Cx26), TECTA, and MYO7A, cause both autosomal dominant and recessive forms of nonsyndromic HHI. In general, the hearing loss associated with dominant genes has its onset in adolescence or adulthood and varies in severity, whereas the hearing loss associated with recessive inheritance is congenital and profound. Connexin 26 is particularly important because it is associated with nearly 20% of cases of childhood deafness; in heterozygotes the onset of hearing loss may be in adolescence or adulthood. Two frame-shift mutations, 30delG and 167delT, account for >50% of the cases, making population screening feasible. The 167delT mutation is highly prevalent in Ashkenazi Jews; it is predicted that 1 in 1765 individuals in this population will be homozygous and affected. The hearing loss can also vary among the members of the same family, suggesting that other genes or factors likely influence the auditory phenotype.

The contribution of genetics to presbycusis (see below) is also becoming better understood. In addition to connexin 26, several other nonsyndromic genes are associated with hear-

</table>

**Note:** AD, autosomal dominant; AR, autosomal recessive.
ing loss that progresses with age. Sensitivity to aminoglycoside ototoxicity can be maternally transmitted through a mitochondrial mutation. Susceptibility to noise-induced hearing loss may also be genetically determined.

There are over 200 syndromic forms of hearing loss. These include Usher syndrome (retinitis pigmentosa and hearing loss), Waardenburg syndrome (pigmentary abnormality and hearing loss), Pendred syndrome (thyroid organification defect and hearing loss), Alport syndrome (renal disease and hearing loss), Jervell and Lange-Nielsen syndrome (prolonged QT interval and hearing loss), neurofibromatosis type 2 (bilateral acoustic schwannoma), and mitochondrial disorders [mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS); myoclonic epilepsy and ragged red fibers (MERRF); progressive external ophthalmoplegia (PEO)].

**DISORDERS OF THE SENSE OF HEARING** Hearing loss can result from disorders of the auricle, external auditory canal, middle ear, inner ear, or central auditory pathways (Fig. 26-2). In general, lesions in the auricle, external auditory canal, or middle ear cause conductive hearing losses, whereas lesions in the inner ear or eighth nerve cause sensorineural hearing losses.

**Conductive Hearing Loss** This results from obstruction of the external auditory canal by cerumen, debris, and foreign bodies; swelling of the lining of the canal; atresia or neoplasms of the canal; perforations of the tympanic membrane; disruption of the ossicular chain, as occurs with necrosis of the incus in trauma or infection; otosclerosis; or fluid, scarring, or neoplasms in the middle ear.

Cholesteatoma, stratified squamous epithelium in the middle ear or mastoid, occurs frequently in adults. This is a benign, slowly growing lesion that destroys bone and normal ear tissue. Theories of pathogenesis include traumatic implantation and invasion, immigration and invasion through a perforation, and metaplasia following chronic infection and irritation. On examination, there is often a perforation of the tympanic membrane filled with cheesy white squamous debris. A chronically draining ear that fails to respond to appropriate antibiotic therapy should raise suspicion of a cholesteatoma. Conductive hearing loss secondary to ossicular erosion is common. Surgery is required to remove this destructive process.

Conductive hearing loss with a normal ear canal and intact tympanic membrane suggests ossicular pathology. Fixation of the stapes from otosclerosis is a common cause of low-frequency conductive hearing loss. It occurs equally in men and women, and has a simple autosomal dominant inheritance with incomplete penetrance. Hearing impairment usually presents between the late teens to the forties. In women, the hearing loss is often first noticeable during pregnancy, as the otosclerotic process is accelerated during pregnancy. A hearing aid or a simple outpatient surgical procedure (stapedectomy) can provide adequate auditory rehabilitation. Extension of otosclerosis beyond the stapes footplate to involve the cochlea (cochlear otosclerosis) can lead to mixed or sensorineural hearing loss. Fluoride therapy to prevent hearing loss associated with cochlear otosclerosis is of uncertain value.

Eustachian tube dysfunction is extremely common in adults and may predispose to acute otitis media (AOM) or serous otitis media (SOM). Trauma, AOM, or chronic otitis media are the usual factors responsible for tympanic membrane perforation. While small perforations often heal spontaneously, larger defects usually require surgical intervention. Tympanoplasty is highly effective (>90%) in the repair of tympanic membrane perforations. Otoscopy is usually sufficient to identify these conditions.

**FIGURE 26-2** An algorithm for the approach to hearing loss. HL, hearing loss; SNHL, sensorineural hearing loss; TM, tympanic membrane; SOM, serous otitis media; AOM, acute otitis media; *, CT scan of temporal bone; †, MRI scan.
diagnose AOM, SOM, chronic otitis media, cerumen impaction, tympanic membrane perforation, and eustachian tube dysfunction.

**Sensorineural Hearing Loss** Damage to the hair cells of the organ of Corti may be caused by intense noise, viral infections, ototoxic drugs (e.g., salicylates, quinine and its synthetic analogues, aminoglycoside antibiotics, loop diuretics such as furosemide and ethacrynic acid, and cancer chemotherapeutic agents such as cisplatin), fractures of the temporal bone, meningitis, cochlear otosclerosis (see above), Ménière’s disease, and aging. Congenital malformations of the inner ear may be the cause of hearing loss in some adults. Genetic predisposition alone or in concert with environmental influences may also be responsible. Presbycusis (age-associated hearing loss) is the most common cause of sensorineural hearing loss in adults. In the early stages, it is characterized by symmetric, gentle to sharply sloping high-frequency hearing loss. With progression, the hearing loss involves all frequencies. More importantly, the hearing impairment is associated with significant loss in clarity. There is a loss of discrimination for phonemes, recruitment (abnormal growth of loudness), and particular difficulty in understanding speech in noisy environments. Hearing aids may provide limited rehabilitation once the word recognition score deteriorates below 50%. Improvements in cochlear implants have made them the treatment of choice when hearing aids prove inadequate.

Ménière’s disease is characterized by episodic vertigo, fluctuating sensorineural hearing loss, tinnitus, and aural fullness. Tinnitus and/or deafness may be absent during the initial attacks of vertigo, but they invariably appear as the disease progresses and are increased in severity during an acute attack. The annual incidence of Ménière’s disease is 0.5 to 7.5 per 1000; onset is most frequently in the fifth decade of life but may also occur in young adults or the elderly. Histologically, there is distention of the endolymphatic system (endolymphatic hydrops) leading to degeneration of vestibular and cochlear hair cells. This may result from endolymphatic sac dysfunction secondary to infection, trauma, autoimmune disease, inflammatory causes, or tumor; an idiopathic etiology constitutes the largest category and is most accurately referred to as Ménière’s disease. Although any pattern of hearing loss can be observed, typically, low-frequency, unilateral sensorineural hearing impairment is present. MRI should be obtained to exclude retrocochlear pathology such as cerebellopontine angle tumors or demyelinating disorders. Therapy is directed towards the control of vertigo. A low-salt diet is the mainstay of treatment of the control of rotatory vertigo. Diuretics, a short course of glucocorticoids, and intratympanic gentamicin may also be useful adjuncts in recalcitrant cases. Surgical therapy of vertigo is reserved for unresponsive cases and includes endolymphatic sac decompression, labyrinthectomy, and vestibular nerve section. Both labyrinthectomy and vestibular nerve section abolish rotatory vertigo in >90% of the cases. Unfortunately, there is no effective therapy for hearing loss, tinnitus, or aural fullness associated with Ménière’s disease.

Sensorineural hearing loss may also result from any neoplastic, vascular, demyelinating, infectious, or degenerative disease or trauma affecting the central auditory pathways. HIV leads to both peripheral and central auditory system pathology and is associated with sensorineural hearing impairment.

A finding of conductive and sensory hearing loss in combination is termed mixed hearing loss. Mixed hearing losses are due to pathology that can affect the middle and inner ear simultaneously such as otosclerosis involving the ossicles and the cochlea, head trauma, chronic otitis media, cholesteatoma, middle ear tumors, and some inner ear malformations.

**Trauma** resulting in temporal bone fractures may be associated with conductive, sensorineural, and mixed hearing loss. If the fracture spares the inner ear, there may simply be conductive hearing loss due to disruption of the tympanic membrane or the ossicular chain. These abnormalities are amenable to surgical correction. Profound hearing loss and severe vertigo are associated with temporal bone fractures involving the inner ear. A perilymphatic fistula associated with leakage of inner-ear fluid into the middle ear can occur and may require surgical repair. An associated facial nerve injury is not uncommon. CT is best suited to assess fracture of the traumatized temporal bone, evaluate the ear canal, and determine the integrity of the ossicular chain and the involvement of the inner ear. CSF leaks that accompany temporal bone fractures are usually self-limited; the use of prophylactic antibiotics is controversial.

**Tinnitus** is defined as the perception of a sound when there is no sound in the environment. It may have a buzzing, roaring, or ringing quality and may be pulsatile (synchronous with the heartbeat). Tinnitus is often associated with either a conductive or sensorineural hearing loss. The pathophysiology of tinnitus is not well understood. The cause of the tinnitus can usually be determined by finding the cause of the associated hearing loss. Tinnitus may be the first symptom of a serious condition such as a vestibular schwannoma. Pulsatile tinnitus requires evaluation of the vascular system of the head to exclude vascular tumors such as glomus jugulare tumors, aneurysms, and stenotic arterial lesions; it may also occur with SOM.

**APPROACH TO THE PATIENT**

The goal in the evaluation of a patient with auditory complaints is to determine (1) the nature of the hearing impairment (conductive vs. sensorineural), (2) the severity of the impairment (mild, moderate, severe, profound), (3) the anatomy of the impairment (external ear, middle ear, inner ear, or central auditory pathway), and (4) the etiology. The history should elicit characteristics of the hearing loss, including the duration of deafness, unilateral vs. bilateral involvement, nature of onset (sudden vs. insidious), and rate of progression (rapid vs. slow). The presence or absence of tinnitus, vertigo, imbalance, aural fullness, otorrhea, headache, facial nerve dysfunction, and head and neck paesthesias should be ascertained. Information regarding head trauma, exposure to ototoxins, occupational or recreational noise exposure, and family history of hearing impairment may also be important. A sudden onset of unilateral hearing loss, with or without tinnitus, may represent a viral infection of the inner ear or a stroke. Patients with unilateral hearing loss (sensory or conductive) usually complain of reduced hearing, poor sound localization, and difficulty hearing clearly with background noise. Gradual progression of a hearing deficit is common with otosclerosis, noise-induced hearing loss, vestibular schwannoma, or Ménière’s disease. Small vestibular schwannomas typically present with asymmetric hearing impairment, tinnitus, and imbalance (rarely vertigo); cranial neuropathy, in particular of the trigeminal or facial nerve, may accompany larger tumors. In addition to hearing loss, Ménière’s disease may be associated with episodic vertigo, tinnitus, and aural fullness. Hearing loss with otorrhea is most likely due to chronic otitis media or cholesteatoma.

Examination should include the auricle, external ear canal, and tympanic membrane. The external ear canal of the elderly is often dry and fragile; it is preferable to clean cerumen with wall-mounted suction and cerumen loops and to avoid irrigation. In examining the eardrum, the topography of the tympanic membrane is more important than presence or absence of the light reflex. In addition to the pars tensa (the lower two-thirds of the eardrum), the pars flaccida above the short process of the malleus should also be examined for retraction pockets that may be evidence of chronic eustachian tube dysfunction or cholesteatoma. Insufflation of the ear canal is necessary to assess tympanic membrane mobility and compliance. Careful inspection of the nose, nasopharynx, and upper respiratory tract is indicated. Unilateral serous effusion should prompt a fiberoptic examination of the nasopharynx to exclude neoplasms. Cranial nerves should be evaluated with special attention to facial and trigeminal nerves, which are commonly disturbed with tympanic membrane or cerebellopontine angle lesions.

The Rinne and Weber tuning fork tests, with a 256- or 512-Hz tuning fork, are used to screen for hearing loss, differentiate con-
LABORATORY ASSESSMENT OF HEARING

Audiologic Assessment

The minimum audiologic assessment for hearing loss should include the measurement of pure tone air-conduction and bone-conduction thresholds, speech reception threshold, discrimination score, tympanometry, acoustic reflexes, and acoustic-reflex decay. This test battery provides a comprehensive screening evaluation of the whole auditory system and allows one to determine whether further differentiation of a sensory (cochlear) from a neural (retrocochlear) hearing loss is indicated.

Pure tone audiometry assesses hearing acuity for pure tones. The test is administered by an audiologist and is performed in a sound-attenuated chamber. The pure tone stimulus is delivered with an audiometer, an electronic device that allows the presentation of specific frequencies (generally between 250 and 8000 Hz) at specific intensities. Air and bone conduction thresholds are established for each ear. Air conduction thresholds are established by presenting the stimulus in air with the use of headphones. Bone conduction thresholds are accomplished by placing the stem of a vibrating tuning fork or an oscillator of an audiometer in contact with the head. In the presence of a hearing loss, broad-spectrum noise is presented to the nontest ear.

The responses are measured in decibels. An audiogram is a plot of intensity in decibels of hearing threshold versus frequency. A decibel (dB) is equal to 20 times the logarithm of the ratio of the sound pressure required to achieve threshold in the patient to the sound pressure required to achieve threshold in a normal hearing person. Therefore, a change of 6 dB represents doubling of sound pressure, and a change of 20 dB represents a tenfold change in sound pressure. Loudness, which depends on the frequency, intensity, and duration of a sound, doubles with approximately each 10-dB increase in sound pressure level. Pitch, on the other hand, does not directly correlate with frequency. The perception of pitch changes slowly in the low and high frequencies. In the middle tones, which are important for human speech, pitch varies more rapidly with changes in frequency.

Pure tone audiometry establishes the presence and severity of hearing impairment, unilateral vs. bilateral involvement, and the type of hearing loss. Conductive hearing losses with a large mass component, as is often seen in middle-ear effusions, produce elevation of thresholds that predominate in the higher frequencies. Conductive hearing losses with a large stiffness component, as in fixation of the footplate of the stapes in early otosclerosis, produce threshold elevations in the lower frequencies. Often, the conductive hearing loss involves all frequencies, suggesting involvement of both stiffness and mass. In general, sensorineural hearing losses affect higher frequencies more than lower frequencies. An exception is Ménière’s disease, which is characteristically associated with low-frequency senсорineural hearing loss. Noise-induced hearing loss has an unusual pattern of hearing impairment in which the loss at 4000 Hz is greater than at higher frequencies. Vestibular schwannomas characteristically affect the higher frequencies, but any pattern of hearing loss can be observed.

Speech recognition requires greater synchronous neural firing than is necessary for appreciation of pure tones. Speech audiometry tests the clarity with which one hears. The speech reception threshold (SRT) is defined as the intensity at which speech is recognized as a meaningful symbol and is obtained by presenting two-syllable words with an equal accent on each syllable. The intensity at which the patient can repeat 50% of the words correctly is the SRT. Once the SRT is determined, discrimination or word recognition ability is tested by presenting one-syllable words at 25 to 40 dB above the speech reception threshold. The words are phonetically balanced in that the phonemes (speech sounds) occur in the list of words at the same frequency that they occur in ordinary conversational English. An individual with normal hearing or conductive hearing loss can repeat 88 to 100% of the phonetically balanced words correctly. Patients with a sensorineural hearing loss have variable loss of discrimination. As a general rule, neural lesions are associated with more deterioration in discrimination ability than are lesions in the inner ear. For example, in a patient with mild asymmetric sensorineural hearing loss, a clue to the diagnosis of vestibular schwannoma is the presence of greater than expected deterioration in discrimination ability. Deterioration in discrimination ability at higher intensities above the SRT also suggests a lesion in the eighth nerve or central auditory pathways.

Tympanometry measures the impedance of the middle ear to sound and is useful in diagnosis of middle-ear effusions. A tympanogram is the graphic representation of change in impedance or compliance as the pressure in the ear canal is changed. Normally, the middle ear is most compliant at atmospheric pressure, and the compliance decreases as the pressure is increased or decreased; this pattern is seen with normal hearing or in the presence of sensorineural hearing loss. Compliance that does not change with change in pressure suggests middle-ear effusion. With a negative pressure in the middle ear, as with eustachian tube obstruction, the point of maximal compliance occurs with negative pressure in the ear canal. A tympanogram in which no point of maximal compliance can be obtained is most commonly seen with discontinuity of the ossicular chain. A reduction in the maximal compliance peak can be seen in otosclerosis.

During tympanometry, an intense tone elicits contraction of the stapedius muscle. The change in compliance of the middle ear with contraction of the stapedius muscle can be detected. The presence or absence of this acoustic reflex is important in the anatomic localization of facial nerve paralysis as well as hearing loss. Normal or elevated acoustic reflex thresholds in an individual with sensorineural hearing impairment suggests a cochlear hearing loss. Assessment of acoustic reflex decay helps differentiate sensory from neural hearing losses. In neural hearing loss, the reflex adapts or decays with time. Otoacoustic emissions (OAE) can be measured with microphones inserted into the external auditory canal. The emissions may be spontaneous or evoked with sound stimulation. The presence of OAEs indicates that the outer hair cells of the organ of Corti are intact and can be used to assess auditory thresholds and to distinguish sensory from neural hearing losses.

Evoked Responses

Electrocochleography measures the earliest evoked potentials generated in the cochlea and the auditory nerve. Receptor potentials recorded include the cochlear microphonic, generated by the outer hair cells of the organ of Corti, and the summing potential, generated by the inner hair cells in response to sound. The whole nerve action potential representing the composite firing of the first-order neurons can also be recorded during electrocochleography. Clinically, the test is useful in the diagnosis of Ménière’s disease, where an elevation of the ratio of summating potential to action potential is seen.
Brainstem auditory evoked responses (BAERs) are useful in differentiating the site of sensorineural hearing loss. In response to sound, five distinct electrical potentials arising from different stations along the peripheral and central auditory pathway can be identified using computer averaging from scalp surface electrodes. BAERs are valuable in situations in which patients cannot or will not give reliable voluntary thresholds. They are also used to assess the integrity of the auditory nerve and brainstem in various clinical situations, including intraoperative monitoring and in determination of brain death.

Imaging Studies The choice of radiologic tests is largely determined by whether the goal is to evaluate the bony anatomy of the external, middle, and inner ear or to image the auditory nerve and brain. Axial and coronal CT of the temporal bone with fine 1-mm cuts is ideal for determining the caliber of the external auditory canal, integrity of the ossicular chain, and presence of middle-ear or mastoid disease; it can also detect inner-ear malformations. CT is also ideal for the detection of bone erosion often seen in the presence of chronic otitis media and cholesteatoma. MRI is superior to CT for imaging of retrocochlear pathology such as vestibular schwannoma, meningioma, other lesions of the cerebellopontine angle, demyelinating lesions of the brainstem, and brain tumors. Recent experience suggests that both CT and MRI are equally capable of identifying inner-ear malformations and assessing cochlear patency for preoperative evaluation of patients for cochlear implantation.

**TREATMENT**

In general, conductive hearing losses are amenable to surgical intervention and correction, while sensorineural hearing losses are permanent. Atresia of the ear canal can be surgically repaired, often with significant improvement in hearing. Tympanic membrane perforations due to chronic otitis media or trauma can be repaired with an outpatient tympanoplasty. Likewise, conductive hearing loss associated with otosclerosis can be treated by stapedectomy, which is successful in 90 to 95% of cases. Tympanostomy tubes allow the prompt return of normal hearing in individuals with middle-ear effusions. Hearing aids are effective and well-tolerated in patients with conductive hearing losses.

Patients with mild, moderate, and severe sensorineural hearing losses are regularly rehabilitated with hearing aids of varying configuration and strength. Hearing aids have been improved to provide greater fidelity and have been miniaturized. The current generation of hearing aids can be placed entirely within the ear canal, thus reducing the stigma associated with their use. In general, the more severe the hearing impairment, the larger the hearing aid required for auditory rehabilitation. Digital hearing aids lend themselves to individual programming, and multiple and directional microphones at the ear level may be helpful in noisy surroundings. Since all hearing aids amplify noise as well as speech, the only absolute solution to the problem found thus far is to place the microphone closer to the speaker than the noise source. This arrangement is not possible with a self-contained, cosmetically acceptable device. It is cumbersome and requires a user-friendly environment.

In many situations, including lectures and the theater, hearing-impaired persons benefit from assistive devices that are based on the principle of having the speaker closer to the microphone than any source of noise. Assistive devices include infrared and frequency modulated (FM) transmission as well as an electromagnetic loop around the room for transmission to the individual’s hearing aid. Hearing aids with telecoils can also be used with properly equipped telephones in the same way.

In the event that the hearing aid provides inadequate rehabilitation, cochlear implants may be appropriate. Criteria for implantation include severe to profound hearing loss with word recognition score ≤30% under best aided conditions. Worldwide, more than 20,000 deaf individuals (including 4000 children) have received cochlear implants. Cochlear implants are neural prostheses that convert sound energy to electrical energy and can be used to stimulate the auditory division of the eighth nerve directly. In most cases of profound hearing impairment, the auditory hair cells are lost but the ganglionic cells of the auditory division of the eighth nerve are preserved. Cochlear implants consist of electrodes that are inserted into the cochlea through the round window, speech processors that extract acoustical elements of speech for conversion to electrical currents, and a means of transmitting the electrical energy through the skin. Patients with implants experience sound that helps with speech reading, allows open-set word recognition, and helps in modulating the person’s own voice. Usually, within 3 months after implantation, adult patients can understand speech without visual cues. With the current generation of multi-channel cochlear implants, nearly 75% of patients are able to converse on the telephone. It is anticipated that improvements in the electrode design and speech processors will permit further enhancement in understanding speech, especially in the presence of background noise.

For individuals who have had both eighth nerves destroyed by trauma or bilateral vestibular schwannomas (e.g., neurofibromatosis type 2), brainstem auditory implants placed near the cochlear nucleus may provide auditory rehabilitation. It is hoped that additional advances may provide benefits similar to those with the cochlear implant.

Tinnitus often accompanies hearing loss. Tinnitus and background noise can significantly affect understanding of speech in individuals with hearing impairment. Therapy for tinnitus is usually directed towards minimizing the appreciation of tinnitus. Relief of the tinnitus may be obtained by masking it with background music. Hearing aids are also helpful in tinnitus suppression, as are tinnitus maskers, devices that present a sound to the affected ear that is more pleasant to listen to than the tinnitus. The use of a tinnitus masker is often followed by several hours of inhibition of the tinnitus. Antidepressants have also shown beneficial effect in helping patients deal with tinnitus.

Tinnitus and background noise can significantly affect understanding of speech in individuals with hearing impairment. Hard-of-hearing individuals often benefit from a reduction in unnecessary noise (e.g., radio or television) to enhance the signal-to-noise ratio. Speech comprehension is aided by lip reading; therefore the impaired listener should be seated so that the face of the speaker is well-illuminated and easily seen. Speaking directly into the ear is occasionally helpful, but usually more is lost than gained because the speaker’s face can no longer be seen. Speech should be slow enough to make each word distinct, but overly slow speech is distracting and loses contextual and speech-reading benefits. Although speech should be in a loud, clear voice, one should be aware that in sensorineural hearing losses in general and in elderly hard-of-hearing persons in particular, recruitment (abnormal perception of loud sounds) may be troublesome. Above all, optimal communication cannot take place without both parties giving it their full and undivided attention.

**PREVENTION** Conductive hearing losses may be prevented by prompt antibiotic therapy of adequate duration for AOM and by ventilation of the middle ear with tympanostomy tubes in middle-ear effusions lasting ≥12 weeks. Loss of vestibular function and deafness due to aminoglycoside antibiotics can largely be prevented by careful monitoring of serum peak and trough levels.

Some 10 million Americans have noise-induced hearing loss, and 20 million are exposed to hazardous noise in their employment. Noise-induced hearing loss can be prevented by avoidance of exposure to loud noise or by regular use of ear plugs or fluid-filled ear muffs to attenuate intense sound. Noise-induced hearing loss results from recreational as well as occupational activities and begins in adolescence. High-risk activities for noise-induced hearing loss include wood and metal working with electrical equipment and target practice and hunt.
ING THE UPPER RESPIRATORY TRACT
Michael A. Rubin, Ralph Gonzales, Merle A. Sande

Infections of the upper respiratory tract (URIs) have a tremendous impact on public health. They are among the most common reasons for visits to primary care providers, and, although the illnesses are typically mild, their high incidence and transmission rates place them among the leading causes of time lost from work or school. Even though the minority (~25%) of cases are caused by bacteria, URIs are the leading diagnoses for which antibiotics are prescribed on an outpatient basis in the United States. The enormous consumption of antibiotics for these illnesses has contributed to the rise in antibiotic resistance among common community-acquired pathogens such as *Streptococcus pneumoniae*—a trend that in itself has had a tremendous impact on public health.

Although most URIs are caused by viruses, distinguishing patients with primary viral infection from those with primary bacterial infection is difficult. Signs and symptoms of bacterial and viral URIs are, in fact, indistinguishable. Because routine, rapid testing is neither available nor practical for most syndromes, acute infections are diagnosed largely on clinical grounds. This situation makes the judicious use of antibiotics in this setting challenging.

**NONSPECIFIC INFECTIONS OF THE UPPER RESPIRATORY TRACT**

Nonspecific URIs are a broadly defined group of disorders that collectively constitute the leading cause of ambulatory care visits in the United States. Nonspecific URIs, by definition, have no prominent localizing features. They are identified by a variety of descriptive names, including acute infectious rhinitis, acute rhinopharyngitis/nasopharyngitis, acute coryza, and acute nasal catarrh, as well as by the inclusive label common cold.

**Etiology**

The large assortment of URI classifications reflects the wide variety of causative infectious agents and the varied manifestations of common pathogens. Nearly all nonspecific URIs are caused by viruses spanning multiple virus families and large numbers of antigenic types. For instance, rhinoviruses (Chap. 170), the most common cause (~30 to 40% of cases), consist of at least 100 immunotypes; other causes include influenza virus (3 immunotypes; Chap. 171) as well as parainfluenza virus (4 immunotypes), coronavirus (at least 3 immunotypes), and adenovirus (47 immunotypes) (Chap. 170). Respiratory syncytial virus (RSV) also accounts for a small percentage of cases each year, as do some viruses not typically associated with URIs (e.g., enteroviruses, rubella virus, and varicella-zoster virus). Even with sophisticated diagnostic and culture techniques, a substantial proportion (25 to 30%) of cases have no assigned pathogen.

**Manifestations**

The signs and symptoms of nonspecific URI are similar to those of other URIs but lack a pronounced localization to one particular anatomic location, such as the sinuses, pharynx, or lower airway. Nonspecific URI is commonly described as an acute, mild, and self-limited catarrhal syndrome, with a median duration of ~1 week. Signs and symptoms are diverse and frequently variable across patients. The principal signs and symptoms of nonspecific URI include rhinorrhea (with or without purulence), nasal congestion, cough, and sore throat; other manifestations, such as fever, malaise, sneezing, and hoarseness, are more variable, with fever more common among infants and young children. Occasionally, clinical features reflect the underlying viral pathogen; myalgias and fatigue, for example, are sometimes seen with influenza and parainfluenza infections, while conjunctivitis may suggest infection with adenovirus or enterovirus. Findings on physical examination are frequently nonspecific and unimpressive. Between 0.5 and 2% of colds are complicated by secondary bacterial infections (e.g., rhinosinusitis, otitis media, and pneumonia), particularly in high-risk populations such as infants, elderly persons, and chronically ill patients. Secondary bacterial infections are usually associated with a prolonged course of illness, worsening of illness severity, and localization of signs and symptoms. The presence of purulent secretions from the nares or throat has often been used as an indication of sinusitis or pharyngitis. However, these secretions are also seen in nonspecific URI and, in the absence of other clinical features, are poor predictors of bacterial infection.

**TREATMENT**

Antibiotics have no role in the treatment of uncomplicated nonspecific URI. In the absence of clinical evidence of bacterial infection, treatment remains entirely symptom-based, with use of decongestants and nonsteroidal anti-inflammatory drugs. Other therapies directed at specific symptoms are often useful, including dextromethorphan for cough and lozenges with topical anesthetic for sore throat. Clinical trials of zinc, vitamin C, echinacea, and other alternative remedies have revealed no consistent benefit for the treatment of nonspecific URI.

**INFECTIONS OF THE SINUS**

*Sinusitis* refers to an inflammatory condition involving the four paired structures surrounding the nasal cavities. Although most cases of sinusitis involve more than one sinus, the maxillary sinus is most commonly involved, followed in frequency by the ethmoid, frontal, and sphenoid sinuses. Each sinus is lined with a respiratory epithelium that produces mucus, which is transported out by ciliary action through the sinus ostium and into the nasal cavity. Normally, mucus does not accumulate in the sinuses, which remain sterile despite their adjacency to the bacterium-filled nasal passages. When the sinus ostia are obstructed, however, or when ciliary clearance is impaired or absent, the secretions can be retained, producing the typical signs and symptoms of sinusitis. The retained secretions may become infected with a variety of pathogens, including viruses, bacteria, and fungi. Sinusitis affects a tremendous proportion of the population, accounts for millions of visits to primary care physicians each year, and is the fifth leading diagnosis for which antibiotics are prescribed. It is typically classified by duration of illness (acute vs. chronic); by etiology (infectious vs. noninfectious); and, when infectious, by the offending pathogen type (viral, bacterial, or fungal).
ACUTE SINUSITIS  Acute sinusitis—defined as sinusitis of <4 weeks' duration—constitutes the vast majority of sinusitis cases. Most cases are diagnosed in the ambulatory care setting and occur primarily as a consequence of a preceding viral URI. Differentiating acute bacterial and viral sinusitis on clinical grounds is difficult. Therefore, it is perhaps unsurprising that antibiotics are prescribed frequently (in 85 to 98% of all cases) for this condition.

Etiology  A number of infectious and noninfectious factors can contribute to acute obstruction of the sinus ostia or impairment of ciliary clearance, with consequent sinusitis. Noninfectious causes include allergic rhinitis (with either mucosal edema or polyol obstruction), baro-trauma (e.g., from deep-sea diving or air travel), or chemical irritants. Illnesses such as nasal and sinus tumors (e.g., squamous cell carcinoma) or granulomatous diseases (e.g., Wegener’s granulomatosis or rhinoscleroma) can also produce obstruction of the sinus ostia, while conditions leading to altered mucus content (e.g., cystic fibrosis) can cause sinusitis through impaired mucus clearance. In the hospital setting, nasotracheal intubation is a major risk factor for nosocomial sinusitis in intensive care units.

Acute infectious sinusitis can be caused by a variety of organisms, including viruses, bacteria, and fungi. Viral rhinosinusitis is far more common than bacterial sinusitis, although relatively few studies have sampled sinus aspirates for the presence of different viruses. In those studies that have done so, the viruses most commonly isolated—both alone and with bacteria—have been rhinovirus, parainfluenza virus, and influenza virus. Bacterial causes of sinusitis have been better described. Among community-acquired cases, *S. pneumoniae* and non-typable *Haemophilus influenzae* are the most common pathogens, accounting for 50 to 60% of cases. *Moraxella catarrhalis* causes disease in a significant percentage (20%) of children but less often in adults. Other streptococcal species and *Staphylococcus aureus* cause a small percentage of cases. Anaerobes are occasionally found in association with infections of the roots of premolar teeth that spread into the adjacent maxillary sinuses. The role of *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* in the pathogenesis of acute sinusitis is still unclear. Nosocomial cases are commonly associated with bacteria found in the hospital environment, including *S. aureus, Pseudomonas aeruginosa, Serratia marcescens, Klebsiella pneumoniae*, and *Enterobacter* species. Often, these infections are polymicrobial and involve organisms that are highly resistant to numerous antibiotics. Fungi are also established causes of sinusitis, although most acute cases are in immunocompromised patients and represent invasive, life-threatening infections. The best-known example is rhinocerebral mucormycosis caused by fungi of the order Mucorales, which includes *Rhizopus, Rhizomucor, Mucor, Absidia*, and *Cunninghamella*. These infections usually occur in diabetic patients with ketoacidosis but also develop in transplant recipients, patients with hematologic malignancies, and patients receiving chronic glucocorticoid or deferoxamine therapy. Other hyaline molds, such as *Aspergillus* and *Fusarium* species, are also occasional causes of this disease.

Manifestations  Most cases of acute sinusitis present after or in conjunction with a viral URI, and it can be difficult to discriminate the clinical features of one from the other. A large proportion of patients with colds have sinus inflammation, although bacterial sinusitis complicates only 0.2 to 2% of these viral infections. Common presenting symptoms of sinusitis include nasal drainage and congestion, facial pain or pressure, and headache. Thick, purulent or discolored nasal discharge is often thought to indicate bacterial sinusitis, but it also occurs early in viral infections such as the common cold and is not specific to bacterial infection. Other nonspecific symptoms include cough, sneezing, and fever. Tooth pain, most often involving the upper molars, is associated with bacterial sinusitis, as is halitosis.

In acute sinusitis, sinus pain or pressure often localizes to the involved sinus (particularly the maxillary sinus) and can be worse when the patient bends over or is supine. Although rare, symptoms of advanced sphenoid or ethmoid sinus infection can be profound, including severe frontal or retroorbital pain radiating to the occiput, thrombosis of the cavernous sinus, and signs of orbital cellulitis. Acute focal sinusitis is uncommon but should be considered in the patient with severe symptoms over the maxillary sinus and fever, regardless of illness duration. Similarly, advanced frontal sinusitis can present with a condition known as *Pott’s puffy tumor*, with soft tissue swelling and pitting edema over the frontal bone from a communicating subperiosteal abscess. Life-threatening complications include meningitis, epidural abscess, and cerebral abscess.

Patients with acute fungal sinusitis (such as mucormycosis) often present with symptoms related to pressure effects, particularly when the infection has spread to the orbits and cavernous sinus. Signs such as eye swelling and cellulitis, proptosis, ptosis, and decreased extraocular movement are common, as is retroorbital or periorbital pain. Nasopharyngeal ulcerations, epistaxis, and headaches are also frequent, and involvement of cranial nerves V and VII has been described in more advanced cases. Bony erosion may be evident on examination. Oftentimes, the patient does not appear seriously ill despite the rapidly progressive nature of these infections.

Patients with acute nosocomial sinusitis are often critically ill and thus do not manifest the typical clinical features of sinus disease. This diagnosis should be suspected, however, when hospitalized patients who have appropriate risk factors (e.g., nasotracheal intubation) develop fever of uncertain origin.

Diagnosis  Distinguishing viral from bacterial sinusitis in the ambulatory setting is usually difficult, given the relatively low sensitivity and specificity of the common clinical features. One clinical feature that has been used to help guide diagnostic and therapeutic decision-making is illness duration. Because acute bacterial sinusitis is uncommon in patients whose symptoms have lasted <7 days, several authorities now recommend reserving this diagnosis for patients with appropriate symptoms (e.g., facial or tooth pain in combination with purulent nasal discharge) that have persisted for >7 days (Table 27-1). Nonetheless, of the patients who meet these criteria, only 40 to 50% have true bacterial sinusitis. The use of computed tomography (CT) or sinus radiography is not recommended for routine cases, particularly early in the course of illness (i.e., <7 days), given the high prevalence of similar abnormalities among cases of acute viral rhinosinusitis. In the evaluation of persistent, recurrent, or chronic sinusitis, CT or the sinuses is the radiographic study of choice.

The clinical history and/or setting can often identify cases of acute anaerobic bacterial sinusitis, acute fungal sinusitis, or sinusitis from noninfectious causes, such as allergic rhinosinusitis. In the case of an immunocompromised patient with acute fungal sinus infection, immediate examination by an otolaryngologist is required. Biopsies of involved areas should be examined by a pathologist for evidence of fungal hyphal elements and tissue invasion. Cases of suspected acute nosocomial sinusitis should be confirmed by a sinus CT scan. Because therapy should target the offending organism, a sinus aspirate should be obtained, if possible, for culture and susceptibility testing.

**TREATMENT**  Most patients with a diagnosis of acute rhinosinusitis based on clinical grounds improve without antibiotic therapy. The preferred initial approach in adult patients with mild to moderate symptoms of <7 days’ duration are therapies aimed at facilitating sinus drainage, such as oral and topical decongestants, nasal saline lavage, and—in patients with a history of chronic sinusitis or allergies—nasal glucocorticoids. Adult patients fulfilling the above criteria who do not improve after 7 days and those with more severe symptoms (regardless of duration) should be treated with antibiotics (Table 27-1). Empirical therapy should consist of the most narrow-spectrum agent active against the most common bacterial pathogens, including *S. pneumoniae* and *H. influenzae*—e.g., amoxicillin. No clinical trials support the use of broad-spectrum agents for routine cases of bacterial sinusitis, even in the current era of drug-resistant *S. pneumoniae*. Up to 10% of patients do not respond...
### ACUTE SINUSITIS

**Adults**
- Moderate symptoms (e.g., nasal purulence/congestion or cough) for >7 d or
- Severe symptoms (any duration), including unilateral/focal facial swelling or tooth pain

**Children**
- Moderate symptoms (e.g., nasal purulence/congestion or cough) for 10–14 d or longer or
- Severe symptoms (any duration), including fever (>102°F), unilateral/focal facial swelling or pain

**Initial therapy:**
- Amoxicillin, 875 mg PO bid for 10 d or
- TMP-SMX, 1 DS tablet PO bid for 10 d

**Exposure to antibiotics within 30 d:**
- Amoxicillin, 1000 mg PO bid for 10 d or
- Amoxicillin/clavulanate, 875 mg PO bid for 10 d or
- Antipneumococcal fluoroquinolone (e.g., levofloxacin, 500 mg PO qd) for 7 d

**Recent treatment failure:**
- Amoxicillin (1500 mg) plus clavulanate (125 mg) PO bid for 10 d or
- Amoxicillin (1500 mg) plus clindamycin (300 mg qid) PO for 10 d or
- Antipneumococcal fluoroquinolone (e.g., levofloxacin, 500 mg PO qd) for 7 d

**ACUTE PHARYNGITIS**

**Adults**
- Clinical suspicion of streptococcal pharyngitis (e.g., fever, tonsillar swelling, exudate, enlarged/tender anterior cervical lymph nodes, absence of cough or coryza) with
- History of rheumatic fever or
- Documented household exposure or
- Positive rapid strep screen

**Children**
- Clinical suspicion of streptococcal pharyngitis (e.g., tonsillar swelling, exudate, enlarged/tender anterior cervical lymph nodes, absence of coryza) with
- History of rheumatic fever or
- Documented household exposure or
- Positive rapid strep screen or
- Positive throat culture (for those with negative rapid strep screen)

**Initial therapy:**
- Penicillin V, 500 mg PO bid for 10 d or
- Cephalexin, 250 mg PO qid for 10 d or
- Erythromycin, 250 mg PO qid for 10 d or
- Benzathine penicillin G, single dose of 1.2 million units IM

**Exposure to antibiotics within 30 d or recent treatment failure:**
- Amoxicillin, 45–90 mg/kg per day (up to 2 g) in divided doses (bid or tid) or
- Cefuroxime axetil, 30 mg/kg per day in divided doses (bid) or
- Cefdinir, 14 mg/kg qd

**ACUTE OTITIS MEDIA**

**Adults and children**
- Fluid in middle ear, evidenced by decreased tympanic membrane mobility, air/fluid level behind tympanic membrane, bulging tympanic membrane, purulent otorrhea and
- Signs and symptoms of middle-ear disease, including fever, irritability, otalgia, decreased hearing, tinnitus, vertigo

**Initial therapy:**
- Amoxicillin, 90 mg/kg per day (up to 2 g) PO in divided doses (bid or tid) or
- Amoxicillin, 90 mg/kg per day (up to 2 g), plus clavulanate, 6.4 mg/kg per day; both PO in divided doses (bid) or
- Cefdinir, 14 mg/kg PO qd or
- Clindamycin, 20 mg/kg per day PO in divided doses (tid), plus
- TMP-SMX, 10 mg/kg per day PO in divided doses (bid)

**Exposure to antibiotics within 30 d or recent treatment failure:**
- Amoxicillin, 90 mg/kg per day (up to 2 g), plus clavulanate, 6.4 mg/kg per day; both PO in divided doses (bid) for 10 d or
- Cefdinir, 14 mg/kg PO qd for 10 d or
- Ceftriaxone, 50 mg/kg IM qd for 3 d or
- Consider myringotomy

---

*Some organizations support treating adults with these symptoms and signs without the need for rapid streptococcal antigen testing. Surgical intervention and intravenous antibiotics are usually reserved for patients with severe disease or those with intracranial complications, such as abscess or orbital involvement. Immunocompromised patients with acute invasive fungal sinusitis usually require extensive surgical debridement and treatment with intravenous antifungal agents active against fungal hyphal forms, such as amphotericin B. Specific therapy should be individualized according to the fungal species and the patient’s attributes. Treatment of nosocomial sinusitis should begin with broad-spectrum antibiotics to cover common pathogens such as S. aureus and*
gram-negative bacilli. Therapy should then be tailored to the results of culture and susceptibility testing of sinus aspirates.

**CHRONIC SINUSITIS** Chronic sinusitis is characterized by symptoms of sinus inflammation lasting >12 weeks. This illness is most commonly associated with either bacteria or fungi, and clinical cure in most cases is very difficult. Many patients have undergone treatment with repeated courses of antibacterial agents and multiple sinus surgeries, increasing their risk of colonization with antibiotic-resistant pathogens and of surgical complications. Patients often suffer significant morbidity, sometimes over many years.

In *chronic bacterial sinusitis*, infection is thought to be due to the impairment of mucociliary clearance from repeated infections rather than to persistent bacterial infection. However, the pathogenesis of this condition is poorly understood. Although certain conditions (e.g., cystic fibrosis) can predispose patients to chronic bacterial sinusitis, most patients with this infection do not have obvious underlying conditions that result in the obstruction of sinus drainage, the impairment of ciliary action, or immune dysfunction. Patients experience constant nasal congestion and sinus pressure, with intermittent periods of greater severity, which may persist for years. CT can be helpful in defining the extent of disease and the response to therapy. The management team should include an otolaryngologist to conduct endoscopic examinations and obtain tissue samples for histologic examination and culture.

*Chronic fungal sinusitis* is a disease of immunocompetent hosts and is usually noninvasive, although slowly progressive invasive disease is sometimes seen. Noninvasive disease, which is typically associated with hyaline molds such as Aspergillus species and dematiaceous molds such as *Curvularia* or *Bipolaris* species, can present as a number of different scenarios. In mild, indolent disease, which usually occurs in the setting of repeated failures of antibacterial therapy, only nonspecific mucosal changes may be seen on sinus CT. Endoscopic surgery is usually curative in these patients, with no need for antifungal therapy. Another form of disease presents with long-standing, often unilateral symptoms and opacification of a single sinus on imaging studies as a result of a mycetoma (fungus ball) within the sinus. Treatment for this condition is also surgical, although systemic antifungal therapy may be warranted in the rare case where bony erosion occurs. A third form of disease, known as *allergic fungal sinusitis*, is seen in patients with a history of nasal polyposis and asthma, who often have had multiple sinus surgeries. Patients with this condition produce a thick, eosinophilic mucus with the consistency of peanut butter that contains sparse fungal hyphae on histologic examination. Patients often present with pansinusitis.

### Treatment

Treatment of chronic bacterial sinusitis can be challenging and consists primarily of repeated culture-guided courses of antibiotics, sometimes for 3 to 4 weeks at a time; administration of intranasal glucocorticoids; and mechanical irrigation of the sinus with sterile saline solution. When this management approach fails, sinus surgery may be indicated and sometimes provides significant, albeit short-term, alleviation. Treatment of chronic fungal sinusitis consists of surgical removal of impacted mucus. Recurrence, unfortunately, is common.

### Infections of the Ear and Mastoid

Infections of the ear and associated structures can involve both the middle and external ear, including the skin, cartilage, periosteum, ear canal, and tympanic and mastoid cavities. Both viruses and bacteria are known causes of these infections, some of which result in significant morbidity if not treated appropriately.

### Infections of the External Ear Structures

**Auricular Cellulitis** Auricular cellulitis is an infection of the skin overlaying the external ear and typically follows minor local trauma. It presents with the typical signs and symptoms of a skin/soft tissue infection, with tenderness, erythema, swelling, and warmth of the external ear (particularly the lobe) but without apparent involvement of the ear canal or inner structures. Treatment consists of warm compresses and oral antibiotics such as dicloxacillin that are active against typical skin and soft tissue pathogens (specifically, *S. aureus* and streptococci). Intravenous antibiotics, such as a first-generation cephalosporin (e.g., cefazolin) or a penicillinase-resistant penicillin (e.g., nafcillin) are occasionally needed for more severe cases.

**Perichondritis** Perichondritis, an infection of the perichondrium of the auricular cartilage, typically follows local trauma (e.g., ear piercing, burns, or lacerations). Occasionally, when the infection spreads down to the cartilage of the pinna itself, patients may also have chondritis. The infection may closely resemble auricular cellulitis, with erythema, swelling, and extreme tenderness of the pinna, although the lobe is less often involved in perichondritis. The most common pathogens are *P. aeruginosa* and *S. aureus*, although other gram-negative and gram-positive organisms are occasionally involved. Treatment consists of systemic antibiotics active against both *P. aeruginosa* and *S. aureus*. An antipseudomonal penicillin (e.g., piperacillin) or a combination of a penicillinase-resistant penicillin plus an antipseudomonal quinolone (e.g., nafcillin plus ciprofloxacin) is typically used. Incision and drainage may be helpful for culture and for resolution of infection, which often takes weeks.

**Otitis Externa** The term *otitis externa* refers to a collection of diseases involving primarily the auditory meatus. Otitis externa usually results from a combination of heat, retained moisture, and desquamation and maceration of the outer canal epithelium. The disease exists in a number of forms, which are identified as localized, diffuse, chronic, or invasive. They are all predominantly bacterial in origin, with *P. aeruginosa* and *S. aureus* the most common pathogens.

Acute localized otitis externa (furunculosis) can develop in the outer third of the ear canal, where skin overlies cartilage and hair follicles are numerous. As with furunculosis elsewhere on the body, *S. aureus* is the usual pathogen, and treatment typically consists of an oral antistaphylococcal penicillin (e.g., dicloxacillin), with incision and drainage in cases of abscess formation.

Acute diffuse otitis externa is also known as “swimmer’s ear,” although it can develop in the absence of swimming. Heat, humidity, and the loss of protective cerumen lead to excessive moisture and elevation of the pH in the ear canal, which in turn lead to skin maceration and irritation. Infection may then occur; the predominant pathogen is *P. aeruginosa*, although other gram-negative and gram-positive organisms have been recovered from patients with this condition. The illness often starts with itching and progresses to severe pain, which is usually triggered by manipulation of the pinna or tragus. The onset of pain is usually accompanied by the development of an erythematous, swollen ear canal, often with scant white, clumpy discharge. Treatment consists of cleansing the canal to remove debris and to enhance the activity of topical therapies—usually hypertonic saline or mixtures of alcohol and acetic acid. Inflammation can also be decreased by adding glucocorticoids to the treatment regimen or by using Burrow’s solution (aluminum acetate in water). Antibiotics are most effective when given topically. Otic mixtures provide adequate pathogen coverage; these preparations usually combine neomycin with polymyxin, with or without glucocorticoids.

**Chronic otitis externa** is caused primarily by repeated local irritation, most commonly arising from persistent drainage from a chronic middle-ear infection. Other causes of repeated irritation, such as cotton swabs or other foreign objects inserted into the ear canal, can lead to this condition, as can rare chronic infections such as syphilis, tuberculosis, or leprosy. Chronic otitis externa typically presents as erythematous, scaling dermatitis in which the predominant symptom is pruritus rather than pain; this condition must be differentiated from several others that produce a similar clinical picture, such as atopic dermatitis, seborrheic dermatitis, psoriasis, and dermatitis herpetiformis. Therapy consists of identifying and treating or removing the offending process, although successful resolution is frequently difficult.
Invasive otitis externa, also known as “malignant” or “necrotizing” otitis externa, is an aggressive and potentially life-threatening disease that occurs predominantly in elderly diabetics and other immunocompromised patients. The disease begins in the external canal, progresses slowly over weeks to months, and often is difficult to distinguish from a severe case of chronic otitis externa because of the presence of purulent otorrhea and an erythematous swollen ear and external canal. Severe, deep-seated otalgia is often noted and can help differentiate invasive from chronic otitis externa. The characteristic finding on examination is granulation tissue in the posterosuperior wall of the external canal, near the junction of bone and cartilage. If left unchecked, the infection can migrate to the base of the skull (resulting in skull-base osteomyelitis) and on to the meninges and brain, with a high associated mortality rate. Cranial nerve involvement is occasionally seen, with the facial nerve usually affected first and most often. Thrombosis of the sigmoid sinus can occur if the infection extends to that area. CT, which can reveal osseous erosion of the temporal bone and skull base, can be used to help determine the extent of disease, as can gallium and technetium-99 scintigraphy studies. *P. aeruginosa* is by far the most common pathogen involved, although *S. aureus, Staphylococcus epidermidis, Aspergillus, Actinomyces,* and some gram-negative bacteria have been associated with this disease. Cleansing of the external canal and biopsy of the granulation tissue within the canal (or of deeper tissues) should be performed in all cases to isolate the offending organism in culture. Intravenous antibiotic therapy is directed specifically toward the recovered pathogen. For *P. aeruginosa,* the regimen typically includes an antipseudomonal penicillin or cephalosporin (e.g., piperacillin or ceftazidime) with an aminoglycoside. A fluoroquinolone antibiotic is frequently used in place of the aminoglycoside and can even be administered orally, given its excellent bioavailability. Antibiotic drops containing an agent active against *Pseudomonas* (e.g., ciprofloxacin) are also usually prescribed and are combined with glucocorticoids to reduce inflammation. Cases of invasive *Pseudomonas* otitis externa recognized in the early stages can sometimes be treated with oral and otic fluoroquinolones alone, albeit with close follow-up. Extensive surgical debridement, once an important component of the treatment approach, is now rarely indicated.

**INFECTIONS OF MIDDLE-EAR STRUCTURES** Otitis media is an inflammatory condition of the middle ear that results from dysfunction of the eustachian tube in association with a number of illnesses, including URI and chronic rhinosinusitis. The inflammatory response to these conditions leads to the development of a sterile transudate within the middle-ear and mastoid cavities. Infection may occur if bacteria or viruses from the nasopharynx contaminate this fluid, producing an acute (or sometimes chronic) illness.

**Acute Otitis Media** Acute otitis media results when pathogens from the nasopharynx are introduced into the inflammatory fluid collected in the middle ear—e.g., by nose blowing during a URI. The proliferation of these pathogens in this space leads to the development of the typical signs and symptoms of acute middle-ear infection. The diagnosis of acute otitis media requires the demonstration of fluid in the middle ear (with tympanic membrane immobility) and the accompanying signs or symptoms of local or systemic illness (Table 27-1).

**ETIOLOGY** Acute otitis media typically follows a viral URI. The causative viruses (most commonly RSV, influenza virus, rhinovirus, and enterovirus) can themselves cause subsequent acute otitis media; more often, they predispose the patient to bacterial otitis media. Studies using tympanocentesis have consistently found *S. pneumoniae* to be the most important bacterial cause, isolated in up to 35% of cases. *H. influenzae* (nontypeable strains) and *M. catarrhalis* are also common bacterial causes of acute otitis media. Viruses, such as those mentioned above, have been recovered either alone or with bacteria in 17 to 40% of cases.

**MANIFESTATIONS** Fluid in the middle ear is typically demonstrated or confirmed with pneumatic otoscopy. In the absence of fluid, the tympanic membrane moves visibly with the application of positive and negative pressure, but this movement is dampened when fluid is present. With bacterial infection, the tympanic membrane can also be erythematous, bulging, or retracted and occasionally can spontaneously perforate. The signs and symptoms accompanying infection can be local or systemic, including otalgia, otorrhea, diminished hearing, fever, or irritability. Erythema of the tympanic membrane is often evident but is nonspecific as it is frequently seen in association with inflammation of the upper respiratory mucosa (e.g., during examination of young children). Other signs and symptoms occasionally reported include vertigo, nystagmus, and tinnitus.

**TREATMENT** There has been considerable debate on the usefulness of antibiotics for the treatment of acute otitis media. Although most cases resolve clinically 1 week after the onset of illness, there appears to be some benefit to the use of antibiotics, with a higher proportion of treated than of untreated patients free of illness 3 to 5 days after diagnosis. The difficulty of predicting which patients will benefit from antibiotic therapy has led to different approaches. In the Netherlands, for instance, physicians typically manage acute otitis media with initial observation and aggressive pain management with anti-inflammatory therapy, reserving antibiotics for high-risk patients, patients with complicated disease, or patients who do not improve after 48 to 72 h. In contrast, many experts in the United States continue to recommend antibiotic therapy for children <2 years old in light of the higher frequency of secondary complications in this young and functionally immunocompromised population.

Given that most studies of the etiologic agents of acute otitis media consistently document similar pathogen profiles, therapy is generally empirical except in those few cases where tympanocentesis is warranted—e.g., cases in newborns, cases refractory to therapy, or cases in patients who are severely ill or who have an immune deficiency. Despite resistance to penicillin and amoxicillin in roughly one-quarter of *S. pneumoniae* isolates, one-third of *H. influenzae* isolates, and nearly all *M. catarrhalis* isolates, outcome studies continue to find that amoxicillin is as successful as any other agent, and it remains the drug of first choice in recommendations from the Centers for Disease Control and Prevention (CDC; Table 27-1). Therapy is typically administered for 5 to 7 days for uncomplicated acute otitis media; longer courses (e.g., 10 days) have traditionally been prescribed, but evidence suggests that this duration should be reserved for complicated cases or for children <2 years old, in whom short-course therapy may be inadequate.

A switch in regimen is recommended if there is no clinical improvement by the third day of therapy, given the possibility of infection with a β-lactamase-producing strain of *H. influenzae* or *M. catarrhalis* or with a strain of penicillin-resistant *S. pneumoniae*. Decongestants and antihistamines are frequently used as adjunctive therapy to reduce congestion and relieve obstruction of the eustachian tube, but clinical trials have yielded no significant evidence of benefit with either class of agents.

**Recurrent Acute Otitis Media** Recurrent acute otitis media (more than three episodes within 6 months or four episodes within 12 months) is generally due to relapse or reinfection, although data indicate that the majority of early recurrences are new infections. In general, the same pathogens responsible for acute otitis media cause recurrent disease; even so, the recommended treatment consists of antibiotics active against β-lactamase-producing organisms. Antibiotic prophylaxis for patients with recurrent acute otitis media [e.g., with trimethoprim-sulfamethoxazole (TMP-SMX) or amoxicillin] can reduce recurrences by an average of one episode per year, but this benefit is small compared with the cost of the drug and the high likelihood of colonization with antibiotic-resistant pathogens. Other approaches, including placement of tympanostomy tubes, adenoidectomy, and tonsillectomy plus ade-
Mastoiditis is a relatively common condition in children before the introduction of antibiotics. Because the mastoid air cells connect with the middle ear, the process of fluid collection and infection in the mastoid is usually the same as in the middle ear. Early and frequent treatment of acute otitis media is most likely the reason that the incidence of acute mastoiditis has declined to only 1.2 to 2.0 cases per 100,000 person-years in countries with high prescribing rates for acute otitis media. In countries like the Netherlands, where antibiotics are used sparingly for acute otitis media, the incidence rate of acute mastoiditis is roughly twice that seen in countries like the United States. However, neighboring Denmark has a rate of acute mastoiditis similar to that in the Netherlands but an antibiotic-prescribing rate for acute otitis media more similar to that in the United States.

In typical acute mastoiditis, purulent exudate collects in the mastoid air cells, producing pressure that may result in erosion of the surrounding bone and the formation of abscess-like cavities that are usually evident on CT. Patients typically present with pain, erythema, and swelling of the mastoid process along with displacement of the pinna, usually in conjunction with the typical signs and symptoms of acute middle-ear infection. Rarely, patients can develop severe complications if the infection tracks under the perosteum of the temporal bone to cause a subperiosteal abscess, erodes through the mastoid tip to cause a deep neck abscess, or extends posteriorly to cause septic thrombosis of the lateral sinus.

Cultures of purulent fluid should be performed whenever possible to help guide antimicrobial therapy. Initial empirical therapy is usually directed against the typical organisms associated with acute otitis media, such as *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Some patients with more severe or prolonged courses of illness should be treated for infection with *S. aureus* and gram-negative bacilli (including *Pseudomonas*). Broad empirical therapy is usually narrowed once culture results become available. Most patients can be treated conservatively with intravenous antibiotics; surgery (cortical mastoidectomy) can be reserved for complicated cases and those in which conservative treatment has failed.

**INFECTIONS OF THE PHARYNX AND ORAL CAVITY**

Oropharyngeal infections range from mild, self-limited viral illnesses to serious, life-threatening bacterial infections. The most common presenting symptom is sore throat—one of the most frequent reasons for ambulatory care visits among adults and children. Although sore throat is a symptom in many noninfectious illnesses as well, the overwhelming majority of patients with a new sore throat have acute pharyngitis of viral or bacterial etiology.

**Acute Pharyngitis**

Millions of visits to primary care providers each year are for sore throat; the majority of cases of acute pharyngitis are caused by typical respiratory viruses. The most important source of concern is infection with group A β-hemolytic *Streptococcus* (*S. pyogenes*), which can progress to acute rheumatic fever and acute glomerulonephritis, the risk for both of which can be reduced by timely penicillin therapy.

**Etiology**

A wide variety of organisms cause acute pharyngitis. The relative importance of the different pathogens can only be estimated, since a significant proportion of cases (~30%) have no identified cause. Respiratory viruses are the most common identifiable cause of acute pharyngitis, with rhinoviruses (~20% of cases) and coronaviruses (at least 5%) accounting for a large proportion. Influenza virus, parainfluenza virus, and adenovirus also account for a measurable share of cases, the latter as part of the more clinically severe syndrome of pharyngocconjunctival fever. Other important but less common viral causes include herpes simplex virus (HSV) types 1 and 2, coxsackievirus A, cytomegalovirus (CMV), and Epstein-Barr virus (EBV). Acute HIV infection can present as acute pharyngitis and should be considered in high-risk populations.

Acute bacterial pharyngitis is typically caused by *S. pyogenes*, which accounts for ~5 to 15% of all cases of acute pharyngitis in adults; rates vary depending on the season and on health care system utilization. Group A streptococcal pharyngitis is primarily a disease of children 5 to 15 years of age; it is uncommon among children <3 years old, as is rheumatic fever. Streptococci of groups C and G account for a minority of cases, although these serogroups are nonhemolytic. The remaining bacterial causes of the acute pharyngitis are seen infrequently (~1% each) but should be considered in appropriate exposure groups because of the severity of illness if left untreated; these etiologic agents include *Neisseria gonorrhoeae*, *Corynebacterium diptheriae*, *Corynebacterium ulcerans*, *Yersinia enterocolitica*, and *Treponema pallidum* (in secondary syphilis). Anaerobic bacteria can also cause acute pharyngitis (*Vincent’s angina*) and can contribute to more serious polymicrobial infections, such as peritonsillar or retropharyngeal abscess (see below). Atypical organisms such as *M. pneumoniae* and *C. pneumoniae* have been recovered from patients with acute pharyngitis; whether these agents are commensals or causes of acute infection is debatable.

**Manifestations**

Although the signs and symptoms accompanying acute pharyngitis are not reliable predictors of the etiologic agent, the clinical presentation occasionally suggests that one etiology is more likely than another. Acute pharyngitis due to respiratory viruses such as rhinovirus or coronavirus is usually not severe and is typically associated with a constellation of coryzal symptoms better characterized as nonspecific URI. Findings on physical examination are uncommon; fever is rare, and tender cervical adenopathy and pharyngeal exudates are not seen. In contrast, acute pharyngitis from influenza virus can be severe and is much more likely to be associated with fever as well as
with myalgias, headache, and cough. The presentation of pharyngoconjunctival fever due to adenovirus infection is similar. Since pharyngeal exudate may be present on examination, this condition can be difficult to differentiate from streptococcal pharyngitis. However, adenoviral pharyngitis is distinguished by the presence of conjunctivitis in one-third to one-half of patients. Acute pharyngitis from primary HSV infection can also mimic streptococcal pharyngitis in some cases, with pharyngeal inflammation and exudate, but the presence of vesicles and shallow ulcers on the palate can help differentiate the two diseases. This HSV syndrome is distinct from pharyngitis caused by coxsackievirus (herpangina), which is associated with small vesicles that develop on the soft palate and uvula and then rupture to form shallow white ulcers. Acute exudative pharyngitis coupled with fever, fatigue, generalized lymphadenopathy, and (on occasion) splenomegaly is characteristic of infectious mononucleosis due to EBV or CMV.

Acute primary infection with HIV is frequently associated with fever and acute pharyngitis as well as with myalgias, arthralgias, malaise, and occasionally a nonpruritic maculopapular rash, which later may be followed by lymphadenopathy and mucosal ulcerations without exudate.

The clinical features of acute pharyngitis caused by streptococci of groups A, C, and G are all similar, ranging from a relatively mild illness without many accompanying symptoms to clinically severe cases with profound pharyngeal pain, fever, chills, and abdominal pain. A hyperemic pharyngeal membrane with tonsillar hypertrophy and exudate is usually seen, along with tender anterior cervical adenopathy. Coryzal manifestations, including cough, are typically absent; when present, they suggest a viral etiology. Strains of *S. pyogenes* that generate erythrogenic toxin can also produce scarlet fever, characterized by an erythematous rash and strawberry tongue. The other types of acute bacterial pharyngitis (e.g., *gonococcus*, diphtherial, and *yersinial*) often present as exudative pharyngitis with or without other clinical features. Their etiologies are often suggested only by the clinical history.

### Diagnosis

The primary goal of diagnostic testing is to separate acute streptococcal pharyngitis from pharyngitis of other etiologies (particularly viral) so that antibiotics can be prescribed more efficiently for patients to whom they may be beneficial. The most appropriate standard for the diagnosis of streptococcal pharyngitis, however, has not been definitively established. Throat swab culture is generally regarded as such. However, this method cannot distinguish between infection and colonization, and it takes 24 to 48 h to yield results that vary according to technique and culture conditions. Rapid antigen-detection tests offer good specificity (>90%) but lower sensitivity that varies across the clinical spectrum of disease (65 to 90%). Several clinical prediction systems (see Table 27-1) can increase the sensitivity of rapid antigen-detection tests to >90% in controlled settings. Since the sensitivities achieved in routine clinical practice are often lower, several medical and professional societies continue to recommend that all negative rapid antigen-detection tests in children be confirmed by a throat culture to limit transmission and complications of illness caused by group A streptococci. The CDC, the Infectious Diseases Society of America, the American College of Physicians, and the American Academy of Family Physicians do not recommend backup culture when adults have a negative rapid antigen-detection test, however, given the lower prevalence and smaller benefit in this age group.

Cultures and rapid diagnostic tests for other causes of acute pharyngitis, such as influenza virus, adenovirus, HSV, EBV, CMV, and *M. pneumoniae*, are available in some locations and can be used when these infections are suspected. In general, the monospot test for EBV is preferable to an assay for EBV antibodies, since the latter does not distinguish antecedent from current infection. Testing is also available for HIV RNA or antigen (p24) when acute primary HIV infection is suspected. If other bacterial causes are suspected (particularly *N. gonorrhoeae*, *C. diphtheriae*, or *Y. enterocolitica*), specific cultures should be requested since these organisms may be missed on routine throat swab culture.

### Treatment

Antibiotic treatment of pharyngitis due to *S. pyogenes* confers numerous benefits, including a decrease in the risk of rheumatic fever. The magnitude of this benefit is fairly small, however, since rheumatic fever is now a rare disease, even in untreated patients. When therapy is started within 48 h of illness onset, however, symptom duration is also decreased. An additional benefit of therapy is the potential to reduce the spread of streptococcal pharyngitis, particularly in areas of overcrowding or close contact. Antibiotic therapy for acute pharyngitis is therefore recommended in cases where *S. pyogenes* is confirmed as the etiologic agent by rapid antigen-detection test or throat swab culture. Otherwise, antibiotics should be given in routine cases only when another bacterial cause has been identified. Effective therapy for streptococcal pharyngitis consists of either a single dose of intramuscular benzathine penicillin or a 10-day course of oral penicillin (Table 27-1). Erythromycin can be used in place of penicillin, although erythromycin resistance among *S. pyogenes* strains in some parts of the world (particularly Europe) can prohibit the use of this drug. Newer (and more expensive) antibiotics are also active against streptococci but offer no greater efficacy than the above agents. Testing for cure is unnecessary and may reveal only chronic colonization. There is no evidence to support antibiotic treatment of group C or G streptococcal pharyngitis or of pharyngitis in which *Mycoplasma* or *Chlamydia* has been recovered. Penicillin prophylaxis (benzathine penicillin G, 1.2 million units intramuscularly every 3 to 4 weeks) is indicated for patients at risk of recurrent rheumatic fever.

Treatment of viral pharyngitis is entirely symptom-based except in infection with influenza virus or HSV. For influenza, a number of therapeutic agents exist, including amantadine, rimantadine, and the two newer agents oseltamivir and zanamivir. All of these agents need to be started within 36 to 48 h of symptom onset to reduce illness duration meaningfully. Of these agents, only oseltamivir and zanamivir are active against both influenza A and influenza B and therefore can be used when local infection patterns are unknown. Oropharyngeal HSV infection sometimes responds to treatment with antiviral agents such as acyclovir, although these drugs are often reserved for patients who are immunosuppressed.

### Complications

Although rheumatic fever is the best-known complication of acute streptococcal pharyngitis, its risk following acute infection remains quite low. Other complications include acute glomerulonephritis and numerous supplicative conditions, such as peritonsillar abscess (*quinsy*), otitis media, mastoiditis, sinusitis, bacteremia, and pneumonia—all of which occur at extremely low rates. Although antibiotic treatment of acute streptococcal pharyngitis can prevent the development of rheumatic fever, there is no evidence that it can prevent acute glomerulonephritis. Some evidence supports antibiotic use to prevent the supplicative complications of streptococcal pharyngitis, particularly peritonsillar abscess, which can also involve oral anaerobes. Abscesses are usually accompanied by severe pharyngeal pain, dysphagia, and fever, often with medial displacement of the tonsil on examination. Oral penicillin remains the recommended therapy for peritonsillar abscess, with clindamycin as an alternative. Early use of antibiotics in these cases has substantially reduced the need for surgical drainage.

### Oral Infections

Aside from periodontal disease such as gingivitis, infections of the oral cavity most commonly involve HSV or *Candida* species. In addition to causing painful cold sores on the lips, HSV can infect the tongue and buccal mucosa, causing the formation of irritant vesicles. Although topical antiviral agents (such as acyclovir or penciclovir) can be used externally for cold sores, oral or intravenous acyclovir is often needed for primary infections, extensive oral infec-

*27 Infections of the URT*
Infections of the Larynx and Epiglottis

**Laryngitis** is defined as any inflammatory process involving the larynx and can be caused by a variety of infectious and noninfectious processes. The vast majority of laryngitis cases seen in clinical practice in developed countries are acute. Acute laryngitis is a common syndrome caused predominantly by the same viruses responsible for many other URIs. In fact, most cases of acute laryngitis occur in the setting of a viral URI.

**Etiology**

Nearly all major respiratory viruses have been implicated in acute viral laryngitis, including rhinovirus, influenza virus, parainfluenza virus, adenovirus, coxsackievirus, coronavirus, and RSV. Acute laryngitis can also be associated with acute bacterial infections, such as those caused by group A Streptococcus or *C. diphtheriae* (although diphtheria has been all but eliminated in the United States).

Another bacterial pathogen thought to play a role (albeit unclear) in the pathogenesis of acute laryngitis is *M. catarrhalis*, which has been recovered on nasopharyngeal culture from a significant percentage of people with acute laryngitis. Chronic laryngitis of infectious etiology is much less common in developed than in developing countries. Laryngitis due to *Mycobacterium tuberculosis* is often difficult to distinguish from laryngeal cancer, in part because of the frequent absence of signs, symptoms, and radiographic findings typical of pulmonary disease. *Histoplasma* and *Blastomyces* may cause laryngitis, often as a complication of systemic infection. *Candida* species can cause laryngitis as well, often in association with thrush or esophagitis and particularly in immunosuppressed patients. Rare cases of chronic laryngitis are due to *Coccidioides* and *Cryptococcus*.

**Manifestations and Diagnosis**

Epiglottitis typically presents more acutely in young children than in adolescents or adults. On presentation, most children with epiglottitis have symptoms for <24 h, including high fever, severe sore throat, tachycardia, systemic toxicity, and (in many cases) drooling while sitting forward. Symptoms and signs of respi-
ratory obstruction may also be present and may progress rapidly. The somewhat milder illness in adolescents and adults often follows 1 or 2 days of severe sore throat and is commonly accompanied by dyspnea, drooling, and stridor. Physical examination of patients with acute epiglottitis may reveal moderate or severe respiratory distress, with inspiratory stridor and retractions of the chest wall. These findings diminish as the disease progresses and the patient tires. Conversely, oropharyngeal examination reveals injection that is much less severe than would be predicted from the symptoms—a finding that should alert the clinician to a cause of symptoms and obstruction that lies beyond the tonsils. The diagnosis is often made on clinical grounds, although direct fiberoptic laryngoscopy is frequently performed in a controlled environment (e.g., an operating room) in order to visualize and culture the typical edematous “cherry-red” epiglottis and to facilitate placement of an endotracheal tube. Direct visualization in an examination room (e.g., with a tongue blade and indirect laryngoscopy) is not recommended because of the risk of immediate laryngospasm and complete airway obstruction. Lateral neck radiographs and laboratory tests can assist in the diagnosis but may delay the critical securing of the airway and cause the patient to be excessively moved or repositioned, risking further airway compromise. Neck radiographs typically show an enlarged edematous epiglottis (the “thumbnail sign”), usually with a dilated hypopharynx and normal subglottic structures. Laboratory tests typically show mild to moderate leukocytosis with a predominance of neutrophils. Blood cultures are positive in a significant proportion of cases.

**TREATMENT**

Security of the airway is always of primary concern in acute epiglottitis, even if the diagnosis is only suspected. Mere observation for signs of impending airway obstruction is not routinely recommended, particularly in children. Many adults have been managed in this way since the illness is perceived to be milder in this age group, but some data suggest that this approach may be risky and probably should be reserved only for adult patients who have yet to develop dyspnea or stridor. Once the airway has been secured and blood and epiglottic specimens have been obtained for culture, treatment with intravenous antibiotics should be given to cover the most likely organisms, particularly *H. influenzae*. Because rates of ampicillin resistance in this organism have risen significantly in recent years, therapy with a β-lactam/β-lactamase inhibitor combination or a second- or third-generation cephalosporin is recommended. Typically, ampicillin/sulbactam, cefuroxime, cefotaxime, or ceftriaxone is given, with clindamycin and TMP-SMX reserved for patients allergic to β-lactams. Antibiotic therapy should be continued for 7 to 10 days and should be tailored, if necessary, to the organism recovered in culture. If the household contacts of a patient with *H. influenzae* epiglottitis include an unvaccinated child under the age of 4, all members of the household (including the patient) should receive prophylactic rifampin for 4 days to eradicate *H. influenzae* carriage.

**INFECTIONS OF THE DEEP NECK STRUCTURES**

Deep neck infections are usually extensions of infection from other primary sites, most often within the pharynx or oral cavity. Many of these infections are life-threatening but are difficult to detect at early stages when they may be more easily managed. Three of the most clinically relevant spaces in the neck are the submandibular (and sublingual) space, the lateral pharyngeal (or parapharyngeal) space, and the retropharyngeal space. These spaces communicate with one another and with other important structures in the head, neck, and thorax, providing infections with easy access to areas including the mediastinum, carotid sheath, skull base, and meninges. Once infection reaches these sensitive areas, mortality rates can be as high as 20 to 50%.

Infection of the submandibular and/or sublingual space typically originates from an infected or recently extracted lower tooth. The result is the severe, life-threatening infection referred to as Ludwig’s angina (see under “Oral Infections,” above). Lateral pharyngeal (or parapharyngeal) space infection is most often a complication of common infections of the oral cavity and upper respiratory tract, including tonsillitis, peritonsillar abscess, pharyngitis, mastoiditis, or periodontal infection. This space, located deep to the lateral wall of the pharynx, contains a number of sensitive structures, including the carotid artery, internal jugular vein, cervical sympathetic chain, and portions of cranial nerves IX through XII; at its distal end, it opens into the posterior mediastinum. Involvement of this space with infection can therefore be rapidly fatal. Examination may reveal some tonsillar displacement, trismus, and neck rigidity, but lateral pharyngeal wall swelling can easily be missed. The diagnosis can be confirmed by CT. Treatment consists of airway management, operative drainage of fluid collections, and at least a 10-day course of intravenous therapy with an antibiotic active against streptococci and oral anaerobes (e.g., ampicillin/sulbactam). A particularly severe form of this infection involving the components of the carotid sheath, called postanginal septicemia (or Lemierre’s disease), is described above (“Oral Infections”). Infection of the retropharyngeal space can also be extremely dangerous, as this space runs posterior to the pharynx from the skull base to the superior mediastinum. Infections in this space are more common in children <5 years old because of the presence of several small retropharyngeal lymph nodes that typically atrophy by the age of 4 years. Infection is usually a consequence of extension from another site of infection, most commonly acute pharyngitis. Other sources include otitis media, tonsillitis, dental infections, Ludwig’s angina, and anterior extension of vertebral osteomyelitis. Retropharyngeal space infection can also follow penetrating trauma to the posterior pharynx (e.g., from an endoscopic procedure). Infections are commonly polymicrobial, with a mixture of aerobes and anaerobes; group A β-hemolytic streptococci and *S. aureus* are the most common pathogens. Tuberculosis was a frequent cause in the past but now is rarely seen in the United States. Patients with retropharyngeal abscess typically present with sore throat, fever, dysphagia, and neck pain and are often drooling because of difficulty and pain with swallowing. Examination may reveal tender cervical adenopathy, neck swelling, and diffuse erythema and edema of the posterior pharynx as well as a bulge in the posterior pharyngeal wall, although the latter may not be obvious on routine inspection. A soft tissue mass is usually demonstrable by lateral neck radiography or CT. Because of the risk of airway obstruction, treatment begins with securing of the airway, which is followed by a combination of surgical drainage and intravenous antibiotic administration. Initial empirical therapy should cover streptococci, oral anaerobes, and *S. aureus*; ampicillin/sulbactam, clindamycin alone, or clindamycin plus ceftriaxone is usually effective. Complications occur primarily as a result of extension to other areas, including rupture into the posterior pharynx, which may lead to aspiration pneumonia and empyema. Extension may also occur to the lateral pharyngeal space and mediastinum, resulting in mediastinitis and pericarditis, or into nearby major blood vessels. All these events are associated with a high mortality rate.

**FURTHER READING**

As primary care physicians and consultants, internists are often asked to evaluate patients with disease of the oral soft tissues, teeth, and pharynx. Knowledge of the oral milieu and its unique structures is necessary to guide preventive services and recognize oral manifestations of local or systemic disease. Furthermore, internists frequently collaborate with dentists in the care of patients with a variety of medical conditions that impact oral health or who undergo dental procedures that increase the patient’s risk of medical complications.

**DISEASES OF THE TEETH AND PERIODONTAL STRUCTURES**

**Tooth and Periodontal Structure**
- Tooth formation begins during the sixth week of embryonic life and continues through the first 17 years of age. Tooth development begins in utero and continues until after the tooth erupts. Normally all 20 deciduous teeth have erupted by age 3 and have been shed by age 13. Permanent teeth, eventually totaling 32, begin to erupt by age 6 and have completely erupted by age 14, though third molars (wisdom teeth) may erupt later.

- The erupted tooth consists of the visible crown covered with enamel and the root submerged below the gum line and covered with bonelike cementum. Dentin, a material that is denser than bone and exquisitely sensitive to pain, forms the majority of the tooth substance. Dentin surrounds a core of myxomatous pulp containing the vascular and nerve supply. The tooth is held firmly in the alveolar socket by the periodontium, supporting structures that consist of the gingivae, alveolar bone, cementum, and periodontal ligament. The periodontal ligament tenaciously binds the tooth’s cementum to the alveolar bone. Above this ligament is a collar of attached gingiva just below the crown. A few millimeters of unattached or free gingiva (1 to 3 mm) overlaps the base of the crown, forming a shallow sulcus along the gum-tooth margin.

**Dental Caries, Pulpal and Periapical Disease, and Complications**
- Dental caries begin asymptptomatically as a destructive process of the hard surface of the tooth. *Streptococcus mutans*, principally, along with other bacteria colonize the organic buffering film on the tooth surface to produce plaque. If not removed by brushing or the natural cleaning action of saliva and oral soft tissues, bacterial acids demineralize the enamel. Fissures and pits on the occlusion surfaces are the most frequent sites of decay. Surfaces adjacent to tooth restorations and exposed roots are also vulnerable, particularly as teeth are retained in an aging population. Over time dental caries extend to the underlying dentin, leading to cavitation of the enamel and ultimately penetration to the tooth pulp, producing *acute pulpitis*. At this early stage when the pulp infection is limited, the tooth becomes sensitive to percussion and hot or cold, and pain resolves immediately when the irritating stimulus is removed. Should the infection spread throughout the pulp, *irreversible pulpitis* occurs leading to pulp necrosis. At this late stage pain is severe and has a sharp or throbbing visceral quality that may be worse when the patient lies down. Once pulp necrosis is complete, pain may be constant or intermittent, but cold sensitivity is lost.

- Treatment of caries involves removal of the softened and infected hard tissue; sealing the exposed dentin; and restoration of the tooth structure with silver amalgam, composite plastic, gold, or porcelain. Once irreversible pulpitis occurs, root canal therapy is necessary and the contents of the pulp chamber and root canals are removed, followed by thorough cleaning, antisepsis, and filling with an inert material. Alternatively, the tooth may be extracted.

- Pulpal infection, if it does not egress through the decayed enamel, leads to *periapical abscess* formation, which produces pain on chewing. If the infection is mild and chronic, a *periapical granuloma* or eventually a *periapical cyst* forms, either of which produces radiolucency at the root apex. When unchecked, a periapical abscess can erode into the alveolar bone producing osteomyelitis, penetrate and drain through the gingivae (*parulis* or *gumboil*), or track along deep fascial planes producing a virulent cellulitis (*Ludwig’s angina*) involving the submandibular space and floor of the mouth (Chap. 148). Elderly patients, those with diabetes mellitus, and patients taking glucocorticoids may experience little or no pain and fever as these complications develop.

**Periodontal Disease**
- Periodontal disease accounts for more tooth loss than caries, particularly in the elderly. Like dental caries, chronic infection of the gingiva and anchoring structures of the tooth begins with formation of bacterial plaque. The process begins invisibly above the gum line and in the gingival sulcus. Plaque, including mineralized plaque (*calculus*), is preventable by appropriate dental hygiene, including periodic professional cleaning. Left undisturbed, chronic inflammation ensues and produces a painless hyperemia of the free and attached gingivae (*gingivitis*) that typically bleeds with brushing. If ignored, severe *periodontitis* occurs, leading to deepening of the physiologic sulcus and destruction of the periodontal ligament. Pockets develop around the teeth that become filled with pus and debris. As the periodontium is destroyed, teeth loosen and exfoliate. Eventually there is resorption of the alveolar bone.

Acute and aggressive forms of periodontal disease are seen less commonly than the chronic forms described above. However, if the host is stressed or exposed to a new pathogen, rapidly progressive and destructive disease of the periodontal tissue can occur. A virulent example is *acute necrotizing ulcerative gingivitis* (ANUG), or *Vincent’s infection*, characterized as “trench mouth” during World War I. Stress, poor oral hygiene, and tobacco and alcohol use are risk factors. The presentation includes sudden gingival inflammation, ulceration, bleeding, interdential gingival necrosis, and fetid halitosis. *Localized juvenile periodontitis*, seen in adolescents, is particularly destructive and appears to be associated with impaired neutrophil chemotaxis. *AIDS-related periodontitis* resembles ANUG in some patients or a more destructive form of adult chronic periodontitis in others. It may also produce a gangrene-like destructive process of the oral soft tissues and bone that resembles *noma*, seen in severely malnourished children in developing nations.

**Prevention of Tooth Decay and Periodontal Infection**
- Despite the reduced prevalence of dental caries and periodontal disease in the United States due in large part to water fluoridation and improved dental care, respectively, both diseases constitute a major public health problem worldwide and for certain groups. The internist can promote prevention by including questions about dental care and hygiene as part of health maintenance. Special populations at high risk for dental caries and periodontal disease include those with xerostomia (*Sjögren’s syndrome*), drug-induced, postirradiation head and neck), diabetics, alcoholics, tobacco users, those with Down’s syndrome, and those with gingival hyperplasia. Furthermore, patients lacking dental care access (low socioeconomic status) and those with reduced ability to provide self-care (e.g., nursing-home residents, those with dementia or upper extremity disability) suffer at a disproportionate rate. It is important to provide counseling regarding regular dental hygiene and professional cleaning, use of fluoride-containing toothpaste, professional fluoride treatments, and use of electric toothbrushes for patients with limited dexterity and to give instruction to caregivers for those unable to perform self-care.

**Developmental and Systemic Disease Affecting the Teeth and Periodontium**
- Malocclusion is the most common developmental problem, which in addition to a problem with cosmetics, can interfere with mastication unless corrected through orthodontic techniques. Impacted third molars are common and occasionally become infected. Acquired prognathism due to *acrognathy* may also lead to malocclusion, as may deformity of the maxilla and mandible due to *Paget’s disease* of the bone. Delayed tooth eruption, receding chin, and a protruding tongue are occasional features of *cretinism* and *hypopituitarism*. Congenital syphilis produces tapering, notched (*Hutchinson’s*) incisors and finely nodular (*mulberry*) molar crowns.

*Enamel hypoplasia* results in crown defects ranging from pits to...
deep fissures of primary or permanent teeth. Intrauterine infection (syphilis, rubella), vitamin deficiency (A, C, D), disorders of calcium metabolism (malabsorption, vitamin D-resistant rickets, hypoparathyroidism), prematurity, high fever, or rare inherited defects (amelogenesis imperfecta) are all causes. Tetracycline, given in sufficiently high doses during the first 8 years, may produce enamel hypoplasia and discoloration. Exposure to endogenous pigments can discolor developing teeth: erythromelalgia (fetalis, green or bluish-black), congenital liver disease (brown or yellow-brown), and porphyria (red or brown that fluoresces with ultraviolet light). Mottled enamel occurs if excessive fluoride is ingested during development. Worn enamel is seen with age, bruxism, or excessive acid exposure (e.g., chronic gastric reflux or bulimia).

Premature tooth loss resulting from periodontitis is seen with cyclic neutropenia, Papillon-Lefèvre syndrome, Chédiak-Higashi syndrome, and leukemia. Rapid focal tooth loosening is most often due to infection, but rarer causes include histiocytosis X, Ewing's sarcoma, osteosarcoma, or Burkitt's lymphoma. Early loss of primary teeth is a feature of hypophosphatasia, a rare inborn error of metabolism.

Pregnancy may produce severe gingivitis and localized pyogenic granulomas. Severe periodontal disease occurs with Down's syndrome and diabetes mellitus. Gingival hyperplasia may be caused by phenytoin, calcium channel blockers (e.g., nifedipine), and cyclosporine. Idiopathic familial gingival fibromatosis and several syndrome-related disorders appear similar. Removal of the medication often reverses the drug-induced form, though surgery may be needed to control both. Linear gingival erythema is variably seen in patients with advanced HIV infection and probably represents immune deficiency and decreased polymorphonuclear activity. Diffuse or focal gingival swelling may be a feature of early or late acute myelomonocytic leukemia as well as of other lymphoproliferative disorders. A rare, but pathognomonic, sign of Wegener's granulomatosis is a red-purplish, granular gingivitis (strawberry gums).

**DISEASES OF THE ORAL MUCOSA**

- **Infection**
  Most oral mucosal diseases involve microorganisms (Table 28-1).

- **Pigmented Lesions**
  See Table 28-2

- **Dermatologic Diseases**
  See Tables 28-1, 28-2, and 28-3 and Chaps. 46 to 51

- **Diseases of the Tongue**
  See Table 28-4

- **HIV Disease and AIDS**
  See Tables 28-1, 28-2, 28-3, and 28-5; Chaps. 172 and 173; and Figs. 165-1 and 187-1.

- **Ulcers**
  Ulceration is the most common oral mucosal lesion encountered. Although there are many possible causes, the host and pattern of lesions, including the presence of systemic features, narrow the differential diagnosis (Table 28-1). Most acute ulcers are painful and self-limited. Recurrent apthous ulcers and herpes simplex infection constitute the majority. Persistent and deep aphthous ulcers can be idiopathic or seen with HIV/AIDS. Aphthous lesions are often the presenting symptom in Behçet's disease. Similar appearing, though less painful, lesions may occur with Reiter's syndrome, and aphthous ulcers are occasionally present during phases of discoid or systemic lupus erythematosus. Aphthous-like ulcers are seen in Crohn's disease, but unlike the common aphthous variety, they may exhibit granulomatous inflammation histologically. Recurrent aphthae in some patients with celiac disease have been reported to remit with elimination of gluten.

  Of major concern are chronic, relatively painless ulcers and mixed red/white patches (erythroleukia and leukoplakia) of more than 2 weeks' duration. Squamous cell carcinoma and premalignant dysplasia should be considered early and a diagnostic biopsy obtained. The importance is underscored because early-stage malignancy is vastly more treatable than late-stage disease. High-risk sites include the lower lip, floor of the mouth, ventral and lateral tongue, and soft palate–tonsillar pillar complex. Significant risk factors for oral cancer in western countries include sun-exposure (lower lip) and tobacco and alcohol use. In India and some other Asian countries, smokeless tobacco mixed with betel nut, slaked lime, and spices is a common cause of oral cancer. Less common etiologies include syphilis and Plummer-Vinson syndrome.

  Rarer causes of chronic ulcer such as tuberculosis, fungal infection, Wegener's granulomatosis, and midline granuloma may look identical to carcinoma. Making the correct diagnosis depends on recognizing other clinical features and biopsy of the lesion. The syphilitic chancre is typically painless and therefore easily missed. Regional lymphadenopathy is invariably present. Confirmation is achieved using appropriate bacterial and serologic tests.

  Disorders of mucosal fragility often produce painful oral ulcers that fail to heal within 2 weeks. Mucous membrane pemphigoid and pemphigus vulgaris are the major acquired disorders. While clinical features are often distinctive, immunohistochemical examination should be performed for diagnosis and to distinguish these entities from lichen planus and drug reactions.

- **Hematologic and Nutritional Disease**
  Internists are more likely to encounter patients with acquired, rather than congenital, bleeding disorders. Bleeding after minor trauma should stop after 15 min and within an hour of tooth extraction if local pressure is applied. Bleeding in excess of this, if not due to continued injury or rupture of a large vessel, should lead to investigation for a clotting abnormality. In addition to bleeding, petechiae and ecchymoses are prone to occur at the line of vibration between the soft and hard palates in patients with platelet dysfunction or thrombocytopenia.

  All forms of leukemia, but particularly acute myelomonocytic leukemia, can produce gingival bleeding, ulcers, and gingival enlargement. Oral ulcers are a feature of agranulocytosis, and ulcers and mucositis are often severe complications of chemotherapy and radiation therapy for hematologic and other malignancies. Plummer-Vinson syndrome (iron deficiency, angular stomatitis, glossitis, and dysphagia) raises the risk of oral squamous cell cancer and esophageal cancer at the postcricoid tissue site. Atrophic papillae and a red, burning tongue may occur with pernicious anemia. B-group vitamin deficiencies produce many of these same symptoms as well as oral ulceration and cheilosis. Swollen, bleeding gums, ulcers, and loosening of the teeth are a consequence of scurvy.

- **NONDENTAL CAUSES OF ORAL PAIN**
  Most oral pain emanates from inflamed or injured tooth pulp or periodontal tissues, and this fact often leads clinicians to overlook nondentogenic causes. In most instances toothache is predictable and proportional to the stimulus applied and an identifiable condition (e.g., caries, abscess) is found. Local anesthesia eliminates pain originating from dental or periodontal structures, but not referred pains. The most common nondental origin is myofascial pain referred from muscles of mastication. The masticatory muscles are tender and ache with increased use. Many sufferers exhibit bruxism that is secondary to stress and anxiety. Temporomandibular disorder is closely related. It predominantly affects females between ages 15 and 45. Features include pain, limited mandibular movement, and temporomandibular joint sounds. The etiologies are complex, and malocclusion does not play the primary role once attributed to it. Osteoarthritis is a common cause of masticatory pain. Anti-inflammatory medication, jaw rest, soft foods, and heat provide relief. With treatment complete, remission of pain is the rule. The temporomandibular joint is involved in 50% of patients with rheumatoid arthritis and is usually a late feature of severe disease. Bilateral preauricular pain, particularly in the morning, limits range of motion.

  **Migrainous neuralgia** is sometimes so localized to the mouth as to present a diagnostic challenge. Episodes of pain and remission without identifiable cause and absence of relief with local anesthesia are important clues. Trigeminal neuralgia (tic douloureux) may involve the entire branch of the mandibular or maxillary branches of the fifth cranial nerve and produce pain in one or a few teeth. Pain may occur spontaneously or may be triggered by touching the lip or ging-

<tr>
<td><strong>VIRAL DISEASES</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Primary acute herpetic gingivostomatitis [herpes simplex virus (HSV) type 1, rarely type 2]</td>
<td>Lip and oral mucosa (buccal, gingival, lingual mucosa)</td>
<td>Labial vesicles that rupture and crust, and intraoral vesicles that quickly ulcerate; extremely painful; acute gingivitis, fever, malaise, foul odor, and cervical lymphadenopathy; occurs primarily in infants, children, and young adults</td>
<td>Heals spontaneously in 10–14 days. Unless secondarily infected, lesions lasting &gt;3 weeks are not due to primary HSV infection.</td>
</tr>
<tr>
<td>Recurrent herpes labialis</td>
<td>Mucocutaneous junction of lip, perioral skin</td>
<td>Eruption of groups of vesicles that may coalesce, then rupture and crust; painful to pressure or spicy foods</td>
<td>Lasts about 1 week, but condition may be prolonged if secondarily infected. If severe, topical or oral antiviral may reduce healing time.</td>
</tr>
<tr>
<td>Recurrent intraoral herpes simplex</td>
<td>Palate and gingiva</td>
<td>Small vesicles on keratinized epithelium that rupture and coalesce; painful</td>
<td>Heals spontaneously in about 1 week. If severe, topical or oral antiviral may reduce healing time.</td>
</tr>
<tr>
<td>Chickenpox (varicella-zoster virus)</td>
<td>Gingiva and oral mucosa</td>
<td>Skin lesions may be accompanied by small vesicles on oral mucosa that rupture to form shallow ulcers; may coalesce to form large bullous lesions that ulcerate; mucosa may have generalized erythema</td>
<td>Lesions heal spontaneously within 2 weeks.</td>
</tr>
<tr>
<td>Herpes zoster (reactivation of varicella-zoster virus)</td>
<td>Cheek, tongue, gingiva, or palate</td>
<td>Unilateral vesicular eruptions and ulceration in linear pattern following sensory distribution of trigeminal nerve or one of its branches</td>
<td>Gradual healing without scarring unless secondarily infected; postherpetic neuralgia is common. Oral acyclovir, famcyclovir, or valacyclovir reduce healing time and postherpetic neuralgia</td>
</tr>
<tr>
<td>Infectious mononucleosis (Epstein-Barr virus)</td>
<td>Oral mucosa</td>
<td>Fatigue, sore throat, malaise, fever, and cervical lymphadenopathy; numerous small ulcers usually appear several days before lymphadenopathy; gingival bleeding and multiple petechiae at junction of hard and soft palates</td>
<td>Oral lesions disappear during convalescence; no treatment though glucocorticoids indicated if tonsillar swelling compromises airway</td>
</tr>
<tr>
<td>Herpangina (coxackievirus A; also possibly coxackie B and echovirus)</td>
<td>Oral mucosa, pharynx, tongue</td>
<td>Sudden onset of fever, sore throat, and oropharyngeal vesicles, usually in children under 4 years, during summer months; diffuse pharyngeal congestion and vesicles (1–2 mm), grayish-white surrounded by red areola; vesicles enlarge and ulcerate</td>
<td>Incubation period 2–9 days; fever for 1–4 days; recovery uneventful</td>
</tr>
<tr>
<td>Hand, foot, and mouth disease (coxackievirus A16 most common)</td>
<td>Oral mucosa, pharynx, palms, and soles</td>
<td>Fever, malaise, headache with oropharyngeal vesicles that become painful, shallow ulcers; highly infectious; usually affects children under age 10</td>
<td>Incubation period 2–18 days; lesions heal spontaneously in 2–4 weeks</td>
</tr>
<tr>
<td>Primary HIV infection</td>
<td>Gingiva, palate, and pharynx</td>
<td>Acute gingivitis and oropharyngeal ulceration, associated with febrile illness resembling mononucleosis and including lymphadenopathy</td>
<td>Followed by HIV seroconversion, asymptomatic HIV infection, and usually ultimately by HIV disease</td>
</tr>
<tr>
<td><strong>BACTERIAL OR FUNGAL DISEASES</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Acute necrotizing ulcerative gingivitis (“trench mouth,” Vincent’s infection)</td>
<td>Gingiva</td>
<td>Painful, bleeding gingiva characterized by necrosis and ulceration of gingival papillae and margins plus lymphadenopathy and foul odor</td>
<td>Debridement and diluted (1:3) peroxide lavage provide relief within 24 h; antibiotics in acutely ill patients; relapse may occur. Tooth deformities in permanent dentition irreversible</td>
</tr>
<tr>
<td>Prenatal (congenital) syphilis</td>
<td>Palate, jaws, tongue, and teeth</td>
<td>Gummatus involvement of palate, jaws, and facial bones; Hutchinson’s incisors, mulberry molar, glossitis, mucous patches, and fissures on corner of mouth</td>
<td>Healing of chancre in 1–2 months, followed by secondary syphilis in 6–8 weeks</td>
</tr>
<tr>
<td>Primary syphilis (chancre)</td>
<td>Lesion appears where organism enters body; may occur on lips, tongue, or tonsillar area</td>
<td>Small papule developing rapidly into a large, painless ulcer with indurated border; unilateral lymphadenopathy; chancre and lymph nodes containing spirochetes; serologic tests positive by third to fourth weeks</td>
<td>Healing of chancre in 1–2 months, followed by secondary syphilis in 6–8 weeks</td>
</tr>
<tr>
<td>Secondary syphilis</td>
<td>Oral mucosa frequently involved with mucous patches, primarily on palate, also at commissures of mouth</td>
<td>Maculopapular lesions of oral mucosa, 5–10 mm in diameter with central ulceration covered by grayish membrane; eruptions occurring on various mucosal surfaces and skin accompanied by fever, malaise, and sore throat</td>
<td>Lesions may persist from several weeks to a year</td>
</tr>
<tr>
<td>Tertiary syphilis</td>
<td>Palate and tongue</td>
<td>Gummatus infiltration of palate or tongue followed by ulceration and fibrosis; atrophy of tongue papillae produces characteristic bald tongue and glossitis</td>
<td>Gumma may destroy palate, causing complete perforation</td>
</tr>

<table>
<thead>
<tr>
<th>Condition</th>
<th>Usual Location</th>
<th>Clinical Features</th>
<th>Course</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gonorrhea</td>
<td>Lesions may occur in mouth at site of inoculation or secondarily by hematogenous spread from a primary focus elsewhere</td>
<td>Most pharyngeal infection is asymptomatic; may produce burning or itching sensation; oropharynx and tonsils may be ulcerated and erythematous; saliva viscous and fetid</td>
<td>More difficult to eradicate than urogenital infection, though pharyngitis usually resolves with appropriate antimicrobial treatment</td>
</tr>
<tr>
<td>Tuberculosis</td>
<td>Tongue, tonsillar area, soft palate</td>
<td>A painless, solitary, 1–5 cm, irregular ulcer covered with a persistent exudate; ulcer has a firm undermined border</td>
<td>Autoinnoculation from pulmonary infection usual; lesions resolve with appropriate antimicrobial therapy</td>
</tr>
<tr>
<td>Cervicofacial actinomycosis</td>
<td>Swellings in region of face, neck, and floor of mouth</td>
<td>Infection may be associated with an extraction, jaw fracture, or eruption of molar tooth; in acute form resembles an acute pyogenic abscess, but contains yellow “sulfur granules” (gram-positive mycelia and their hyphae)</td>
<td>Typically swelling is hard and grows painlessly; multiple abscesses with draining tracks develop; penicillin first choice; surgery usually necessary</td>
</tr>
<tr>
<td>Histoplasmosis</td>
<td>Any area of the mouth, particularly tongue, gingiva, or palate</td>
<td>Nodular, verrucous, or granulomatous lesions; ulcers are indurated and painful; usual source hematogenous or pulmonary source, but may be primary</td>
<td>Systemic antifungal therapy necessary to treat</td>
</tr>
<tr>
<td>Candidiasis (Table 28-3)</td>
<td>DERMATOLOGIC DISEASES</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Mucous membrane pemphigoid</td>
<td>Typically produces marked gingival erythema and ulceration; other areas of oral cavity, esophagus, and vagina may be affected</td>
<td>Painful, grayish-white collapsed vesicles or bullae of full-thickness epithelium with peripheral erythematous zone; gingival lesions desquamate, leaving ulcerated area</td>
<td>Protracted course with remissions and exacerbations; involvement of different sites occurs slowly; glucocorticoids may temporarily reduce symptoms but do not control the disease</td>
</tr>
<tr>
<td>Erythema multiforme minor and major (Stevens-Johnson syndrome)</td>
<td>Primarily the oral mucosa and the skin of hands and feet</td>
<td>Intracutaneous bullae surrounded by an inflammatory area; lips may show hemorrhagic crusts; the “iris,” or “target,” lesion on the skin is pathognomonic; patient may have severe signs of toxicity</td>
<td>Onset very rapid; usually idiopathic, but may be associated with trigger such as drug reaction; condition may last 3–6 weeks; mortality with EM major 5–15% if untreated</td>
</tr>
<tr>
<td>Pemphigus vulgaris</td>
<td>Oral mucosa and skin; sites of mechanical trauma (soft/hard palate, frenulum, lips buccal mucosa)</td>
<td>Usually (&gt;70%) presents with oral lesions; fragile, ruptured bullae and ulcerated oral areas; mostly in older adults</td>
<td>With repeated occurrence of bullae, toxicity may lead to cachexia, infection, and death within 2 years; often controllable with oral glucocorticoids</td>
</tr>
<tr>
<td>Lichen planus</td>
<td>Oral mucosa and skin</td>
<td>White striae in mouth; purplish nodules on skin at sites of friction; occasionally causes oral mucosal ulcers and erosive gingivitis</td>
<td>White striae alone usually asymptomatic; erosive lesions often difficult to treat, but may respond to glucocorticoids</td>
</tr>
<tr>
<td><strong>OTHER CONDITIONS</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Recurrent aphthous ulcers</td>
<td>Usually on nonkeratinized oral mucosa (buccal and labial mucosa, floor of mouth, soft palate, lateral and ventral tongue)</td>
<td>Single or clusters of painful ulcers with surrounding erythematous border; lesions may be 1–2 mm in diameter in crops (herpetiform), 1–5 mm (minor), or 5–15 mm (major)</td>
<td>Lesions heal in 1–2 weeks but may recur monthly or several times a year; protective barrier with orabase and topical steroids give symptomatic relief; systemic glucocorticoids may be needed in severe cases</td>
</tr>
<tr>
<td>Behçet’s syndrome</td>
<td>Oral mucosa, eyes, genitalia, gut, and CNS</td>
<td>Multiple aphthous ulcers in mouth; inflammatory ocular changes, ulcerative lesions on genitalia; inflammatory bowel disease and CNS disease</td>
<td>Oral lesions often first manifestation; persist several weeks and heal without scarring</td>
</tr>
<tr>
<td>Traumatic ulcers</td>
<td>Anywhere on oral mucosa; dentures frequently responsible for ulcers in vestibule</td>
<td>Localized, discrete ulcerated lesions with red border; produced by accidental biting of mucosa, penetration by a foreign object, or chronic irritation by a denture</td>
<td>Lesions usually heal in 7–10 days when irritant is removed, unless secondarily infected</td>
</tr>
<tr>
<td>Squamous cell carcinoma</td>
<td>Any area in the mouth, most commonly on lower lip, tongue, and floor of mouth</td>
<td>Ulcer with elevated, indurated border; failure to heal, pain not prominent; lesions tend to arise in areas of erythrophy leukoplakia or in smooth atrophic tongue</td>
<td>Invases and destroys underlying tissues; frequently metastasizes to regional lymph nodes</td>
</tr>
<tr>
<td>Acute myeloid leukemia (usually monocytic)</td>
<td>Gingiva</td>
<td>Gingival swelling and superficial ulceration followed by hyperplasia of gingiva with extensive necrosis and hemorrhage; deep ulcers may occur elsewhere on the mucosa complicated by secondary infection</td>
<td>Usually responds to systemic treatment of leukemia; occasionally requires local radiation therapy</td>
</tr>
<tr>
<td>Lymphoma</td>
<td>Gingiva, tongue, palate and tonsillar area</td>
<td>Elevated, ulcerated area that may proliferate rapidly, giving the appearance of traumatic inflammation</td>
<td>Fatal if untreated; may indicate underlying HIV infection</td>
</tr>
<tr>
<td>Chemical or thermal burns</td>
<td>Any area in mouth</td>
<td>White slough due to contact with corrosive agents (e.g., aspirin, hot cheese) applied locally; removal of slough leaves raw, painful surface</td>
<td>Lesion heals in several weeks if not secondarily infected</td>
</tr>
</tbody>
</table>

**Note:** CNS, central nervous system.
giva, brushing the teeth, or chewing. Glossopharyngeal neuralgia produces similar acute neuropathic symptoms in the distribution of the ninth cranial nerve. Swallowing, sneezing, coughing, or pressure on the tragus of the ear triggers pain that is felt in the base of the tongue, palate, and may be referred to the temporomandibular joint. Neuritis involving the maxillary and mandibular divisions of the trigeminal nerve (e.g., maxillary sinusitis, neuritis, and leukemia infiltrate) is distinguished from ordinary toothache by the neuropathic quality of the pain. Occasionally phantom pain follows tooth extraction. Often the earliest symptom of Bell’s palsy in the day or so before facial weakness develops is pain and hyperalgesia behind the ear and side of the face. Likewise, similar symptoms may precede visible lesions of herpes zoster infecting the seventh nerve (Ramsey-Hunt syndrome) or trigeminal nerve. Either condition may leave postherpetic neuralgia in its wake. Coronary ischemia may produce pain exclusively in the face and jaw. Like typical angina pectoris, it is usually reproducible with increased myocardial demand. Aching in several upper molar or premolar teeth may point to maxillary sinusitis. Failure to relieve by anesthetizing the teeth and confirmation with appropriate radiographs support the clinical diagnosis.

Giant cell arteritis is notorious for producing headache, but it may also produce facial pain or sore throat that is mistaken for other causes. Jaw and tongue claudication with prolonged chewing or talking is relatively common. Tongue infarction is rare. Patients with subacute thyroiditis often experience pain referred to the face or jaw. Oral and pharyngeal causes may be sought before the tender thyroid gland and transient hyperthyroidism are appreciated.

Burning mouth syndrome (glossodynia) is present in the absence of mucosal lesions and predominantly affects women over 50. Poorly fitting dentures, anxiety, and depression are common and treatable causes. Tongue-thrusting habit is a cause in some elderly sufferers. The symptom occasionally leads to the discovery of vitamin B12 deficiency, iron deficiency, Plummer-Vinson syndrome, diabetes mellitus, low-grade Candida infection, food sensitivity (e.g., cinnamon), or subtle xerostomia.

DISEASES OF THE SALIVARY GLANDS Saliva is essential to oral health. Its major components, water and mucin, serve as a cleansing solvent and lubricating fluid. In addition it contains antimicrobial factors (e.g., lysozyme, lactoperoxidase, secretory IgA), epidermal growth factor, minerals, and buffering systems. The major salivary glands secrete intermittently in response to autonomic stimulation, which is high during a meal but low otherwise. The parotid secretion is serous or watery, the sublingual is mostly mucus, and the submandibular is a balance of the two elements. Hundreds of minor glands in the lips and cheeks secrete mucus continuously. It is easy to appreciate how oral function becomes impaired when salivary function is reduced. Dry mouth (xerostomia) is perceived when salivary flow is reduced by 50%. The most common etiology is medication, especially drugs with anticholinergic properties, but also alpha and beta blockers, calcium channel blockers, and diuretics. Other causes of chronic dryness include Sjögren’s syndrome, chronic parotitis, salivary duct obstruction, diabetes mellitus, HIV/AIDS, and irradiation for head and neck cancer. Management involves eliminating or limiting drying medications, preventive dental care, and supplementing oral liquid. Sugarless mints or chewing gum may stimulate salivary secretion if dysfunction is mild. When sufficient exocrine tissue remains, pilocarpine or cevimeline has been shown to increase secretions and reduce symptoms. Commercial

saliva substitutes or gels relieve dryness but must be supplemented with fluoride applications to prevent caries.

Sialolithiasis presents most often as painful swelling but in some instances as just swelling or pain. The obstructing stone produces spasm upon eating. Conservative therapy consists of local heat, massage, and hydration. Promotional saliva secretion and subsequent bacterial infection. In adults antibiotic treatment is necessary when bacterial out small stones. Antibiotic treatment may flush massage, and hydration. Promotional therapy consists of local heat, spasm upon eating. Conservative instances as just swelling or pain. The obstructing stone produces malignancy, lympho- expanded to include benign and malignant neoplasms, lympho-proliferative disorders, Sjögren’s syndrome, sarcoidosis, tuberculosis, lymphadenitis, actinomycosis, and Wegener’s granulomatosis. Bilateral nontender parotid enlargement occurs with diabetes mellitus, cirrhosis, bulimia, HIV/AIDS, and drugs (e.g., iodide, propylthiouracil).

Strongly associated with HIV infection.

42704 Harrison/Braunwald:HPIM16/e McGraw-Hill

Pleomorphic adenoma comprises two-thirds of all salivary neoplasms. The parotid is the principle salivary gland affected, and the tumor presents as a firm, slow-growing mass. Though benign, recurrence is common if not completely resected. Malignant tumors such as mucoepidermoid carcinoma, adenoid cystic carcinoma, and adenocarcinoma tend to grow relatively fast, depending upon grade. They may ulcerate and invade nerves, producing numbness and facial paresthesia.

Procedures performed in the course of routine dental care (e.g., extraction, scaling and cleaning, tooth restoration, and root canal) are remarkably safe. The most common concerns that arise in the care of dental patients with medical disease are fear of excessive bleeding for patients on anticoagulants, infection of the heart valves and prosthetic devices from hematogenous seeding of oral flora, and cardiovascular complication resulting from vasopressors used with local anesthetic during dental treatment. Experience has confirmed that the risks of any of these complications are very low—far lower than many physicians or dentists imagine.

In the event of emergency, the dentist should have elective dental care deferred until 6 months after the cerebrovascular accident. In both situations, effective stress reduction requires good pain control. This includes using the minimal amount of vasoconstrictors necessary to provide good hemostasis and local anesthesia.

Elective dental treatments should be postponed for at least 1 month after myocardial infarction. After this time the risk of reinfarction is low provided the patient is medically stable (e.g., stable rhythm, stable angina, and free of heart failure). Patients who have suffered a stroke should have elective dental care deferred until 6 months after the cerebrovascular accident. In both situations, effective stress reduction requires good pain control. This includes using the minimal amount of vasoconstrictors necessary to provide good hemostasis and local anesthesia.

| | Addison’s disease
| | Linear gingival erythema

* Strongly associated with HIV infection.
responsible for symptoms that are sometimes considered “exasperation of the disease.” However, for others, the symptoms are genuinely new and qualitatively different from the disease that occurred before. The patient’s understanding of the disease, perceptions of its potential sequelae, and the strength of his or her emotional response play a critical role in determining the relative contribution of the disease to new symptoms. In some cases, the relatedness of the disease to new symptoms is so clear-cut that the clinician is able to address the disease directly, without confusion from related new symptoms. In other cases, it may be necessary to address the new symptoms first, reassuring the patient that the disease has remained constant and reinforcing the patient’s trust in the clinician’s experience.

Dyspnea

Dyspnea is a subjective feeling of breathlessness that is often described as a sensation of not being able to get enough air, a sense of air hunger, or a desire to breathe more deeply. It can be caused by a variety of factors, including respiratory diseases, cardiovascular diseases, metabolic disorders, and neurologic conditions. Dyspnea is a common complaint in patients with chronic obstructive pulmonary disease (COPD), asthma, and heart failure, among other conditions. The evaluation of dyspnea requires a thorough history and physical examination, and may involve the use of diagnostic tests such as chest X-ray, spirometry, and echocardiography.

Quantitation of Dyspnea

The gradation of dyspnea is based on the amount of physical exertion required to produce the sensation. In assessing the severity of dyspnea, it is important to obtain a clear understanding of the patient’s general physical condition, work history, and recreational habits. For example, the development of dyspnea in a trained runner upon running 2 miles may signify a much more serious disturbance than a similar degree of breathlessness in a sedentary person upon running a fraction of this distance. Interindividual variation in perception must also be considered. Some patients with severe disease may complain of only mild dyspnea; others with mild disease may experience more severe shortness of breath. Some patients with lung or heart disease may have such reduced capabilities due to other disease (e.g., peripheral vascular insufficiency or severe osteoarthritis of the hips or knees) that exertional dyspnea is precluded despite serious impairment of pulmonary or cardiac function.

Some patterns of dyspnea are not directly related to physical exertion. Sudden and unexpected dyspneic episodes at rest can be associated with pulmonary emboli, spontaneous pneumothorax, hypercapneic secondary to breath holding, or anxiety. Nocturnal episodes of severe paroxysmal dyspnea are characteristic of left ventricular failure. Dyspnea upon assuming the supine posture, orthopnea (see below and Chap. 216), thought to be mainly characteristic of congestive heart failure, may also occur in some patients with asthma and chronic obstruction of the airways and is a regular finding in the rare occurrence of bilateral diaphragmatic paralysis. Trepopnea is used to describe the unusual circumstance in which dyspnea occurs only in a lateral decubitus position, most often in patients with heart disease, while platypnea is dyspnea that occurs only in the upright position. Positional alterations in ventilation-perfusion relationships (Chap. 234) have been invoked to explain these patterns.

Mechanisms of Dyspnea

(See Fig. 29-1) Dyspnea occurs whenever the work of breathing is excessive. Increased force generation is required of the respiratory muscles to produce a given volume change if the chest wall or lungs are less compliant or if resistance to airflow is increased. Increased work of breathing also occurs when the venti-
Differential Diagnosis

Obstructive Disease of Airways

(See also Chaps. 236 and 242) Obstruction to airflow can be present anywhere from the extrathoracic airways out to the small airways in the periphery of the lung. Large extrathoracic airway obstruction can occur acutely, as with aspiration of food or a foreign body, or with angioedema of the glottis. An allergic history together with a few scattered hives should raise the possibility of glottic edema. Acute upper airway obstruction is a medical emergency. More chronic forms can occur with tumors or with fibrotic stenosis following tracheostomy or prolonged endotracheal intubation. Whether acute or chronic, the cardinal symptom is dyspnea, and the characteristic signs are stridor and retraction of the supraclavicular fossae with inspiration.

Obstruction of intrathoracic airways can occur acutely and intermittently or can be present chronically with worsening during respiratory infections. Acute intermittent obstruction with wheezing is typical of asthma (Chap. 236). Chronic cough with expectoration is typical of chronic bronchitis (Chap. 242) and bronchiectasis (Chap. 240). Most often there are prolongation of expiration and coarse rhonchi that are generalized in chronic bronchitis and may be localized in the case of bronchiectasis. Intercurrent infection results in worsening of the cough, increased expectoration of purulent sputum, and more severe dyspnea. During such episodes, the patient may complain of nocturnal paroxysms of dyspnea with wheezing relieved by cough and expectoration of sputum. Despite the fact that severe limitation of expiratory flow and hyperinflation of the lung are characteristic of these diseases, the sensory experience is often that of an inability to take in a sufficiently deep breath rather than difficulty in exhaling.

The patient with predominant emphysema is characterized by many years of exertional dyspnea progressing to dyspnea at rest (Chap. 242). Although a parenchymal disease by definition, emphysema is invariably accompanied by obstruction of airways.

Diffuse Parenchymal Lung Diseases

(See also Chap. 243) This category includes a large number of diseases ranging from acute pneumonia to chronic disorders such as sarcoidosis and the various forms of pneumocystosis (Chap. 238). History, physical findings, and radiographic abnormalities often provide clues to the diagnosis. The patients are often tachypneic with arterial P_{O_2} and P_{CO_2} values below normal. Exertion often further reduces the arterial P_{O_2}. Lung volumes are decreased, and the lungs are stiffer, i.e., less compliant, than normal.

Pulmonary Vascular Occlusive Diseases

(See also Chap. 244) Repeated episodes of dyspnea at rest often occur with recurrent pulmonary em-
boli. Near syncope on exertion is another suggestive symptom. Evidence of a source for emboli, such as phlebitis of a lower extremity or the pelvis, is quite helpful in leading the physician to suspect the diagnosis. Arterial blood gases are most often abnormal, but lung volumes are frequently normal or only minimally abnormal.

**Diseases of the Chest Wall or Respiratory Muscles** (See also Chap. 246) The physical examination establishes the presence of a chest wall disease such as severe kyphoscoliosis, pectus excavatum, or ankylosing spondylitis. Although all three of these deformities may be associated with dyspnea, only severe kyphoscoliosis regularly interferes with ventilation sufficiently to produce chronic cor pulmonale and respiratory failure.

Both weakness and paralysis of respiratory muscles can lead to respiratory failure and dyspnea (Chap. 246), but most often the signs and symptoms of the neurologic or muscular disorder are more prominently manifested in other systems.

**Heart Disease** In patients with cardiac disease, exertional dyspnea occurs most commonly as a consequence of an elevated pulmonary capillary pressure, which in turn may be due to left ventricular dysfunction (Chaps. 215 and 216), reduced left ventricular compliance, and mitral stenosis. The elevation of hydrostatic pressure in the pulmonary vascular bed tends to upset the Starling equilibrium (see “Pulmonary Edema,” below) with resulting transudation of liquid into the interstitial space, reducing the compliance of the lungs and stimulating J (juxta-capillary) receptors in the alveolar interstitial space. When it is prolonged, pulmonary venous hypertension results in thickening of the walls of small pulmonary vessels and an increase in perivascular cells and fibrous tissue, causing a further reduction in compliance. The competition for space among vessels, airways, and increased fluid within the interstitial space compromises the lumina of small airways, increasing the airway’s resistance. Diminution in compliance and an increase in the airways’ resistance increase the work of breathing. In advanced congestive heart failure, usually involving elevation of both pulmonary and systemic venous pressures, hydrothorax may develop, interfering further with pulmonary function and intensifying dyspnea.

Orthopnea, i.e., dyspnea in the supine position, is the result of the alteration of gravitational forces when this position is assumed, which elevates pulmonary venous and capillary pressures. These, in turn, increase the pulmonary closing volume (Chap. 234) and reduce the vital capacity.

**Paroxysmal Nocturnal Dyspnea** Also known as *cardiac asthma*, this condition is characterized by attacks of severe shortness of breath that generally occur at night and usually awaken the patient from sleep. The attack is precipitated by stimuli that aggravate previously existing pulmonary congestion; frequently, the total blood volume is augmented at night because of the readorption of edema from dependent portions of the body during recumbency. A sleeping patient can tolerate relatively severe pulmonary engorgement and may awaken only when actual pulmonary edema and bronchospasm have developed, with the feeling of suffocation and with wheezing respirations.

Two other forms of nocturnal dyspnea must be distinguished from that due to heart failure. Chronic bronchitis is characterized by mucus hypersecretion and, after a few hours sleep, secretions can accumulate and produce dyspnea and wheezing, both of which are relieved by cough and expectoration of sputum. Asthma patients have circadian variations in their degree of airway obstruction. The obstruction becomes most severe between 2 A.M. and 4 A.M. and can be sufficiently severe that the patient awakens with a sense of suffocation, extreme dyspnea, and wheezing. Although there is a prominent inflammatory component to nocturnal asthma, inhaled bronchodilators usually improve symptoms quickly.

**Cheyne-Stokes Respiration** See Chap. 216 ■ Diagnosis The diagnosis of cardiac dyspnea depends on the recognition of heart disease on the basis of the clinical examination supplemented by noninvasive testing. There may be a history of antecedent myocardial infarction; third and fourth heart sounds may be audible; and/or there may be evidence of left ventricular enlargement, jugular vein distention, and/or peripheral edema. Often there are radiographic signs of heart failure, with evidence of interstitial edema, pulmonary vascular redistribution, and accumulation of liquid in the septal planes and pleural cavity. Thoracic echocardiography is particularly useful in establishing the diagnosis of structural heart disease, which can be responsible for dyspnea. Specifically, left atrial and/or left ventricular dilatation, left ventricular hypertrophy, a reduced left ventricular ejection fraction, and disorders of left ventricular wall motion may be clues to the presence of a cardiac etiology of otherwise unexplained dyspnea.

**Differential Diagnosis Between Cardiac and Pulmonary Dyspnea** In most patients with dyspnea there is obvious clinical evidence of disease of the heart and/or lungs. Like patients with cardiac dyspnea, patients with chronic obstructive lung disease may also awaken at night with dyspnea, but, as pointed out above, this is usually associated with sputum production; the dyspnea is relieved after these patients rid themselves of secretions. The difficulty in the distinction between cardiac and pulmonary dyspnea may be compounded by the coexistence of diseases involving both organ systems.

In patients in whom the etiology of dyspnea is not clear, it is desirable to carry out pulmonary function testing, for these tests may be helpful in determining whether dyspnea is produced by heart disease, lung disease, abnormalities of the chest wall, or anxiety (Chap. 235). In addition to the usual means of assessing patients for heart disease, determination of the ejection fraction at rest and during exercise by echocardiography or radionuclide ventriculography is helpful in the differential diagnosis of dyspnea. The left ventricular ejection fraction is depressed in left ventricular failure, while the right ventricular ejection fraction may be low at rest or may decline during exercise in patients with severe lung disease. Both left and right ventricular ejection fractions are normal at rest and during exercise in dyspnea due to anxiety or malingering. Careful observation during the performance of an exercise treadmill test will often help in the identification of the patient who is malingering or whose dyspnea is secondary to anxiety. Under these circumstances, the patient usually complains of severe shortness of breath but appears to be breathing either effortlessly or totally irregularly. Cardiopulmonary testing, in which the patient’s maximal functional exercise capacity is assessed while measurements of the electrocardiogram, blood pressure, oxygen consumption, arterial saturation (oximetry), and ventilation are carried out, is useful in the differentiation between cardiac and pulmonary dyspnea (Table 29-2).

**Anxiety States** Dyspnea experienced by a patient with anxiety alone is difficult to evaluate. The signs and symptoms of acute and chronic...
hyperventilation do not serve to distinguish between anxiety states and other processes, such as recurrent pulmonary emboli. Another potentially confusing situation is seen when chest pain and electrocardiographic changes accompany the hyperventilation syndrome. When present and attributable to this condition, also referred to as neurocirculatory asthenia, the chest pain is often sharp, fleeting, and in various loci, and the electrocardiographic changes are most often seen during repolarization. Frequent sighing respirations and an irregular breathing pattern point to a psychogenic origin of the dyspnea. Anxiety and depression in association with heart or lung disease can serve to intensify dyspnea symptoms beyond what would be expected for a given degree of dysfunction.

PULMONARY EDEMA

CARDIOGENIC PULMONARY EDEMA (See Table 29-3, IA) An increase in pulmonary venous pressure, which results initially in engorgement of the pulmonary vasculature, is common in most instances of dyspnea in association with congestive heart failure. The lungs become less compliant, the resistance of small airways increases, and there is an increase in lymphatic flow that apparently serves to maintain a constant pulmonary extravascular liquid volume. Mild tachypnea is present. If the increase in intravascular pressure is sufficient both in magnitude and duration, there is a net gain of liquid in the extravascular space, i.e., interstitial edema. At this point symptoms worsen, tachypnea increases, gas exchange deteriorates further, and radiographic changes, such as Kerley B lines and loss of distinct vascular margins, are seen. At this stage, the capillary endothelial intercellular junctions widen and allow passage of macromolecules into the interstices.

Further elevations in intravascular pressure disrupt the tight junctions between alveolar lining cells, and alveolar edema ensues, with outpouring of liquid that contains both red blood cells and macromolecules. With yet more severe disruption of the alveolar-capillary membrane, edematous liquid floods the alveoli and airways. At this point, full-blown clinical pulmonary edema with bilateral wet rales and discomfort occurs, and the chest radiograph may show diffuse haziness of the lung fields with greater density in the more proximal hilar regions. Typically, the patient is anxious and perspires freely, and the sputum is frothy and bloodtinged. Gas exchange is more severely compromised with worsening hypoxia. Without effective treatment (Chap. 255), progressive acidemia, hypercapnia, and respiratory arrest ensue.

The sequence of liquid accumulation described above follows the Starling law of capillary-interstitial liquid exchange:

\[ \text{Liquid accumulation} = K(P_c - P_{lym}) - \sigma(p_f - p_v) - Q_{lym} \]

where \( K \), hydraulic conductance (directly proportional to membrane surface area and inversely proportional to membrane thickness); \( P_c \), mean intracapillary pressure; \( p_f \), oncotic pressure of interstitial liquid; \( \sigma \), reflection coefficient of macromolecules; \( P_v \), mean interstitial liquid pressure; \( p_v \), oncotic pressure of the plasma; \( Q_{lym} \), lymphatic flow.

The pressures tending to move liquid out of the vessel are \( P_c \) and \( p_v \), which are normally more than offset by pressures tending to move liquid back into the vasculature, i.e., the algebraic sum of \( P_f \) and \( p_f \). Implicit in the preceding equation is that lymphatic flow can increase in the case of imbalance of forces and result in net accumulation of interstitial liquid. Further elevations in \( P_c \) not only increase the outward movement of liquid in each capillary region but also recruit more of the capillary bed, which increases \( K \). These two effects lead to liquid filtration that exceeds clearance capability by the lymphatics, and liquid accumulates in the loose interstitial spaces of the lung. Even greater increases in \( P_c \) open first the loose endothelial intercellular junctions and later the tight alveolar intercellular junctions with an increase in permeability to macromolecules. This secondary disruption of both the function and structure of the alveolar-capillary membrane leads to alveolar flooding.

NONCARDIOGENIC PULMONARY EDEMA (See Table 29-3, IB, IC, II, III, and IV) Several clinical conditions are associated with pulmonary edema based on an imbalance of Starling forces other than through primary elevations of pulmonary capillary pressure. Although diminished plasma oncotic pressure in hypoalbuminemic states (e.g., severe liver disease, nephrotic syndrome, protein-losing enteropathy) might be expected to lead to pulmonary edema, the balance of forces normally so strongly favors resorption that even in these conditions some elevation of capillary pressure is usually necessary before interstitial edema develops. Increased negativity of interstitial pressure has been implicated in the genesis of unilateral pulmonary edema following rapid evacuation of a large pneumothorax. In this situation, the findings may be apparent only by radiography, but occasionally the patient experiences dyspnea with physical findings localized to the edematous lung. It has been proposed that large negative intrapleural pressures during acute severe asthma may be associated with the development of interstitial edema. Lymphatic blockade secondary to fibrotic and inflammatory diseases or lymphangitic carcinomatosis may lead to interstitial edema. In such instances, both clinical and radiographic manifestations are dominated by the underlying disease process.

Other conditions characterized by increases in the interstitial liquid content of the lungs appear to be associated primarily with disruption of the alveolar-capillary membranes. Any number of spontaneously occurring or environmental toxic insults, including diffuse pulmonary infections, aspiration, and shock (particularly due to sepsis, hemor-
rhagic pancreatitis, and following cardiopulmonary bypass), are associated with diffuse pulmonary edema that clearly does not have a hemodynamic origin. These conditions, which may lead to the acute respiratory distress syndrome, are discussed in Chap. 251.

**Other Forms of Pulmonary Edema**

There are three forms of pulmonary edema whose precise mechanism remains unexplained. Narcotic overdose is a well-recognized antecedent to pulmonary edema. Although illicit use of parenteral heroin is the most frequent cause, parenteral and oral overdoses of legitimate preparations of morphine, methadone, and dextropropoxyphene have also been associated with pulmonary edema. The earlier idea that injected impurities lead to the disorder is untenable. Available evidence suggests that there are alterations in the permeability of alveolar and capillary membranes rather than an elevation of pulmonary capillary pressure.

*Exposure to high altitude* in association with severe physical exertion is a well-recognized setting for pulmonary edema in unacclimatized yet otherwise healthy persons. Acclimatized high-altitude natives also develop this syndrome upon return to high altitude after a relatively brief sojourn at low altitudes. The syndrome is far more common in persons under the age of 25 years. The mechanism for high-altitude pulmonary edema (HAPE) remains obscure, and studies have been conflicting, some suggesting pulmonary venous constriction and others indicating pulmonary arteriolar constriction as the prime mechanisms. A role for hypoxia at high altitude is suggested by the fact that patients respond to the administration of oxygen and/or return to lower altitudes. Hypoxia per se does not alter permeability of the alveolar-capillary membrane. Hence increased cardiac output and pulmonary arterial pressures with exercise combined with hypoxic pulmonary arteriolar constriction, which is more prominent in young persons, may combine to make this an example of prearteriolar, high-pressure pulmonary edema. HAPE has also been attributed to a defect in the absorption of liquid driven by active alveolar transepithelial sodium transport. Prophylactic inhalation of the β₂ agonist salmeterol has been shown to reduce the incidence of this condition.

**Neurogenic pulmonary edema** has been described in patients with central nervous system disorders and without apparent preexisting left ventricular dysfunction. Although most experimental studies have implicated sympathetic nervous system activity, the mechanism whereby sympathetic efferent activity leads to pulmonary edema is a matter of speculation. It is known that a massive adrenergic nerve discharge leads to peripheral vasoconstriction with elevation of blood pressure and shifts of blood to the central circulation. In addition, it is probable that a reduction in left ventricular compliance also occurs, and both factors serve to increase left atrial pressures sufficiently to induce pulmonary edema on a hemodynamic basis. Some experimental evidence suggests that stimulation of adrenergic receptors increases capillary permeability directly, but this effect is relatively minor as compared with the imbalance of Starling forces.

**TREATMENT OF PULMONARY EDEMA**

See Chap. 255

**COUGH**

Cough is an explosive expiration that provides a normal protective mechanism for clearing the tracheobronchial tree of secretions and foreign material. When excessive or bothersome, it is also one of the most common symptoms for which medical attention is sought. Reasons for the latter include discomfort from the cough itself, interference with normal lifestyle, and concern for the cause of the cough, especially fear of cancer.

**MECHANISM**

Coughing may be initiated either voluntarily or reflexively. As a defensive reflex it has both afferent and efferent pathways. The *afferent limb* includes receptors within the sensory distribution of the trigeminal, glossopharyngeal, superior laryngeal, and vagus nerves. The *afferent limb* includes the recurrent laryngeal nerve and the spinal nerves. The cough starts with a deep inspiration followed by glottic closure, relaxation of the diaphragm, and muscle contraction against a closed glottis. The resulting markedly positive intrathoracic pressure causes narrowing of the trachea. Once the glottis opens, the large pressure differential between the airways and the atmosphere coupled with tracheal narrowing produces rapid flow rates through the trachea. The shearing forces that develop aid in the elimination of mucus and foreign materials.

**ETIOLOGY**

Cough can be initiated by a variety of irritant triggers either from an exogenous source (smoke, dust, fumes, foreign bodies) or from an endogenous origin (upper airway secretions, gastric contents). These stimuli may affect receptors in the upper airway (especially the pharynx and larynx) or in the lower respiratory tract, following access to the tracheobronchial tree by inhalation or by aspiration. When cough is triggered by upper airway secretions (as with postnasal drip) or gastric contents (as with gastroesophageal reflux), the initiating factor may go unrecognized and the cough can be persistent. Additionally, prolonged exposure to such irritants may initiate airway inflammation, which can itself precipitate cough and sensitize the airway to other irritants. Cough associated with gastroesophageal reflux is due only in part to irritation of upper airway receptors or to aspiration of gastric contents, as a vagally mediated reflex mechanism secondary to acid in the distal esophagus may also contribute.

Any disorder resulting in inflammation, constriction, infiltration, or compression of airways can be associated with cough. Inflammation commonly results from airway infections, ranging from viral or bacterial bronchitis to bronchiectasis. In viral bronchitis, airway inflammation sometimes persists long after resolution of the typical acute symptoms, thereby producing a prolonged cough, lasting for weeks. Pertussis infection is also a possible cause of persistent cough in adults; however, diagnosis is generally made on clinical grounds (Chap. 133). Asthma is a common cause of cough. Although the clinical setting commonly suggests when a cough is secondary to asthma, some patients present with cough in the absence of wheezing or dyspnea, thus making the diagnosis more subtle (“cough variant asthma”). A neoplasms infiltrating the airway wall, such as bronchogenic carcinoma or a carcinoid tumor, is commonly associated with cough. Airway infiltration with granulomas may also trigger a cough, as seen with endobronchial sarcoidosis or tuberculosis. Compression of airways results from extrinsic masses, including lymph nodes, mediastinal tumors, and aortic aneurysms.

Examples of parenchymal lung disease potentially producing cough include interstitial lung disease, pneumonia, and lung abscess.
Congestive heart failure may be associated with cough, probably as a consequence of interstitial as well as peribronchial edema. A nonproductive cough complicates the use of angiotensin-converting enzyme (ACE) inhibitors in 5 to 20% of patients taking these agents. Onset is usually within 1 week of starting the drug but can be delayed up to 6 months. Although the mechanism is not known with certainty, it may relate to accumulation of bradykinin or substance P, both of which are degraded by ACE.

The most common causes of cough can be categorized according to the duration of the cough. Acute cough (<3 weeks) is most often due to upper respiratory infection (especially the common cold, acute bacterial sinusitis, and pertussis), but more serious disorders, such as pneumonia, pulmonary embolus, and congestive heart failure, can also present in this fashion. Chronic cough (>3 weeks) in a smoker raises the possibilities of chronic obstructive lung disease or bronchogenic carcinoma. In a nonsmoker who has a normal chest radiograph and is not taking an ACE inhibitor, the most common causes of chronic cough are postnasal drip, asthma, and gastroesophageal reflux. Eosinophilic bronchitis in the absence of asthma has also been recognized as a potential cause of chronic cough.

**APPROACH TO THE PATIENT**

A detailed **history** frequently provides the most valuable clues for etiology of the cough. Particularly important questions include:

1. Is the cough acute or chronic?
2. At its onset, were there associated symptoms suggestive of a respiratory infection?
3. Is it seasonal or associated with wheezing?
4. Is it associated with symptoms suggestive of postnasal drip (nasal discharge, frequent throat clearing, a “tickle in the throat”) or gastroesophageal reflux (heartburn or sensation of regurgitation)? (The absence of such suggestive symptoms does not exclude either of these diagnoses, particularly in the case of gastroesophageal reflux.)
5. Is it associated with fever or sputum? If sputum is present, what is its character?
6. Does the patient have any associated disorders or risk factors for disease (e.g., cigarette smoking, risk factors for infection with HIV, environmental exposures)?
7. Is the patient taking an ACE inhibitor?

The general **physical examination** may point to a systemic or nonpulmonary cause of cough, such as heart failure, primary nonpulmonary neoplasm, or AIDS. Examination of the oropharynx may provide suggestive evidence for postnasal drip, including oropharyngeal mucus or erythema, or a “cobblestone” appearance to the mucosa. Auscultation of the chest may demonstrate inspiratory crackles (indicative of upper airway disease), rhonchi or expiratory wheezing (indicative of lower airway disease), or inspiratory crackles (suggestive of a process involving the pulmonary parenchyma, such as interstitial lung disease, pneumonia, or pulmonary edema).

**Chest radiography** may be particularly helpful in suggesting or confirming the cause of the cough. Important potential findings include the presence of an intrathoracic mass lesion, a localized pulmonary parenchymal infiltrate, or diffuse interstitial or alveolar disease. An area of honeycombing or cyst formation may suggest bronchiectasis, while symmetric bilateral hilar adenopathy may suggest sarcoidosis.

**Pulmonary function testing** (Chap. 234) is useful for assessing the functional abnormalities that accompany certain disorders producing cough. Measurement of forced expiratory flow rates can demonstrate reversible airflow obstruction characteristic of asthma. When asthma is considered but flow rates are normal, broncho-provocation testing with methacholine or cold-air inhalation can demonstrate hyperreactivity of the airways to a bronchoconstrictive stimulus. Measurement of lung volumes and diffusing capacity is useful primarily for demonstration of a restrictive pattern, often seen with any of the diffuse interstitial lung diseases.

If **sputum** is produced, gross and microscopic examination may provide useful information. Purulent sputum suggests chronic bronchitis, bronchiectasis, pneumonia, or lung abscess. Blood in the sputum may be seen in the same disorders, but its presence also raises the question of an endobronchial tumor. Greater than 3% eosinophils seen on staining of induced sputum in a patient without asthma suggests the possibility of eosinophilic bronchitis. Gram and acid-fast stains and cultures may demonstrate a particular infectious pathogen, while sputum cytology may provide a diagnosis of a pulmonary malignancy.

More specialized studies are helpful in specific circumstances. **Fiberoptic bronchoscopy** is the procedure of choice for visualizing an endobronchial tumor and collecting cytologic and histologic specimens. Inspection of the tracheobronchial mucosa can demonstrate endobronchial granulomas often seen in sarcoidosis, and endobronchial biopsy of such lesions or transbronchial biopsy of the lung interstitium can confirm the diagnosis. Inspection of the airway mucosa by bronchoscopy can also demonstrate the characteristic appearance of endobronchial Kaposi’s sarcoma in patients with AIDS. **High-resolution computed tomography (HRCT)** can confirm the presence of interstitial disease and frequently suggests a diagnosis based on the pattern of disease. It is the procedure of choice for demonstrating dilated airways and confirming the diagnosis of bronchiectasis.

A diagnostic algorithm for evaluation of chronic cough is presented in Fig. 30-1.

**COMPLICATIONS**

Common complications of coughing include chest and abdominal wall soreness, urinary incontinence, and exhaustion. On occasion, paroxysms of coughing may precipitate syncope (cough syncope; Chap. 20), consequent to markedly positive intrathoracic and alveolar pressures, diminished venous return, and decreased cardiac output. Although cough fractures of the ribs may occur in otherwise normal patients, their occurrence should at least raise the possibility of pathologic fractures, which are seen with multiple myeloma, osteoporosis, and osteolytic metastases.

**TREATMENT**

Definitive treatment of cough depends on determining the underlying cause and then initiating specific therapy. Elimination of an exogenous inciting agent (cigarette smoke, ACE inhibitors) or an endogenous trigger (postnasal drip, gastroesophageal reflux) is usually effective when such a precipitant can be identified. Other important management considerations are treatment of specific respiratory tract infections, bronchodilators for potentially reversible airflow obstruction, inhaled glucocorticoids for eosinophilic bronchitis, chest physiotherapy and other methods to enhance clearance of secretions in patients with bronchiectasis, and treatment of endobronchial tumors or interstitial lung disease when such therapy is available and appropriate. In patients with chronic, unexplained cough, an empirical approach to treatment is often used for both diagnostic and therapeutic purposes, starting with an antihistamine-decongestant combination or nasal ipratropium spray to treat unrecognized postnasal drip. If ineffective, this may be followed sequentially by treatment for asthma and for gastroesophageal reflux.

Symptomatic or nonspecific therapy of cough should be considered when: (1) the cause of the cough is not known or specific treatment is not possible, and (2) the cough performs no useful function or causes marked discomfort. An irritative, nonproductive cough may be suppressed by an antitussive agent, which increases the latency or threshold of the cough center. Such agents include codeine (15 mg qid) or nonnarcotics such as dextromethorphan (15 mg qid). These drugs pro-
Cough persists

**HEMOPTYSIS**

Hemoptysis is defined as the expectoration of blood from the respiratory tract, a spectrum that varies from blood-streaking of sputum to coughing up large amounts of pure blood. Massive hemoptysis is variably defined as the expectoration of >100 to >600 mL over a 24-h period, although the patient’s estimation of the amount of blood is notoriously unreliable. Expectoration of even relatively small amounts of blood is a frightening symptom and can be a marker for potentially serious disease, such as bronchogenic carcinoma. Massive hemoptysis, on the other hand, can represent an acutely life-threatening problem. Large amounts of blood can fill the airways and the alveolar spaces, not only seriously disturbing gas exchange but potentially causing the patient to suffocate.

**ETIOLOGY**

Because blood originating from the nasopharynx or the gastrointestinal tract can mimic blood coming from the lower respiratory tract, it is important to determine initially that the blood is not coming from one of these alternative sites. Clues that the blood is originating from the gastrointestinal tract include a dark red appearance and an acidic pH, in contrast to the typical bright red appearance and alkaline pH of true hemoptysis.

An etiologic classification of hemoptysis can be based on the site of origin within the lungs (Table 30-1). The most common site of bleeding is the airways, i.e., the tracheobronchial tree, which can be affected by inflammation (acute or chronic bronchitis, bronchiectasis) or by neoplasm (bronchogenic carcinoma, endobronchial metastatic carcinoma, or bronchial carcinoid tumor). The bronchial arteries, which originate either from the aorta or from intercostal arteries and are therefore part of the high-pressure systemic circulation, are the source of bleeding in bronchitis or bronchiectasis or with endobronchial tumors. Blood originating from the pulmonary parenchyma can be either from a localized source, such as an infection (pneumonia, lung abscess, tuberculosis), or from a process diffusely affecting the parenchyma (as with a coagulopathy or with an autoimmune process such as Goodpasture’s syndrome). Disorders primarily affecting the pulmonary vasculature include pulmonary embolic disease and those conditions associated with elevated pulmonary venous and capillary pressures, such as mitral stenosis or left ventricular failure.

Although the relative frequency of the different etiologies of hemoptysis varies from series to series, most recent studies indicate that bronchitis and bronchogenic carcinoma are the two most common causes. Despite the lower frequency of tuberculosis and bronchiectasis seen in recent compared to older series, these two disorders still represent the most common causes of massive hemoptysis in several series. Even after extensive evaluation, a sizable proportion of patients (up to 30% in some series) have no identifiable etiology for their hemoptysis. These patients are classified as having idiopathic or cryptogenic hemoptysis, and subtle airway or parenchymal disease is presumably responsible for the bleeding.

![Figure 30-1](image.jpg)

**APPROACH TO THE PATIENT**

The history is extremely valuable. Hemoptysis is described as blood-streaking of mucopurulent or purulent sputum often suggests bronchitis. Chronic production of sputum with a recent change in quantity or appearance favors an acute exacerbation of chronic bronchitis. Fever or chills accompanying blood-streaked purulent sputum suggests pneumonia, whereas a putrid smell to the sputum raises the possibility of lung abscess. When sputum production has been chronic and copious, the diagnosis of bronchiectasis should be considered. Hemoptysis following the acute onset of pleuritic chest pain and dyspnea is suggestive of pulmonary embolism.

A history of previous or coexisting disorders should be sought, such as renal disease (seen with Goodpasture’s syndrome or Wegener’s granulomatosis), lupus erythematosus (with associated pulmonary hemorrhage from lupus pneumonitis), or a previous malignancy (either recurrent lung cancer or endobronchial metastasis from a nonpulmonary primary tumor). In a patient with AIDS, endobronchial or pulmonary parenchymal Kaposi’s sarcoma should be considered. Risk factors for bronchogenic carcinoma, particularly smoking and asbestos exposure, should be sought. Patients should be questioned about previous bleeding disorders,

---

The rapidity of bleeding and its effect on gas exchange determine the urgency of management. When the bleeding is confined to either blood-streaking of sputum or production of small amounts of pure blood, gas exchange is usually preserved; establishing a diagnosis is the first priority. When hemoptysis is massive, maintaining adequate gas exchange, preventing blood from spilling into unaffected areas of lung, and avoiding asphyxiation are the highest priorities. Keeping the patient at rest and partially suppressing cough may help the bleeding to subside. If the origin of the blood is known and is limited to one lung, the bleeding lung should be placed in the dependent position, so that blood is not aspirated into the unaffected lung.

With massive bleeding, the need to control the airway and maintain adequate gas exchange may necessitate endotracheal intubation and mechanical ventilation. In patients in danger of flooding the lung contralaterally to the side of hemorrhage despite proper positioning, isolation of the right and left mainstem bronchi from each other can be achieved by selectively intubating the non-

HYPOXIA

The fundamental purpose of the cardiorespiratory system is to deliver O₂ (and substrates) to the cells and to remove CO₂ (and other metabolic products) from them. Proper maintenance of this function depends on intact cardiovascular and respiratory systems and a supply of inspired gas containing adequate O₂. When hypoxia occurs consequent to respiratory failure, PaO₂ declines, PaCO₂ usually rises (Chap. 234), and the hemoglobin-oxygen (Hb-O₂) dissociation curve (see Fig. 91-2) is displaced to the right, with greater quantities of O₂ released at any level of tissue Po₂. Arterial hypoxemia, i.e., a reduction of O₂ saturation of arterial blood (SaO₂), and consequent cyanosis are likely to be more marked when such depression of PaO₂ results from pulmonary disease than when the depression occurs as the result of a decline in the fraction of oxygen in inspired air (FiO₂). In this situation PaO₂ falls secondary to anoxia-induced hyperventilation and the Hb-O₂ dissociation curve is displaced to the left, limiting the decline in SaO₂ at any level of Po₂.

CAUSES OF HYPOXIA

ANEMIC HYPOXIA A reduction in the hemoglobin concentration of the blood is attended by a corresponding decline in the O₂-carrying capacity of the blood. In anemic hypoxia, the PaO₂ is normal; but as a consequence of the reduction of the hemoglobin concentration, the absolute quantity of O₂ transported per unit volume of blood is diminished. As the anemic blood passes through the capillaries and the usual quantity of O₂ is removed from it, the PaO₂ in the venous blood declines to a greater degree than would normally be the case.

CARBON MONOXIDE INTOXICATION (See also Chap. 377) Hemoglobin that is combined with carbon monoxide (carboxyhemoglobin, COHb) is unavailable for O₂ transport. In addition, the presence of COHb shifts the Hb-O₂ dissociation curve to the left (see Fig. 91-2) so that O₂ is unloaded only at lower tensions. By such formation of COHb, a given degree of reduction in O₂-carrying power produces a far greater degree of tissue hypoxia than the equivalent reduction in hemoglobin due to simple anemia.

RESPIRATORY HYPOXIA Arterial unsaturation is a common finding in advanced pulmonary disease. The most common cause of respiratory hypoxia is ventilation-perfusion mismatch, which results from perfusion of poorly ventilated alveoli. As discussed in Chap. 234, it may also be caused by hypoventilation, and it is then associated with an elevation of PaCO₂. These two forms of respiratory hypoxia may be recognized because they are usually correctable by inspiring 100% O₂ for several minutes. A third cause is shunting of blood across the lung from right to left by perfusion of nonventilated portions of the lung, as in pulmonary atelectasis or through arteriovenous connections in the lung. The low PaO₂ in this situation is correctable only in part by an FiO₂ of 100%.

HYPOXIA SECONDARY TO HIGH ALTITUDE As one ascends rapidly to 3000 m (approximately 10,000 ft), the alveolar Po₂ declines to about 60 mmHg, and impaired memory and other cerebral symptoms of hypoxia may develop. At higher altitudes, arterial saturation declines rapidly and symptoms become more serious; and at 5000 m (approximately 15,000 ft) unacclimatized individuals usually cease to be able to function normally.

HYPOXIA SECONDARY TO RIGHT-TO-LEFT EXTRAPULMONARY SHUNTING From a physiologic viewpoint, this cause of hypoxia resembles intrapulmonary right-to-left shunting but is caused by congenital cardiac malformations such as tetralogy of Fallot, transposition of the great arteries, and Eisenmenger’s syndrome (Chap. 218). As in pulmonary right-to-left shunting, the PaO₂ cannot be restored to normal with inspiration of 100% O₂.

CIRCULATORY HYPOXIA As in anemic hypoxia, the PaO₂ is usually normal, but venous and tissue Po₂ values are reduced as a consequence of reduced tissue perfusion and greater tissue O₂ extraction. Generalized circulatory hypoxia occurs in heart failure (Chap. 216) and in most forms of shock (Chap. 253).

SPECIFIC ORGAN HYPOXIA Decreased perfusion of any organ resulting in localized circulatory hypoxia may occur secondary to organic arterial obstruction, as in atherosclerosis, or as a consequence of vasocnstriction (Chap. 232), as observed in Raynaud’s phenomenon. Localized hypoxia may also result from venous obstruction and the resultant congestion and reduced arterial inflow. Edema, which increases the distance through which O₂ diffuses before it reaches cells, also can cause localized hypoxia. In an attempt to maintain adequate perfusion to more vital organs, vasocnstriction may reduce perfusion in the limbs and skin, causing hypoxia of these regions in patients with heart failure or hypovolemic shock.

INCREASED O₂ REQUIREMENTS If the O₂ consumption of the tissues is elevated without a corresponding increase in perfusion, tissue hypoxia ensues and the PaO₂ in venous blood becomes reduced. Ordinarily, the clinical picture of patients with hypoxia due to an elevated metabolic rate is quite different from that in other types of hypoxia; the skin is warm and flushed, owing to increased cutaneous blood flow that dissipates the excessive heat produced, and cyanosis is usually absent.

HYPOXIA AND CYANOSIS Eugene Braunwald

31
Exercise is a classic example of increased tissue O₂ requirements. These increased demands are normally met by several mechanisms operating simultaneously: (1) increasing the cardiac output and ventilation and thus O₂ delivery to the tissues; (2) preferentially directing the blood to the exercising muscles by changing vascular resistances in various circulatory beds, directly and/or reflexly; (3) increasing O₂ extraction from the delivered blood and widening the arteriovenous O₂ difference; and (4) reducing the pH of the tissues and capillary blood, shifting the Hb-O₂ curve to the right and unloading more O₂ from hemoglobin. If the capacity of these mechanisms is exceeded, then hypoxia, especially of the exercising muscles, will result.

**IMPROPER OXYGEN UTILIZATION** Cyanide (Chap. 377) and several other similarly acting poisons cause cellular hypoxia. The tissues are unable to utilize O₂, and as a consequence, the venous blood tends to have a high O₂ tension. This condition has been termed **histotoxic hypoxia**.

### EFFECTS OF HYPOXIA

Changes in the central nervous system, particularly the higher centers, are especially important consequences of hypoxia. Acute hypoxia causes impaired judgment, motor incoordination, and a clinical picture closely resembling that of acute alcoholism. When hypoxia is long-standing, fatigue, drowsiness, apathy, inattentiveness, delayed reaction time, and reduced work capacity occur. As hypoxia becomes more severe, the centers of the brainstem are affected, and death usually results from respiratory failure. With the reduction of PaO₂, cerebrovascular resistance decreases and cerebral blood flow increases, in an attempt to maintain O₂ delivery to the brain. However, when the reduction of PaO₂ is accompanied by hyperventilation and a reduction of PaCO₂, cerebrovascular resistance rises, cerebral blood flow falls, and hypoxia is intensified. Hypoxia also causes pulmonary arterial constriction, which shunts blood away from poorly ventilated toward better-ventilated portions of the lung. However, it also increases pulmonary vascular resistance and right ventricular afterload.

Glucose is normally broken down to pyruvic acid. However, the further breakdown of pyruvate and the generation of adenosine triphosphate (ATP) consequent to it require O₂, and in the presence of hypoxia increasing proportions of pyruvate are reduced to lactic acid, which cannot be broken down further, causing metabolic acidosis. Under these circumstances, the total energy obtained from the breakdown of carbohydrate is greatly reduced, and the quantity of energy available for the production of ATP becomes inadequate.

An important component of the respiratory response to hypoxia originates in special chemosensitive cells in the carotid and aortic bodies and in the respiratory center in the brainstem. The stimulation of these cells by hypoxia increases ventilation, with a loss of CO₂, and leads to respiratory alkalosis. When combined with the metabolic acidosis resulting from the production of lactic acid, the serum bicarbonate level declines (Chap. 42).

Diminished PₐO₂ in any tissue results in local vasodilation, and the diffuse vasodilation that occurs in generalized hypoxia raises the cardiac output. In patients with underlying heart disease, the requirements of the peripheral tissues for an increase of cardiac output with hypoxia may precipitate congestive heart failure. In patients with ischemic heart disease, a reduced PₐO₂ may intensify myocardial ischemia and further impair left ventricular function.

One of the important mechanisms of compensation for chronic hypoxia is an increase in the hemoglobin concentration and in the number of red blood cells in the circulating blood, i.e., the development of polycythemia secondary to erythropoietin production (Chap. 95).

→The approach to the patient with hypoxia is presented in Chap. 234.

### CYANOSIS

Cyanosis refers to a bluish color of the skin and mucous membranes resulting from an increased quantity of reduced hemoglobin, or of hemoglobin derivatives, in the small blood vessels of those areas. It is usually most marked in the lips, nail beds, ears, and malar eminences. Cyanosis, especially if developed recently, is more commonly detected by a family member than the patient. The florid skin characteristic of polycythemia vera (Chap. 95) must be distinguished from the true cyanosis discussed here. A cherry-colored flush, rather than cyanosis, is caused by COHb (Chap. 377). The degree of cyanosis is modified by the color of the cutaneous pigment and the thickness of the skin, as well as by the state of the cutaneous capillaries. The accurate clinical detection of the presence and degree of cyanosis is difficult, as proved by oximetric studies. In some instances, central cyanosis can be detected reliably when the SaO₂ has fallen to 85%; in others, particularly in dark-skinned persons, it may not be detected until it has declined to 75%. In the latter case of the mucous membranes in the oral cavity and the conjunctivae rather than examination of the skin is more helpful in the detection of cyanosis.

The increase in the quantity of reduced hemoglobin in the mucocutaneous vessels that produces cyanosis may be brought about either by an increase in the quantity of venous blood as the result of dilatation of the venules and venous ends of the capillaries or by a reduction in the SaO₂, in the capillary blood. In general, cyanosis becomes apparent when the mean capillary concentration of reduced hemoglobin exceeds 40 g/L (4 g/dL). It is the absolute rather than the relative quantity of reduced hemoglobin that is important in producing cyanosis. Thus, in a patient with severe anemia, the relative amount of reduced hemoglobin in the venous blood may be very large when considered in relation to the total amount of hemoglobin in the blood. However, since the concentration of the latter is markedly reduced, the absolute amount of reduced hemoglobin may still be small, and therefore patients with severe anemia and even marked arterial desaturation may not display cyanosis. Conversely, the higher the total hemoglobin content, the greater is the tendency toward cyanosis; thus, patients with marked polycythemia tend to be cyanotic at higher levels of SaO₂ than patients with normal hematocrit values. Likewise, local passive congestion, which causes an increase in the total amount of reduced hemoglobin in the vessels in a given area, may cause cyanosis. Cyanosis is also observed when nonfunctional hemoglobin such as methemoglobin or sulfhemoglobin (Chap. 91) is present in blood.

Cyanosis may be subdivided into central and peripheral types. In the central type, the SaO₂ is reduced or an abnormal hemoglobin derivative is present, and the mucous membranes and skin are both affected. Peripheral cyanosis is due to a slowing of blood flow and abnormally great extraction of O₂ from normally saturated arterial blood. It results from vasoconstriction and diminished peripheral blood flow, such as occurs in cold exposure, shock, congestive failure, and peripheral vascular disease. Often in these conditions the mucous membranes of the oral cavity or those beneath the tongue may be spared. Clinical differentiation between central and peripheral cyanosis may not always be simple, and in conditions such as cardiogenic shock with pulmonary edema there may be a mixture of both types.

### DIFFERENTIAL DIAGNOSIS

**CENTRAL CYANOSIS** (Table 31-1) Decreased SaO₂ results from a marked reduction in the PaO₂. This reduction may be brought about by a decline in the FIO₂ without sufficient compensatory alveolar hyperventilation to maintain alveolar PₐO₂. Cyanosis does not occur to a significant degree in an ascendant to an altitude of 2500 m (8000 ft) but is marked in a further ascent to 5000 m (16,000 ft). The reason for this difference becomes clear on studying the S shape of the Hb-O₂ dissociation curve (see Fig. 91-2). At 2500 m (8000 ft) the FIO₂ is about 120 mmHg, the alveolar PₐO₂ is approximately 80 mmHg, and the SaO₂ is nearly normal. However, at 5000 m (16,000 ft) the FIO₂ and alveolar PₐO₂ are about 85 and 50 mmHg, respectively, and the SaO₂ is only about 75%. This leaves 25% of the hemoglobin in the arterial blood in the reduced form, an amount likely to be associated with cyanosis in the absence of anemia. Similarly, a mutant hemoglobin with a low affinity for O₂ (e.g., Hb Kansas) causes lowered SaO₂ saturation and resultant central cyanosis (Chap. 91).

Seriously impaired pulmonary function, through perfusion of unventilated or poorly ventilated areas of the lung or alveolar hypoventilation, is a common cause of central cyanosis (Chap. 234). This condition may occur acutely, as in extensive pneumonia or pulmonary edema, or chronically with chronic pulmonary diseases (e.g., emphysema). In the latter situation, secondary polycythemia is generally present and clubbing of the fingers may occur. However, in many types of chronic pulmonary disease with fibrosis and obliteration of the capillary vascular bed, cyanosis does not occur because there is relatively little perfusion of underventilated areas.

Another cause of reduced SaO2 is shunting of systemic venous blood into the arterial circuit. Certain forms of congenital heart disease are associated with cyanosis (Chap. 218). Since blood flows from a high-pressure to a lower-pressure region, for a cardiac defect to result in a right-to-left shunt, it must ordinarily be combined with an obstructive lesion distal (downstream) to the defect or with elevated pulmonary vascular resistance. The most common congenital cardiac lesion associated with cyanosis in the adult is the combination of ventricular septal defect and pulmonary outflow tract obstruction (tetralogy of Fallot). The more severe the obstruction, the greater the degree of right-to-left shunting and resultant cyanosis. In patients with patent ductus arteriosus, pulmonary hypertension, and right-to-left shunt, differential cyanosis results; that is, cyanosis occurs in the lower but not in the upper extremities. \( \text{The mechanisms for the elevated pulmonary vascular resistance} \) \( \text{that may produce cyanosis in the presence of intra- and extracardiac communications without pulmonic stenosis (Eisenmenger syndrome) are discussed in Chap. 218.} \)

Pulmonary arteriovenous fistulae (Chap. 48) may be congenital or acquired, solitary or multiple, microscopic or massive. The severity of cyanosis produced by these fistulae depends on their size and number. They occur with some frequency in hereditary hemorrhagic telangiectasia. SaO2 reduction and cyanosis may also occur in some patients with cirrhosis, presumably as a consequence of pulmonary arteriovenous fistulas or portal vein–pulmonary vein anastomoses.

In patients with cardiac or pulmonary right-to-left shunts, the presence and severity of cyanosis depend on the size of the shunt relative to the systemic flow as well as on the Hb-O2 saturation of the venous blood. With increased extraction of O2 from the blood by the exercising muscles, the venous blood returning to the right side of the heart is more unsaturated than at rest, and shunting of this blood intensifies the cyanosis. As soon as the systemic vascular resistance falls with exercise, the right-to-left shunt is augmented by exercise in patients with congenital heart disease and communications between the two sides of the heart. Secondary polycythemia occurs frequently in patients with arterial O2 unsaturation and contributes to the cyanosis.

Cyanosis can be caused by small amounts of circulating methemoglobin and by even smaller amounts of sulfhemoglobin (Chap. 91). Although they are uncommon causes of cyanosis, these abnormal hemoglobin pigments should be sought by spectroscopy when cyanosis is not readily explained by malfunction of the circulatory or respiratory systems. Generally, digital clubbing does not occur with them. The diagnosis of methemoglobinemia can be suspected if the patient’s blood remains brown after being mixed in a test tube and exposed to air.

PERIPHERAL CYANOSIS. Probably the most common cause of peripheral cyanosis is the normal vasoconstriction resulting from exposure to cold air or water. When cardiac output is reduced, cutaneous vasoconstriction occurs as a compensatory mechanism so that blood is diverted from the skin to more vital areas such as the central nervous system and heart, and cyanosis of the extremities may result, even though the arterial blood is normally saturated.

Arterial obstruction to an extremity, as with an embolus, or arteriolar constriction, as in cold-induced vasospasm (Raynaud’s phenomenon, Chap. 323), generally results in pallor and coldness, but there may be associated cyanosis. Venous obstruction, as in thrombophlebitis, dilates the subpapillary venous plexuses and thereby intensifies cyanosis.

Certain features are important in arriving at the cause of cyanosis:

1. A careful history must be obtained, particularly timing of the onset of cyanosis. Cyanosis present since birth or infancy is usually due to congenital heart disease.

2. Central and peripheral cyanosis must be differentiated. Evidence of disorders of the respiratory or cardiovascular systems are helpful. Massage or gentle warming of a cyanotic extremity will increase peripheral blood flow and abolish peripheral but not central cyanosis.

3. The presence or absence of clubbing of the digits (see below) should be ascertained. Clubbing without cyanosis is frequent in patients with infective endocarditis and inflammatory bowel disease; it may occasionally occur in healthy persons, and in some instances it may be occupational, e.g., in jackhammer operators. The combination of cyanosis and clubbing is frequent in patients with congenital heart disease and right-to-left shunting and is seen occasionally in patients with pulmonary disease such as lung abscess or pulmonary arteriovenous fistulae. In contrast, peripheral cyanosis or acutely developing central cyanosis is not associated with clubbed digits.

4. PaO2 and SaO2 should be ascertained and in patients in whom the mechanism of cyanosis is obscure spectroscopic and other examinations of the blood performed to look for abnormal types of hemoglobin (critical in the differential diagnosis of cyanosis).

CLUBBING

The selective bullous enlargement of the distal segments of the fingers and toes due to proliferation of connective tissue, particularly on the dorsal surface, is termed clubbing; there is increased sponginess of the soft tissue at the base of the nail. Clubbing may be hereditary, idopathic, or acquired and associated with a variety of disorders, including cyanotic congenital heart disease, infective endocarditis, and a variety of pulmonary conditions (among them primary and metastatic lung cancer, bronchiectasis, lung abscess, cystic fibrosis, and mesothelioma), as well as with some gastrointestinal diseases (including inflammatory bowel disease and hepatic cirrhosis).
Edema is defined as a clinically apparent increase in the interstitial fluid volume, which may expand by several liters before the abnormality is evident. Therefore, a weight gain of several kilograms usually precedes overt manifestations of edema, and a similar weight loss from diuresis can be induced in a slightly edematous patient before “dry weight” is achieved. Anasarca refers to gross, generalized edema. Ascites (Chap. 39) and hydrothorax refer to accumulation of excess fluid in the peritoneal and pleural cavities, respectively, and are considered to be special forms of edema.

Depending on its cause and mechanism, edema may be localized or have a generalized distribution; it is recognized in its generalized form by puffiness of the face, which is most readily apparent in the periorbital areas, and by the persistence of an indentation of the skin following pressure; this is known as “pitting” edema. In its more subtle form, edema may be detected by noting that after the stethoscope is removed from the chest wall, the rim of the bell leaves an indentation on the skin of the chest for a few minutes. When the ring on a finger fits more snugly than in the past or when a patient complains of difficulty in putting on shoes, particularly in the evening, edema may be present.

**PATHOGENESIS**

About one-third of the total-body water is confined to the extracellular space. Approximately 25% of the latter, in turn, is composed of the plasma volume, and the remainder is interstitial fluid.

**STARLING FORCES**

The forces that regulate the disposition of fluid between these two components of the extracellular compartment are frequently referred to as the Starling forces (see p. 204). The hydrostatic pressure within the vascular system and the colloid oncotic pressure in the interstitial fluid tend to promote movement of fluid from the vascular to the extravascular space. On the other hand, the colloid oncotic pressure contributed by the plasma proteins and the hydrostatic pressure within the interstitial fluid, referred to as the tissue tension, promote the movement of fluid into the vascular compartment. Consequently, there is a movement of water and diffusible solutes from the vascular space at the arteriolar end of the capillaries. Fluid is returned from the interstitial space into the vascular system at the venous end of the capillary and by way of the lymphatics. Unless these channels are obstructed, lymph flow rises with increases in net movement of fluid from the vascular compartment to the interstitium. These flows are usually balanced so that a steady state exists in the sizes of the intravascular and interstitial compartments, and yet a large exchange between them occurs. However, should any one of the hydrostatic or oncotic pressure gradients be altered significantly, a further net movement of fluid between the two components of the extracellular space will take place. The development of edema then depends on one or more alterations in the Starling forces so that there is increased flow of fluid from the vascular system into the interstitium or into a body cavity.

Edema due to increase in capillary pressure may result from an elevation of venous pressure due to obstruction in venous drainage. This increase in capillary pressure may be generalized, as occurs in congestive heart failure. The Starling forces may be imbalanced when the colloid oncotic pressure of the plasma is reduced, owing to any factor that may induce hypoalbuminemia, such as saline expansion, malnutrition, liver disease, loss of protein into the urine or into the gastrointestinal tract, or a severe catabolic state.

**CAPILLARY DAMAGE**

Edema may also result from damage to the capillary endothelium, which increases its permeability and permits the transfer of protein into the interstitial compartment. Injury to the capillary wall can result from drugs, viral or bacterial agents, and thermal or mechanical trauma. Increased capillary permeability may also be a consequence of a hypersensitivity reaction and is characteristic of immune injury. Damage to the capillary endothelium is presumably responsible for inflammatory edema, which is usually nonpitting, localized, and accompanied by other signs of inflammation—redness, heat, and tenderness.

**REDUCTION OF EFFECTIVE ARTERIAL VOLUME**

In many forms of edema the effective arterial blood volume, an as yet poorly defined parameter of the filling of the arterial tree, is reduced, and as a consequence a series of physiologic responses designed to restore it to normal are set into motion. A key element of these responses is the retention of salt and therefore of water, principally by the renal proximal tubule, ultimately leading to edema.

**REDUCED CARDIAC OUTPUT**

A reduction of cardiac output, whatever the cause, is associated with a lowering of the effective arterial blood volume as well as of renal blood flow, constriction of the efferent renal arterioles, and an elevation of the filtration fraction, i.e., the ratio of glomerular filtration rate to renal plasma flow. In severe heart failure there is a reduction in the glomerular filtration rate. Activation of the sympathetic nervous system and of the renin-angiotensin systems is responsible for renal vasoconstriction. The finding that α-adrenergic blocking agents and/or angiotensin-converting enzyme (ACE) inhibitors augment renal blood flow and induce diuresis supports the role of these two systems in elevating renal vascular resistance and salt and water retention when cardiac output is reduced.

**RENAI FACTORS**

Heart failure and other conditions, such as nephrotic syndrome and cirrhosis that reduce effective arterial blood volume, cause renal efferent arteriolar constriction. This, in turn, reduces the hydrostatic pressure while the increased filtration fraction raises the colloid osmotic pressure in the peritubular capillaries, thus enhancing salt and water reabsorption in the proximal tubule as well as in the ascending limb of the loop of Henle.

In addition, the diminished renal blood flow characteristic of states in which the effective arterial blood volume is reduced is translated by the renal juxtaglomerular cells into a signal for increased renin...
release (Chap. 321). The mechanisms responsible for this release include: (1) a baroreceptor response in which reduced renal perfusion results in incomplete filling of the renal arterioles and diminished stretch of the juxtaglomerular cells, a signal that provides for the elaboration and/or release of renin (see below); (2) reduced glomerular filtration which lowers the sodium chloride load reaching the distal renal tubules; this is sensed by the macula densa, which signals the neighboring juxtaglomerular cells to secrete renin; (3) activation of the \( \beta \)-adrenergic receptors in the juxtaglomerular cells by the sympathetic nervous system and circulating catecholamines stimulates renin release. These three mechanisms generally act in concert.

THE RENIN-ANGIOTENSIN-ALDOSTERONE (RAA) SYSTEM (See also Chap. 321) Renin, an enzyme with a molecular weight of about 40,000, acts on its substrate, angiotensinogen, an \( \alpha \)-globulin synthesized by the liver, to release angiotensin I, a decapeptide, which is broken down to angiotensin II (AII), an octapeptide. AII has generalized vasconstrictor properties; it is especially active on the efferent arterioles and independently increases Na\(^{+}\) reabsorption in the proximal tubule. The RAA system has long been recognized as a hormone system. However, it also operates locally. Both circulating and intrarenally produced AII contribute to renal vasoconstriction and to salt and water retention. These renal effects of AII are mediated by activation of AII type 1 receptors, which can be blocked by specific antagonists (angiotensin receptor blockers) such as losartan. AII also enters the circulation and stimulates the production of aldosterone by the zona glomerulosa of the adrenal cortex. In patients with heart failure, not only is aldosterone secretion elevated but the biologic half-life of aldosterone is prolonged, which further increases the plasma level of the hormone. A depression of hepatic blood flow, particularly during exercise, secondary to a reduction in cardiac output, is responsible for the reduced hepatic catabolism of aldosterone. Aldosterone, in turn, enhances Na\(^{+}\) reabsorption (and K\(^{+}\) excretion) by the collecting tube. The activation of the RAA system is most striking in the early phase of acute, severe heart failure and is less intense in patients with chronic, stable, compensated heart failure.

Although increased quantities of aldosterone are secreted in heart failure and in other edematous states and although blockade of the action of aldosterone by spironolactone (an aldosterone antagonist) or amiloride (a blocker of epithelial Na\(^{+}\) channels) often induces a moderate diuresis in edematous states, persistent augmented levels of aldosterone (or other mineralocorticoids) alone do not always promote accumulation of edema, as witnessed by the lack of striking fluid retention in most instances of primary aldosteronism (Chap. 321). Furthermore, although normal individuals retain some salt and water with the administration of potent mineralocorticoids, such as deoxycorticosterone acetate or fludrocortisone, this accumulation is self-limiting, despite continued exposure to the steroid, a phenomenon known as \textit{mineralocorticoid escape}. The failure of normal individuals who receive large doses of mineralocorticoids to accumulate large quantities of extracellular fluid and to develop edema is probably a consequence of an increase in glomerular filtration rate (pressure natriuresis) and through the action of natriuretic substance(s) (see below). The continued secretion of aldosterone may be more important in the accumulation of fluid in edematous states because patients with edema secondary to heart failure, nephrotic syndrome, and cirrhosis are generally unable to repair the deficit in effective arterial blood volume. As a consequence they do not develop pressure natriuresis.

ARGININE VASOPRESSIN (AVP) (See also Chap. 319) The secretion of AVP occurs in response to increased intracellular osmolar concentration and by stimulating \( V_2 \) receptors increases the reabsorption of free water in the renal distal tubule and collecting duct, thereby increasing total-body water. Circulating AVP is elevated in many patients with heart failure secondary to a nonosmotic stimulus associated with decreased effective arterial volume. Such patients fail to show the normal reduction of AVP with a reduction of osmolality, contributing to hypernatremia and edema formation.

ENDOTHELIN This is a potent peptide vasconstrictor released by endothelial cells; its concentration is elevated in heart failure and contributes to renal vasoconstriction, Na\(^{+}\) retention, and edema in heart failure.

NATRIURETIC PEPTIDES (See also Chap. 215) Atrial distention and/or a sodium load cause release into the circulation of atrial natriuretic peptide (ANP), a polypeptide; a high-molecular-weight precursor of ANP is stored in secretory granules within atrial myocytes. Release of ANP causes (1) excretion of sodium and water by augmenting glomerular filtration rate, inhibiting sodium reabsorption in the proximal tubule, and inhibiting release of renin and aldosterone; and (2) arteriolar and venous dilatation by antagonizing the vasconstrictor actions of AII, AVP, and sympathetic stimulation. Thus, ANP has the capacity to oppose sodium retention and arterial pressure elevation in hypervolemic states.

The closely related brain natriuretic peptide (BNP) is stored primarily in cardiac ventricular myocardium and is released when ventricular diastolic pressure rises. Its actions are similar to those of ANP. Circulating levels of ANP and BNP are elevated in congestive heart failure but obviously not sufficiently to prevent edema formation. In addition, in edematous states (particularly heart failure), there is abnormal resistance to the actions of natriuretic peptides.

CLINICAL CAUSES OF EDEMA OSTRUCTION OF VENOUS (AND LYMPHATIC) DRAINAGE OF A LIMB In this condition the hydrostatic pressure in the capillary bed upstream (proximal) to the obstruction increases so that an abnormal quantity of fluid is transferred from the vascular to the interstitial space. Since the alternative route (i.e., the lymphatic channels) may also be obstructed, an increased volume of interstitial fluid in the limb develops, i.e., there is trapping of fluid in the extremity, causing local edema at the expense of the blood volume in the remainder of the body, thereby reducing effective arterial blood volume and leading to the retention of salt and water until the deficit in plasma volume has been corrected. Tissue tension rises in the affected limb until it counterbalances the primary alterations in the Starling forces, at which time no further fluid accumulates. The net effect is a local increase in the volume of interstitial fluid. This same sequence occurs in ascites and hydrothorax, in which fluid is trapped or accumulates in the cavity space, depleting the intravascular volume and leading to secondary salt and fluid retention, as already described.

CONGESTIVE HEART FAILURE (See also Chap. 216) In this disorder, the impaired systolic emptying of the ventricle(s) and/or the impairment of ventricular relaxation promotes an accumulation of blood in the venous circulation at the expense of the effective arterial volume, and the aforementioned sequence of events (Fig. 32-1) is initiated. In mild heart failure, a small increment of total blood volume may repair the deficit of arterial volume and establish a new steady state. Through the operation of Starling’s law of the heart, an increase in ventricular diastolic volume promotes a more forceful contraction and may thereby restore the cardiac output (Fig. 216-1). However, if the cardiac disorder is more severe, fluid retention continues, and the increment in blood volume accumulates in the venous circulation. With reduction in cardiac output, a decrease in baroreflex-mediated inhibition of the vasomotor center activates renal vasconstrictor nerves and the RAA system, causing sodium and water retention.

Incomplete ventricular emptying (systolic heart failure) and/or inadequate ventricular relaxation (diastolic heart failure) both lead to an elevation of ventricular diastolic pressure. If the impairment of cardiac function primarily involves the right ventricle, pressures in the systemic veins and capillaries rise, augmenting the transudation of fluid into the interstitial space and enhancing the likelihood of peripheral edema. The elevated systemic venous pressure is transmitted to the thoracic duct with consequent reduction of lymph drainage, further increasing the accumulation of edema.
CIRRHOSIS (See also Chap. 39 and Chap. 289) This condition is characterized by hepatic venous outflow blockade, which in turn expands the splanchic blood volume and increases hepatic lymph formation. Intrahepatic hypertension acts as a potent stimulus for renal Na⁺ retention and a reduction of effective arterial blood volume. These alterations are frequently complicated by hypoalbuminemia secondary to reduced hepatic synthesis, which reduce the effective arterial blood volume further, leading to activation of the RAA system, of renal sympathetic nerves, and other salt- and water-retaining mechanisms. The concentration of circulating aldosterone is elevated by the liver’s failure to metabolize this hormone. Initially, the excess interstitial fluid is localized preferentially proximal (upstream) to the congested portal venous system and obstructed hepatic lymphatics, i.e., in the peritoneal cavity. In later stages, particularly when there is severe hypoalbuminemia, peripheral edema may develop. The excess production of prostaglandins (PGE₂ and PGI₃) in cirrhosis attenuates renal Na⁺ retention. When the synthesis of these substances is inhibited by non-steroidal anti-inflammatory agents, renal function deteriorates and Na⁺ retention increases.

**DRUG-INDUCED EDEMA** A large number of widely used drugs can cause edema (Table 32-1). Mechanisms include renal vasoconstriction (nonsteroidal anti-inflammatory agents and cyclosporine), arteriolar dilatation (vasodilators), augmented renal sodium reabsorption (steroid hormones), and capillary dilatation (vasodilators), augmented renal sodium reabsorption.

**IDIOPATHIC EDEMA** This syndrome, which occurs almost exclusively in women, is characterized by periodic episodes of edema (unrelated to

Source: From Chertow.
the menstrual cycle), frequently accompanied by abdominal distention. Diurnal alterations in weight occur with orthostatic retention of sodium and water, so that the patient may weigh several pounds more after having been in the upright posture for several hours. Such large diurnal weight changes suggest an increase in capillary permeability that appears to fluctuate in severity and to be aggravated by hot weather. There is some evidence that a reduction in plasma volume occurs in this condition with secondary activation of the RAA system and impaired suppression of AVP release. There are also some cases in which the edema appears to be diuretic-induced. Idiopathic edema should be distinguished from cyclical or premenstrual edema, in which the sodium and water retention may be secondary to excessive estrogen stimulation. There are also some cases in which the edema appears to be diuretic-induced. It has been postulated that in these patients, chronic diuretic administration leads to mild blood volume depletion, which causes chronic hyperreninemia and juxtaglomerular hyperplasia. Salt-retaining mechanisms appear to overcompensate for the direct effects of the diuretics. Acute withdrawal of diuretics can then leave the sodium-retaining forces unopposed, leading to fluid retention and edema. Decreased dopaminergic activity and reduced urinary kallikrein and kinin excretion have been reported in this condition and may also be of pathogenetic importance.

**TREATMENT**

The treatment of idiopathic cyclic edema includes a reduction in salt intake, rest in the supine position for several hours each day, the wearing of elastic stockings (which should be put on before arising in the morning), and an attempt to understand any underlying emotional problems. A variety of pharmacologic agents including ACE inhibitors, proges-terone, the dopamine receptor agonist bromocriptine, and the sympa-thomimetic amine dextroamphetamine have all been reported to be useful when administered to patients who do not respond to simpler measures. Diuretics may be helpful initially but may lose their effectiveness with continuous administration; accordingly, they should be employed sparingly, if at all. Discontinuation of diuretics paradoxically leads to diuresis in diuretic-induced edema, described above.

**DIFFERENTIAL DIAGNOSIS**

**LOCALIZED EDema** (See also Chap. 232)

Edema originating from inflammation or hypersensitivity is usually readily identified. Localized edema due to venous or lymphatic obstruction may be caused by thrombophlebitis, chronic lymphangitis, resection of regional lymph nodes, filariasis, etc. Lymphedema is particularly intractable because restriction of lymphatic flow results in increased protein concentration in the interstitial fluid, a circumstance that aggravates retention of fluid.

**GENERALIZED EDema**

The differences between the three major causes of generalized edema are shown in Table 32-2.

The great majority of patients with generalized edema suffer from advanced cardiac, renal, hepatic, or nutritional disorders. Consequently, the differential diagnosis of generalized edema should be directed toward identifying or excluding these several conditions.

**EDema of Heart Failure** (See also Chap. 216) The presence of heart disease, as manifested by cardiac enlargement and gallop rhythm, together with evidence of cardiac failure, such as dyspnea, basilar rales, venous distention, and hepatomegaly, usually indicate that edema results from heart failure. Noninvasive tests such as echocardiography and radionuclide angiography may be helpful in establishing the diagnosis of heart failure.

**EDema of the Nephrotic Syndrome** (See also Chap. 264) Marked proteinuria (>3.5 g/d), hypoalbuminemia (<35 g/L), and in some instances hypercholesterolemia are present. This syndrome may occur during the course of a variety of kidney diseases, which include glomerulonephritis, diabetic glomerulosclerosis, and hypersensitivity reactions. A history of previous renal disease may or may not be elicited.

**EDema of acute Glomerulonephritis and Other Forms of Renal Failure**

The edema occurring during the acute phases of glomerulonephritis is characteristically associated with hematuria, proteinuria, and hypertension. Although some evidence supports the view that the fluid retention is due to increased capillary permeability, in most instances the edema results from primary retention of sodium and water by the kidneys owing to renal insufficiency. This state differs from congestive heart failure in that it is characterized by a normal (or sometimes even increased) cardiac output and a normal arterial–mixed venous oxygen difference. Patients with edema due to renal failure commonly have evidence of pulmonary congestion on chest roentgenograms before cardiac enlargement is significant, but they may not develop orthopnea. Patients with chronic renal failure may also develop edema due to primary renal retention of sodium and water.

| Table 32-2 | Principal Causes of Generalized Edema: History, Physical Examination, and Laboratory Findings |
| Organ System | History | Physical Examination | Laboratory Findings |
| Cardiac | Dyspnea with exertion prominent—often associated with orthopnea—or paroxysmal nocturnal dyspnea | Elevated jugular venous pressure, ventricular (S3) gallop; occasionally with displaced or dyskinetic apical pulse; peripheral cyanosis, cool extremities, small pulse pressure when severe | Elevated urea nitrogen-to-creatinine ratio common; elevated uric acid; serum sodium often diminished; liver enzymes occasionally elevated with hepatic congestion |
| Hepatic | Dyspnea infrequent, except if associated with significant degree of ascites; most often a history of ethanol abuse | Frequently associated with ascites; jugular venous pressure normal or low; blood pressure lower than in renal or cardiac disease; one or more additional signs of chronic liver disease (jaundice, palmar erythema, Dupuytren’s contracture, spider angiomata, male gynecomastia; asterixis and other signs of encephalopathy) may be present | If severe, reductions in serum albumin, cholesterol, other hepatic proteins (transferrin, fibrinogen); liver enzymes elevated, depending on the cause and acuteness of liver injury; tendency toward hypokalemia, respiratory alkalosis; macrocytosis from folate deficiency |
| Renal | Usually chronic: may be associated with uremic signs and symptoms, including decreased appetite, altered (metallic or fishy) taste, altered sleep pattern, difficulty concentrating, restless legs or myoclonus; dyspnea can be present, but generally less prominent than in heart failure | Blood pressure may be elevated; hypertensive or diabetc retinopathy in selected cases; nitrogenous fetor; periorbital edema may predominate; pericardial friction rub in advanced cases with uremia | Albuminuria, hypoalbuminemia; sometimes, elevation of serum creatinine and urea nitrogen; hyperkalemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, anemia (usually normocytic) |

*Source: From Chertow.*

*Note: S3, third heart sound.*
EDEMA OF CIRRHOSIS (See also Chap. 289) Ascites and biochemical and clinical evidence of hepatic disease (collateral venous channels, jaundice, and spider angiomata) characterize edema of hepatic origin. The ascites (Chap. 39) is frequently refractory to treatment because it collects as a result of a combination of obstruction of hepatic lymphatic drainage, portal hypertension, and hypoalbuminemia. Edema may also occur in other parts of the body in these patients as a result of hypoalbuminemia. Furthermore, a sizable accumulation of ascitic fluid may increase intraabdominal pressure and impede venous return from the lower extremities; hence, it tends to promote accumulation of edema in this region as well.

EDEMA OF NUTRITIONAL ORIGIN A diet grossly deficient in protein over a prolonged period may produce hypoproteinemia and edema. The latter may be intensified by the development of beriberi heart disease (Chap. 223), also of nutritional origin, in which multiple peripheral arteriovenous fistulae result in reduced effective systemic perfusion and effective arterial blood volume, thereby enhancing edema formation (Chap. 61). Edema may actually become intensified when famished subjects are first provided with an adequate diet. The ingestion of more food may increase the quantity of NaCl ingested, which is then retained along with water. So-called refeeding edema may also be linked to increased release of insulin, which directly increases tubular sodium reabsorption. In addition to hypoalbuminemia, hypokalemia and caloric deficits may be involved in the edema of starvation.

OTHER CAUSES OF EDEMA These include hypothyroidism, in which the edema (myxedema) is located typically in the pretibial region and which may also be associated with periorbital puffiness. Exogenous hyperadrenocorticism, pregnancy, and administration of estrogens and vasodilators, particularly dihydropyridines such as nifedipine, may also cause edema.

DISTRIBUTION OF EDEMA The distribution of edema is an important guide to the cause. Thus, edema limited to one leg or to one or both arms is usually the result of venous and/or lymphatic obstruction. Edema resulting from hypoproteinemia characteristic is generalized, but it is especially evident in the very soft tissues of the eyelids and face and tends to be most pronounced in the morning because of the recumbent posture assumed during the night. Less common causes of facial edema include trichinosis, allergic reactions, and myxedema. Edema associated with heart failure, on the other hand, tends to be more extensive in the legs and to be accentuated in the evening, a feature also determined largely by posture. When patients with heart failure have been confined to bed, edema may be most prominent in the presacral region. Paralysis reduces lymphatic and venous drainage on the affected side and may be responsible for unilateral edema.

ADDITIONAL FACTORS IN DIAGNOSIS The color, thickness, and sensitivity of the skin are significant. Local tenderness and warmth suggest inflammation. Local cyanosis may signify a venous obstruction. In individuals who have had repeated episodes of prolonged edema, the skin over the involved areas may be thickened, indurated, and often red.

Measurement or estimation of the venous pressure is of importance in evaluating edema. Elevation in an isolated part of the body usually reflects localized venous obstruction. Generalized elevation of systemic venous pressure usually indicates the presence of congestive heart failure. Ordinarily, a significant generalized increase in venous pressure can be recognized by the level at which cervical veins collapse (Chap. 209). In patients with obstruction of the superior vena cava, edema is confined to the face, neck, and upper extremities, where the venous pressure is elevated compared with that in the lower extremities. Measurement of venous pressure in the upper extremities is also useful in patients with massive edema of the lower extremities and ascites; it is elevated in the upper extremities when the edema is on a cardiac basis (e.g., advanced heart failure, constrictive pericarditis, or tricuspid stenosis) but is normal when it is secondary to cirrhosis. Severe heart failure may cause ascites that may be distinguished from the ascites caused by hepatic cirrhosis by the jugular venous pressure, which usually is elevated in heart failure and normal in cirrhosis.

Determination of the concentration of serum albumin aids importantly in identifying those patients in whom edema is due, at least in part, to diminished intravascular colloid oncotic pressure. The presence of proteinuria also affords useful clues. The absence of proteinuria excludes nephrotic syndrome but cannot exclude nonproteinuric causes of renal failure. Slight to moderate proteinuria is the rule in patients with heart failure.

An important first question is whether the edema is localized or generalized. If it is localized, those phenomena that may be responsible should be concentrated upon. If the edema is generalized, it should be determined, first, if there is serious hypoalbuminemia, e.g., serum albumin <25 g/L. If so, the history, physical examination, urinalysis, and other laboratory data will help evaluate the question of cirrhosis, severe malnutrition, protein-losing gastroenteropathy, or the nephrotic syndrome as the underlying disorder. If hypoalbuminemia is not present, it should be determined if there is evidence of congestive heart failure of a severity to promote generalized edema. Finally, it should be determined whether the patient has an adequate urine output, or if there is significant oliguria or even anuria. These abnormalities are discussed in Chaps. 40, 260, and 261.

FURTHER READING

Dysphagia is defined as a sensation of “sticking” or obstruction of the passage of food through the mouth, pharynx, or esophagus. It should be distinguished from other symptoms related to swallowing. Aphagia signifies complete esophageal obstruction, which is usually due to bolus impaction and represents a medical emergency. Difficulty in initiating a swallow occurs in disorders of the voluntary phase of swallowing. However, once initiated, swallowing is completed normally. Odynophagia means painful swallowing. Frequently, odynophagia and dysphagia occur together. Globus pharyngeus is the sensation of a lump lodged in the throat. However, no difficulty is encountered when swallowing is performed. Misdirection of food, resulting in nasal regurgitation and laryngeal and pulmonary aspiration of food during swallowing, is characteristic of oropharyngeal dysphagia. Phagophobia, meaning fear of swallowing, and refusal to swallow may occur in hysteria, rabies, tetanus, and pharyngeal paralysis due to fear of aspiration. Painful inflammatory lesions that cause odynophagia may also cause refusal to swallow. Some patients may feel the food as it goes down the esophagus. This esophageal sensitivity is not associated with either food sticking or obstruction, however. Similarly, the feeling of fullness in the epigastrium that occurs after a meal or after swallowing air should not be confused with dysphagia.

**Physiology of Swallowing**

The process of swallowing begins with a voluntary (oral) phase during which a bolus of food is pushed into the pharynx by the contraction of the tongue. The bolus then Activate oropharyngeal sensory receptors that initiate the involuntary (pharyngeal and esophageal) phase, or deglutition reflex. The deglutition reflex is a complex series of events and serves both to propel food through the pharynx and the esophagus and to prevent its entry into the airway. When the bolus is propelled backward by the tongue, the larynx moves forward and the upper esophageal sphincter opens. As the bolus moves into the pharynx, contraction of the superior pharyngeal constrictor against the contracted soft palate initiates a peristaltic contraction that proceeds rapidly downward to move the bolus through the pharynx and the esophagus. The lower esophageal sphincter opens as the food enters the esophagus and remains open until the peristaltic contraction has swept the bolus into the stomach. Peristaltic contraction in response to a swallow is called primary peristalsis. It involves inhibition followed by sequential contraction of muscles along the entire swallowing passage. The inhibition that precedes the peristaltic contraction is called deglutitive inhibition. Local distention of the esophagus from food activates intramural reflexes in the smooth muscle and results in secondary peristalsis, which is limited to the thoracic esophagus. Tertiary contractions are nonperistaltic because they occur simultaneously over a long segment of the esophagus. Tertiary contractions may occur in response to a swallow or esophageal distention, or they may occur spontaneously.

**Pathophysiology of Dysphagia**

The normal transport of an ingested bolus through the swallowing passage depends on the size of the ingested bolus; the luminal diameter of the swallowing passage; the force of peristaltic contraction; and deglutitive inhibition, including normal relaxation of upper and lower esophageal sphincters during swallowing. Dysphagia caused by a large bolus or luminal narrowing is called mechanical dysphagia, whereas dysphagia due to weakness of peristaltic contractions or to impaired deglutitive inhibition causing nonperistaltic contractions and impaired sphincter relaxation is called motor dysphagia.

**Mechanical Dysphagia**

Mechanical dysphagia can be caused by a very large food bolus, intrinsic narrowing, or extrinsic compression of the lumen. In an adult, the esophageal lumen can distend up to 4 cm in diameter. When the esophagus cannot dilate beyond 2.5 cm in diam-eter, dysphagia to normal solid food can occur. Dysphagia is always present when the esophagus cannot distend beyond 1.3 cm. Circumferential lesions produce dysphagia more consistently than do lesions that involve only a portion of circumferences of the esophageal wall, as uninvolved segments retain their distensibility. The causes of mechanical dysphagia are listed in Table 33-1. Common causes include carcinoma, peptic and other benign strictures, and lower esophageal ring.

**Motor Dysphagia**

Motor dysphagia may result from difficulty in initiating a swallow or from abnormalities in peristalsis and deglutitive inhibition due to diseases of the esophageal striated or smooth muscle. Diseases of the striated muscle involve the pharynx, upper esophageal sphincter, and cervical esophagus. The striated muscle is innervated by a somatic component of the vagus with cell bodies of the lower motor neurons located in the nucleus ambiguus. These neurons are cholinergic and excitatory and are the sole determinant of the muscle activity. Peristalsis in the striated muscle segment is due to sequential central activation of neurons innervating muscles at different levels along the esophagus. Motor dysphagia of the pharynx results from neuromuscular disorders causing muscle paralysis, simultaneous nonperistaltic contraction, or loss of opening of the upper esophageal sphincter. Loss of opening of the upper sphincter is caused by paralysis of geniohyoid and other suprahyoid muscles or loss of deglutitive inhibition of the cricopharyngeus muscle. Because each side of the pharynx is innervated by ipsilateral nerves, a unilateral lesion of motor neurons leads to unilateral pharyngeal paralysis. Although lesions of striated muscle also involve the cervical part of the esophagus, the clinical manifestations of pharyngeal dysfunction usually overshadow those due to esophageal involvement.

Diseases of the smooth-muscle segment involve the thoracic part of the esophagus and the lower esophageal sphincter. The smooth muscle is innervated by the parasympathetic component of the vagal preganglionic fibers and postganglionic neurons in the myenteric ganglia. The vagal pathway consists of parallel excitatory and inhibitory pathways that use acetylcholine and nitric oxide as neurotransmitters, respectively. The activation of inhibitory nerves causes inhibition that is followed by rebound contraction. These pathways are involved in the resting tone of the lower esophageal sphincter, swallow-induced lower esophageal sphincter opening, and inhibition followed by peristaltic contractions in the esophageal body. Dysphagia results when the peristaltic contractions are weak or nonperistaltic or when the lower sphincter fails to relax normally. Loss of contractile power occurs due to muscle weakness, as in scleroderma. The nonperistaltic contractions and impaired relaxation of the lower esophageal sphincter result from a defect in inhibitory vagal innervation and account for dysphagia in achalasia.

The causes of motor dysphagia are also listed in Table 33-1. Important causes are pharyngeal paralysis, cricopharyngeal achalasia, scleroderma of the esophagus, achalasia, and diffuse esophageal spasm and related motor disorders.
progressive dysphagia lasting a few weeks to a few months is suggestive of carcinoma of the esophagus. Episodic dysphagia to solids lasting several years indicates a benign disease characteristic of a lower esophageal ring.

The site of dysphagia described by the patient helps to determine the site of esophageal obstruction; the lesion is at or below the perceived location of dysphagia.

Associated symptoms provide important diagnostic clues. Nasal regurgitation and tracheobronchial aspiration with swallowing are hallmarks of pharyngeal paralysis or a tracheoesophageal fistula. Tracheobronchial aspiration unrelated to swallowing may be secondary to achalasia, Zenker’s diverticulum, or gastroesophageal reflux.

Severe weight loss that is out of proportion to the degree of dysphagia is highly suggestive of carcinoma. When hoarseness precedes dysphagia, the primary lesion is usually in the larynx.

Hoarseness following dysphagia may suggest involvement of the recurrent laryngeal nerve by extension of esophageal carcinoma. Sometimes hoarseness may be due to laryngitis secondary to gastroesophageal reflux. Association of laryngeal symptoms and dysphagia also occurs in various neuromuscular disorders. Hiccups sometimes hoarseness may be due to laryngitis secondary to gastroesophageal reflux.

**34 Nausea, Vomiting, and Indigestion**

**William L. Hasler**

**Nausea** is the subjective feeling of a need to vomit. **Vomiting** (emesis) is the oral expulsion of upper gastrointestinal contents resulting from contractions of gut and thoracoabdominal wall musculature. Vomiting is contrasted with **regurgitation**, the effortless passage of gastric contents into the mouth. **Rumination** is the repeated regurgitation of stomach contents, which are often rechewed and then reswallowed. In contrast to vomiting, these phenomena often exhibit some volitional control. **Indigestion** is a nonspecific term that encompasses a variety of upper abdominal complaints including nausea, vomiting, heartburn, regurgitation, and dyspepsia (upper abdominal discomfort or pain). Some individuals with dyspepsia report ulcer-like symptoms such as epigastric burning or gnawing discomfort. Others experience symptoms of gastric dysmotility such as postprandial fullness, bloating, eructation (belching), anorexia (loss of appetite), and early satiety (an inability to complete a meal due to premature fullness).

**Nausea and Vomiting**

**Mechanisms**  
Vomiting is coordinated by the brainstem and is effected by neuromuscular responses in the gut, pharynx, and thoracoabdominal wall. The mechanisms underlying nausea are poorly understood but likely involve the cerebral cortex, as nausea requires conscious perception. Electroencephalographic studies show activation of temporo-pontal cortical regions with induction of nausea.

**Coordination of Emesis**  
Several brainstem nuclei initiate emesis, including the nucleus tractus solitarius, the dorsal vagal and phrenic nuclei, and medullary nuclei that regulate respiration; nuclei that control pharyngeal, facial, and tongue movements coordinate the initiation of emesis. The neurotransmitters involved in this coordination are uncertain; however, roles for neurokinin NK₁, serotonin, and vasopressin pathways are postulated.

Somatic and visceral muscles exhibit stereotypic responses during emesis. Inspiratory thoracic and abdominal wall muscles contract, producing high intrathoracic and intraabdominal pressures that facilitate expulsion of gastric contents. The gastric cardia herniates across the diaphragm, and the larynx moves upward to promote oral propulsion of the vomitus. Under normal conditions, distally migrating gut contractions are regulated by an electrical phenomenon, the slow wave, which cycles at 3 cycles/min in the stomach and 11 cycles/min in the duodenum. With emesis, slow waves are replaced by orally propagating spike activity, which induces retrograde contractions that assist in the oral expulsion of small-intestinal contents.

**Activators of Emesis**  
Emetic stimuli act at several anatomic sites. Emesis provoked by noxious thoughts or smells originates in the cerebral cortex, whereas cranial nerves mediate vomiting after gag reflex activation. Motion sickness and inner ear disorders act on the labyrinthine apparatus, while gastric irritants and emetogenic anticancer agents such as cisplatin stimulate gastroduodenal vagal afferent nerves. Nongastric visceral afferents are activated by small intestinal and colonic obstruction and mesenteric ischemia. The area postrema, a medullary nucleus, responds to bloodborne emetic stimuli and is termed the chemoreceptor trigger zone. Many emetic drugs act on the area postrema as do bacterial toxins and metabolic disorders such as uremia, hypoxia, and ketoacidosis.

Neurotransmitters that mediate induction of vomiting are selective for these anatomic sites. Labyrinthine disorders stimulate vestibular cholinergic muscarinic M₁ and histaminergic H₁ receptors, whereas gastroduodenal vagal afferent stimuli activate serotonin 5-HT₁ receptors. The area postrema is richly served by nerve fibers acting on 5-HT₁, M₁, H₁, and dopamine D₂ receptor subtypes. Optimal pharmacologic management requires an understanding of these pathways.

**Differential Diagnosis**  
Nausea and vomiting are caused by conditions within and outside the gut as well as by drugs and circulating toxins (Table 34-1).

**Intraperitoneal Disorders**  
Visceral obstruction and inflammation of hollow and solid viscera may produce vomiting as the main symptom. Gastric obstruction results from ulcer disease and malignancy, whereas small-bowel and colonic obstructions occur as a consequence of adhesions, benign or malignant tumors, volvulus, intussusception, or inflammatory diseases such as Crohn’s disease. The superior mesenteric artery syndrome, occurring after weight loss or prolonged bed rest, results when the duodenum is compressed by the overlying superior mesenteric artery. Abdominal irradiation impairs intestinal contractile function and induces strictures. Biliary colic causes nausea by action...
on visceral afferent nerves. Vomiting with pancreatitis, cholecystitis, and appendicitis is due to localized visceral irritation and induction of ileus. Enteric infections with viruses or bacteria such as *Staphylococcus aureus* and *Bacillus cereus* are among the most common causes of acute vomiting, especially in children. Opportunistic infections such as cytomegalovirus or herpes simplex induce emesis in immunocompromised individuals.

Disordered gut motor function also commonly causes nausea and vomiting. *Gastroparesis* is defined as a delay in emptying of food from the stomach and occurs after vagotomy for peptic ulcer; with pancreatic adenocarcinoma; with mesenteric vascular insufficiency; or in systemic diseases such as diabetes, scleroderma, and amyloidosis. Idiopathic gastroparesis occurring in the absence of systemic illness may follow a viral prodrome suggesting an infectious etiology. *Intestinal pseudoobstruction* is characterized by disrupted intestinal and colonic motor activity and leads to intestinal retention of food residue and secretions; bacterial overgrowth; nutrient malabsorption; and symptoms of nausea, vomiting, bloating, pain, and altered defecation. Intestinal pseudoobstruction may be idiopathic, inherited as a familial visceral myopathy or neuropathy, or result from systemic disease or as a paraneoplastic consequence of malignancy (especially small-cell lung carcinoma). Patients with functional dyspepsia and irritable bowel syndrome may report prominent nausea and vomiting, as do some individuals with gastroesophageal reflux.

**Extraperitoneal Disorders** Myocardial infarction and congestive heart failure are cardiac causes of nausea and vomiting. Emesis occurs after 25% of surgical operations, most commonly laparotomy and orthopedic surgery, and is more prevalent in women. Increased intracranial pressure from tumors, bleeding, abscess, or obstruction to cerebral spinal fluid outflow produces prominent vomiting with or without nausea. Motion sickness, labyrinthitis, and Ménière’s disease evoke symptoms via labyrinthine pathways. Cyclic vomiting syndrome is a rare disorder of unknown etiology that produces episodes of intractable nausea and vomiting, usually in children. The syndrome shows a strong association with migraine headaches, suggesting that some cases may be migraine variants. Patients with psychiatric illnesses, including anorexia nervosa, bulimia, anxiety, and depression, may report significant nausea. Psychogenic vomiting occurs most commonly in women with other emotional problems.

**Medications and Metabolic Disorders** Drugs evoke vomiting by action on the stomach (analogesics, erythromycin) or area postrema (digoxin, opiates, anti-parkinsonian drugs). Emetogenic agents include antibiotics, antiarrhythmics, antihypertensives, oral hypoglycemics, and contraceptives. Cancer chemotherapy causes vomiting that is acute (within hours of administration), delayed (after 1 or more days), or anticipatory. Acute emesis resulting from highly emetogenic agents such as cisplatin is mediated by 5-HT₁ pathways, whereas delayed emesis is 5-HT₃ independent. Anticipatory nausea often responds better to anxiolytic therapy than to antiemetics. Metabolic disorders elicit nausea and vomiting in certain settings. Pregnancy is the most prevalent endocrinologic cause of nausea, occurring in 70% of women in the first trimester. Hyperemesis gravidarum is a severe form of nausea of pregnancy that can produce significant fluid loss and electrolyte disturbances. Uremia, ketoacidosis, adrenal insufficiency, as well as parathyroid and thyroid disease are other metabolic causes of emesis.

Cirulating toxins evoke symptoms through effects on the area postrema. Endogenous toxins are generated in fulminant liver failure, whereas exogenous enterotoxins may be produced by enteric bacterial infection. Ethanol intoxication is a common toxic cause of nausea and vomiting.

### Approach to the Patient

**History and Physical Examination** The history helps define the etiology of unexplained nausea and vomiting. Drugs, toxins, and gastrointestinal infections often cause acute symptoms, while established illnesses evoke chronic complaints. Pyloric obstruction and gastroparesis produce vomiting within 1 h of eating, whereas emesis from intestinal obstruction occurs later. In severe cases of gastroparesis, the vomitus may contain food residue ingested hours or days previously. Hematemesis raises suspicion of an ulcer or malignancy or a Mallory-Weiss tear, whereas feculent emesis is noted with distal intestinal or colonic obstruction. Bilius vomiting excludes gastric obstruction, whereas emesis of undigested food is consistent with a Zenker’s diverticulum or achalasia. Relief of abdominal pain by emesis characterizes small-bowel obstruction, but vomiting has no effect on pancreatitis or cholecystitis pain. Pronounced weight loss raises concern about malignancy or obstruction. Fevers suggest inflammation, while an intracranial source is considered if there are headaches or visual field changes. Vertigo or tinnitus indicates labyrinthine disease.

The physical examination complements the history. Orthostatic hypotension and poor skin turgor suggest intravascular fluid depletion. Pulmonary abnormalities raise concern that vomitus was aspirated. Abdominal auscultation may reveal absent bowel sounds with ileus. High-pitched rushes suggest bowel obstruction, while a succession splash on abrupt lateral movement of the patient is consistent with a Zenker’s diverticulum or achalasia. Relief of abdominal pain by emesis characterizes small-bowel obstruction, but vomiting has no effect on pancreatitis or cholecystitis pain. Pronounced weight loss raises concern about malignancy or obstruction. Fevers suggest inflammation, while an intracranial source is considered if there are headaches or visual field changes. Vertigo or tinnitus indicates labyrinthine disease.

**Diagnostic Testing** With intractable symptoms or an elusive diagnosis, selected diagnostic tests can direct clinical management. Electrolyte replenishment is indicated for hypokalemia or metabolic alkalosis. Detection of iron-deficiency anemia mandates a search for mucosal injury. Pancreaticobiliary disease is suggested by abnormal pancreatic enzymes or liver biochemistries, whereas endocrinologic, rheumatologic, or paraneoplastic etiologies are di-
agnosed by specific hormone or serologic testing. If luminal obstruction is suspected, supine and upright abdominal radiographs may show intestinal air-fluid levels with reduced colonic air. Ileus is characterized by diffusely dilated air-filled bowel loops.

Anatomic studies may be indicated if initial testing is nondiagnostic. Upper endoscopy detects ulcer or malignancy, and small-bowel barium radiography diagnoses partial small-bowel obstruction. Colonoscopy or contrast barium enema can detect colonic obstruction. Abdominal ultrasound or computed tomography (CT) defines intraperitoneal inflammatory processes, while CT or magnetic resonance imaging (MRI) of the head can delineate intracranial sources of nausea and vomiting. Mesenteric angiography or MRI is useful when ischemia is considered.

Gastrointestinal motility testing may detect a motor disorder that contributes to symptoms when anatomic abnormalities are absent. Gastroparesis is most commonly diagnosed with gastric scintigraphy, by which emptying of a radiolabeled meal is measured. Electrogastrography, a noninvasive method to test gastric slow-wave activity using cutaneous electrodes placed over the stomach, has been proposed as an alternative means of diagnosing gastroparesis. The diagnosis of intestinal pseudoobstruction is suggested by abnormal barium transit on small-bowel contrast radiography. Small-intestinal manometry may provide confirmation of the diagnosis and further characterize the motor abnormality as neuropathic or myopathic based on contractile patterns. Such investigation can obviate the need for open intestinal biopsy to evaluate for smooth-muscle or neuronal degeneration.

### TREATMENT

**General Principles** Therapy of vomiting is tailored to correction of medically or surgically remediable abnormalities, if possible. Hospitalization is considered for severe dehydration, especially if oral fluid replenishment cannot be sustained. Once oral intake is tolerated, nutrients are restarted with liquids that are low in fat, as lipids delay gastric emptying. Foods high in indigestible residues are avoided because these also prolong gastric retention.

**Antiemetic Medications** The most commonly used antiemetics act on the central nervous system (Table 34-2). Antihistamines such as meclizine and dimenhydrinate and anticholinergic drugs such as scopolamine act on labyrinthine-activated pathways and are useful in motion sickness and inner ear disorders. Phenothiazine and butyrophenone dopamine D₂ antagonists are used to treat emesis evoked by area postrema stimuli and are effective for medication, toxic, and metabolic etiologies. Dopamine antagonists freely cross the blood-brain barrier and may cause anxiety, dystonic reactions, hyperprolactinemic effects (galactorrhea and sexual dysfunction), and irreversible tardive dyskinesia.

Other drug classes have antiemetic properties. Serotonin 5-HT₃ antagonists such as ondansetron and granisetron are useful in the treatment of postoperative vomiting, after radiation therapy, and in the prevention of cancer chemotherapy–induced emesis. The usefulness of 5-HT₃ antagonists for other causes of emesis is less well established. Low-dose tricyclic antidepressants provide symptomatic benefit in patients with unexplained nausea of a functional nature, as well as in diabetic patients with nausea and vomiting whose disease is of long standing.

**Gastrointestinal Motor Stimulants** Drugs that stimulate gastric emptying are indicated for gastroparesis (Table 34-2). Metoclopramide, a combined 5-HT₄ agonist and D₂ antagonist, is effective in gastroparesis, but antidopaminergic side effects limit its use in 20% of patients. Erythromycin, a macrolide antibiotic, potently increases gastroduodenal motility by action on receptors for motilin, an endogenous stimulant of fasting motor activity. Intravenous erythromycin is useful in patients with refractory gastroparesis; however, oral forms of the drug also have some effect. Domperidone, a D₂ antagonist not available in the United States, has prokinetic and antiemetic effects but does not cross into most other brain regions; thus, anxiety and dystonic reactions are rare. The main side effects of domperidone are induction of hyperprolactinemia through effects on pituitary regions served by a porous blood-brain barrier.

Patients with refractory upper gut motility disorders pose significant challenges. Liquid suspensions of prokinetic drugs may be beneficial as liquids empty from the stomach more rapidly than pills. Metoclopramide can be administered subcutaneously in patients who do not respond to oral drugs. Intestinal pseudoobstruction may respond to the somatostatin analogue octreotide, which induces propagative small-intestinal motor complexes. Pyloric injections of botulinum toxin are reported in uncontrolled studies to benefit patients with idiopathic or diabetic gastroparesis. Placement of a feeding jejunostomy reduces hospitalizations and improves overall health in some patients with gastroparesis who do not respond to drug therapy. Surgical options are limited for refractory cases, but postvagotomy gastroparesis may improve with near-total resection of the stomach. Implanted gastroelectric pacemakers and neurostimulators may reduce symptoms, improve quality-of-life, and decrease health care expenditures in patients with medication-refractory gastroparesis.

**Selected Clinical Settings** Cancer chemotherapeutic agents such as cisplatin are intensely emetogenic. Given prophylactically, 5-HT₃ antag-
MECHANISMS

The most common causes of indigestion are gastroesophageal acid reflux and functional dyspepsia. Other cases are a consequence of a more serious organic illness.

Gastroesophageal Acid Reflux

Acid reflux can result from a variety of physiologic defects. Reduced lower esophageal sphincter (LES) tone is an important cause of reflux in scleroderma and pregnancy and may also be a factor in patients without other systemic conditions. Many individuals show frequent transient LES relaxations, during which acid bathes the esophagus. Overeating and aerophagia can transiently override the barrier function of the LES, whereas impaired esophageal body motility and reduced salivary secretion prolong acid exposure. The role of hiatal hernias is controversial—although most reflux patients exhibit hiatal hernias, most individuals with hiatal hernias do not have excess heartburn.

Gastric Motor Dysfunction

Disturbed gastric motility is purported to cause acid reflux in some cases of indigestion. Delayed gastric emptying also is found in 25 to 50% of functional dyspeptics. The relation of these defects to symptom induction is uncertain; many studies show poor correlation between symptom severity and the degree of motor dysfunction. Abnormal gastric fundic relaxation after eating may cause selected dyspeptic symptoms such as bloating, fullness, nausea, and early satiety. A current focus of investigation is developing drugs that enhance fundic relaxation.

Visceral Afferent Hypersensitivity

Disturbed gastric sensory function may also cause functional dyspepsia. Visceral afferent hypersensitivity was first demonstrated in patients with irritable bowel syndrome who had heightened perception of rectal balloon inflation without changes in rectal compliance. Patients with dyspepsia may experience discomfort with fundic distention to lower pressures than healthy control subjects.

Other Factors

Helicobacter pylori has a clear etiologic role in peptic ulcer disease, but ulcers cause only a minority of cases of dyspepsia. The importance of H. pylori in the genesis of functional dyspepsia is controversial, but most investigators believe it is of minor importance. In contrast, functional dyspepsia is associated with a reduced sense of physical and mental well-being and is exacerbated by stress, suggesting an important role for psychological factors. Analgesics cause dyspepsia; nitrates, calcium channel blockers, theophylline, and proges-
terone promote acid reflux. Other exogenous factors that induce acid reflux include ethanol, tobacco, and caffeine via LES relaxation. Genetic factors may contribute to development of acid reflux.

DIFFERENTIAL DIAGNOSIS

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is prevalent in Western society. Heartburn is reported once monthly by 40% of Americans and daily by 7 to 10%. Most cases of heartburn occur because of excess acid reflux; however, some patients exhibit heightened sensitivity to normal amounts of acid exposure.

Functional Dyspepsia

Functional dyspepsia, defined as ≥3 months of dyspepsia without an organic cause, is also common. Nearly 25% of the populace has abdominal discomfort at least six times yearly, but only 10 to 20% consult physicians. Functional dyspepsia accounts for 60% of cases of dyspepsia. Most patients with functional dyspepsia follow a benign course, but a small number with H. pylori infection or on nonsteroidal anti-inflammatory drugs (NSAIDs) progress to ulcer formation. As with idiopathic gastroparesis, some cases of functional dyspepsia appear to result from prior gastrointestinal infection.

Ulcer Disease

In most cases of GERD, the esophagus is not damaged. However, 5% of patients develop esophageal ulcers, and some form strictures. Symptoms do not reliably distinguish erosive or ulcerative esophagitis. From 15 to 25% of cases of dyspepsia stem from ulcers of the stomach or duodenum. The most common causes of ulcer disease are gastric infection with H. pylori and use of NSAIDs. Other rare causes of gastroduodenal ulcer include Crohn's disease and Zollinger-Ellison syndrome, a condition resulting from gastrin overproduction by an endocrine tumor (Chap. 274).

Malignancy

Dyspeptic patients often seek care because of fear of cancer. However, <2% of cases result from gastroesophageal malignancy. Esophageal squamous cell carcinoma occurs most often in those patients with histories of tobacco or ethanol intake. Other risk factors include prior caustic ingestion, achalasia, and the hereditary disorder tylosis. Esophageal adenocarcinoma usually complicates long-standing acid reflux. Between 8 and 20% of GERD patients exhibit glandular mucosal (intestinal) metaplasia of the squamous epithelium in the lower esophagus, termed Barrett's metaplasia. This condition predisposes to esophageal adenocarcinoma. Gastric malignancies include adenocarcinoma, which is more prevalent in certain Asian societies, and lymphoma (Chap. 77).

Other Causes

Alkaline reflux esophagitis produces GERD-like symptoms in patients who have had surgery for peptic ulcer disease. Opportunistic fungal or viral esophageal infections may produce heartburn or chest discomfort but more often cause odynophagia. Biliary colic is in the differential diagnosis of dyspepsia, but most patients with true biliary colic report discrete episodes of right upper quadrant or epigastric pain rather than chronic burning discomfort, nausea, and bloating. Intestinal lactase deficiency produces gas, bloating, discomfort, and diarrhea after lactose ingestion; it occurs in 15% of Caucasians of northern European descent but is more common in African Americans and Asians. Other carbohydrate intolerance syndromes (e.g., fructose, sorbitol) produce similar symptoms. Pancreatic disease (chronic pancreatitis and malignancy), hepatocellular carcinoma, celiac sprue, Ménétrier’s disease, infiltrative diseases (sarcoidosis and eosinophilic gastroenteritis), mesenteric ischemia, thyroid and parathyroid disease, and abdominal wall strain cause dyspepsia. Extra-peritoneal etiologies of indigestion include congestive heart failure and tuberculosis.

APPROACH TO THE PATIENT

History and Physical Examination

GERD classically produces heartburn, a substernal warmth beginning in the epigastrium that moves toward the neck. Heartburn is often exacerbated by meals and may awaken the patient. Associated symptoms include regurgitation of acid and water brash, the reflex release of salty salivary secretions.
into the mouth. Atypical symptoms include pharyngitis, asthma, cough, bronchitis, hoarseness, and chest pain that mimics angina. Some patients with acid reflux on esophageal pH testing do not report heartburn and instead note abdominal pain or other symptoms.

Some individuals with dyspepsia report ulcer-like symptoms including epigastric gnawing or burning that is relieved by meals or acid suppression. Others experience dysmotility-like fullness or pain that is aggravated by eating and associated with nausea, eructation, and early satiety. There is overlap of functional dyspepsia with other functional disorders such as irritable bowel syndrome.

The physical examination of individuals with GERD and functional dyspepsia is usually normal. In atypical GERD, pharyngeal erythema and wheezing may be present. Poor dentition may occur with prolonged acid regurgitation. Patients with functional dyspepsia may have epigastric tenderness or abdominal distention.

Discrimination between functional and organic causes of indigestion mandates exclusion of selected historic and examination features. Odynophagia suggests esophageal infection; dysphagia promotes concern about a benign or malignant esophageal blockage. Other features that raise alarm include unexplained weight loss, recurrent vomiting, occult or gross gastrointestinal bleeding, jaundice, and a palpable mass or adenopathy.

**Diagnostic Testing** Because indigestion is prevalent and because most cases result from GERD or functional dyspepsia, a general principle of diagnostic testing is to perform only limited and directed testing of selected individuals.

Once alarm factors are excluded, patients with typical GERD do not need further evaluation and are treated empirically. Upper endoscopy is indicated to exclude mucosal injury in patients with atypical symptoms, symptoms unresponsive to acid-suppressing drugs, or alarm factors. For heartburn >5 years in duration, especially in patients >50 years old, endoscopy is recommended by some experts to screen for Barrett’s metaplasia. However, the benefits of this approach have not been validated in controlled studies. Ambulatory esophageal pH testing is considered for drug-refractory symptoms and atypical symptoms such as unexplained chest pain. Esophageal manometry is most commonly ordered when surgical treatment of GERD is considered. A low LES pressure may predict failure with drug therapy and identify patients who may require surgery. Demonstration of disordered esophageal body peristalsis may affect the decision to operate or modify the type of operation chosen. Manometry with provocative testing may clarify the diagnosis in patients with atypical symptoms. Blinded perfusion of saline then acid into the esophagus, known as the Bernstein test, can delineate whether unexplained chest discomfort results from acid reflux.

Upper endoscopy is performed as the initial diagnostic test in patients with unexplained dyspepsia who are >45 years old, have alarm factors, or are on NSAIDs because of the elevated risk of malignancy and ulcer in these groups. For younger patients without alarm factors not on NSAIDs, the “test and treat” approach is commonly applied. Determination of *H. pylori* status is made with urea breath testing, stool antigen measurement, or blood serology testing. Those who are *H. pylori* positive are treated to eradicate the infection. For those with negative tests, an acid suppressive regi- men is offered empirically. If symptoms resolve on these regimens, no further intervention is required. Endoscopy is reserved for those who fail to respond to treatment of *H. pylori*—positive or –negative dyspepsia. Some clinicians advocate an alternative approach in which those with *H. pylori* undergo endoscopy before treatment. Eradication therapy is then offered only to those with proven ulcer disease. This approach may be preferred where gastric cancer is prevalent and endoscopy less costly. Further testing is indicated if other factors are present. If bleeding is reported, a blood count is obtained to exclude anemia. Thyroid chemistries or calcium levels are done to screen for metabolic disease. For suspected pancreaticobiliary causes, pancreatic and liver chemistry are obtained. If abnormalities are found, abdominal ultrasound or CT may give important information. Gastric emptying scintigraphy is considered for patients with dysmotility-like dyspepsia when drug treatment fails. Hydrogen breath testing after lactose ingestion may be performed for suspected lactase deficiency.

**Rx TREATMENT**

**General Principles** In mild indigestion, reassurance that a careful evaluation revealed no serious organic disease may be the only intervention required. Drugs that cause acid reflex or dyspepsia should be stopped if possible. Patients with GERD should limit ethanol, caffeine, chocolate, and tobacco use because of their effects on the LES. Other measures in GERD include ingestion of a low-fat diet, avoidance of snacks before bedtime, and elevation of the head of the bed.

Specific therapies for organic disease should be offered when possible. Surgery is appropriate in biliary colic, while diet changes are indicated for lactase deficiency and celiac sprue. Some illnesses such as peptic ulcer disease may be cured by specific medical regimens. However, as most indigestion is caused by GERD or functional dyspepsia, medications that reduce gastric acid, stimulate motility, or blunt gastric sensitivity are indicated.

**Acid Suppressing or Neutralizing Medications** Drugs that reduce or neutralize gastric acid are the most prescribed agents for GERD. Histamine H2 receptor antagonists such as cimetidine, ranitidine, famotidine, and nizatidine are useful in mild to moderate GERD. For uncomplicated heartburn, H2 receptor antagonists are given for 4 weeks before considering endoscopy. For severe symptoms or for many cases of erosive or ulcerative esophagitis, proton pump inhibitors such as omeprazole, lansoprazole, rabeprazole, pantoprazole, or esomeprazole are needed. These drugs, which inhibit gastric H+·K+ ATPase, are more potent than H2 receptor antagonists. Acid suppressants may be taken continuously or as needed, depending on symptom severity. Many patients initially started on a proton pump inhibitor can be stepped down to an H2 antagonist. The role of combined therapy with a proton pump inhibitor and an H2 antagonist is undefined. Liquid antacids are useful for short-term control of mild GERD but are less effective for severe disease unless given at high doses that produce side effects (diarrhea with magnesium-containing agents and constipation with aluminum-containing agents). Sucralfate is a salt of aluminum hydroxide and sucrose octasulfate and buffers acid and binds peptic acid and bile salts. Its efficacy in GERD and functional dyspepsia is unproven.

Acid-suppressing drugs are advocated for first-line therapy of *H. pylori*—negative dyspepsia, especially with ulcer-like symptoms. Ranitidine is of benefit in the treatment of functional dyspepsia versus placebo. In young patients without alarm symptoms, a 4-week trial of an H2 receptor antagonist or proton pump inhibitor is given. Endoscopy is performed only if symptoms do not improve.

**Helicobacter pylori Eradication** *H. pylori* eradication is indicated only for peptic ulcer and gastric mucosa–associated lymphoid tissue lymphoma. The usefulness of *H. pylori* eradication in patients with functional dyspepsia is unproven, but evidence suggests that <15% of cases relate to *H. pylori*. Patients with ulcer-like symptoms may respond. *H. pylori* eradication is not useful in the treatment of GERD; some reports suggest that elimination of the organism increases the risk of developing GERD and others show no effect. Several drug combinations show efficacy; most include 10 to 14 days of a proton pump inhibitor or bismuth subsalicylate in concert with two antibiotics.

**Gastrointestinal Motor Stimulants** Motor stimulants such as metoclopramide, erythromycin, and domperidone have limited utility in GERD.
The γ-aminobutyric acid B (GABA-B) agonist baclofen reduces esophageal acid exposure by inhibiting transient LES relaxations; the clinical role of the drug is being studied. Domperidone may be useful in functional dyspepsia and may be given instead of acid suppressants as initial empirical therapy of young patients without alarm symptoms and without H. pylori infection. Patients with dysmotility-like dyspepsia may respond preferentially to motor-stimulating drugs.

**Other Options**

Antireflux surgery may be offered to GERD patients with poorly controlled symptoms, disease complications, or unbearable life-style impairments. Fundoplication can be performed laparoscopically; the Nissen and Toupet procedures involve wrapping the proximal stomach around the LES to increase LES pressure. Dysphagia may be a long-term complication of these procedures. Endoscopic interventions at the gastroesophageal junction including radiofrequency energy delivery, suturing, biopolymer implantation, and gas- troplasty have been used in refractory GERD; their efficacy is being assessed.

Some patients with functional dyspepsia are refractory to acid suppressants or prokinetic drugs but may respond to low-dose tricyclic antidepressant therapy. The mechanism of action in functional dyspepsia is unknown but may involve blunting of visceral pain processing in the brain. Gas and bloating may be the most troubling symptoms in some patients with indigestion and can be difficult to treat. Dietary exclusion of gas-producing foods such as legumes and use of simethicone or activated charcoal benefit some patients. Psychological treatments may be offered for refractory functional dyspepsia, but no convincing data suggest efficacy.

**FURTHER READING**

**DIARRHEA AND CONSTIPATION**

**David A. Ahlquist, Michael Camilleri**

Diarrhea and constipation are exceedingly common and together exact an enormous toll in terms of morbidity, loss of work productivity, and consumption of medical resources. Worldwide, more than 1 billion people suffer one or more episodes of acute diarrhea each year. Among the 100 million persons affected annually by acute diarrhea in the United States, nearly half must restrict activities, 10% consult physi- cians, 250,000 require hospitalization, and roughly 3000 die (primarily the elderly). The annual economic burden to society is estimated at >$20 billion. Because of poor sanitation and more limited access to health care, acute infectious diarrhea remains one of the most common causes of mortality in developing countries, particularly among children, accounting for 5 to 8 million deaths per year. Population statistics on chronic diarrhea and constipation are more uncertain, perhaps due to variable definitions and reporting, but the frequency of these conditions is also high. Based on United States population surveys, prev- alence rates for chronic diarrhea range from 2 to 7% and for chronic constipation from 3 to 17%. Diarrhea and constipation are among the most common patient complaints faced by internists and primary care physicians, and they account for nearly 50% of referrals to gastroen- terologists.

Although diarrhea and constipation may present as mere nuisance symptoms at one extreme, they can be severe or life-threatening at the other. Even mild symptoms may signal a serious underlying gastro- intestinal lesion, such as colorectal cancer, or systemic disorder, such as thyroid disease. Given the heterogeneous causes and potential se- verity of these common complaints, it is imperative for clinicians to appreciate the pathophysiology, etiologic classification, diagnostic strategies, and therapeutic principles of diarrhea and constipation so that rational and cost-effective care can be delivered.

**NORMAL PHYSIOLOGY**

The human small intestine and colon perform important functions includ- ing the secretion and absorption of water and electrolytes, the storage and subsequent transport of intraluminal contents aborally, and the salvage of some nutrients after bacterial metabolism of carbohy- drate that are not absorbed in the small intestine. The main motor functions are summarized in Table 35-1. Alterations in fluid and electrolyte handling contribute significantly to diarrhea. Alterations in mo-
to the brain along the lateral spinothalamic tract and the nociceptive dorsal column pathway and are then perceived. Other afferent fibers synapse in the prevertebral ganglia and reflexly modulate intestinal motility.

**INTESTINAL FLUID ABSORPTION AND SECRETION** On an average day, 9 L of fluid enters the gastrointestinal tract; approximately 1 L of residual fluid reaches the colon; the stool excretion of fluid constitutes about 0.2 L/d. The colon has a large capacitance and functional reserve and may recover up to four times its usual volume of 0.8 L/d, provided the rate of flow permits reabsorption to occur. Thus, the colon can partially compensate for intestinal absorptive or secretory disorders.

In the colon, sodium absorption is predominantly electrogenic, and uptake takes place at the apical membrane; it is compensated for by the export functions of the basolateral sodium pump. A variety of neural and non-neural mediators regulate colonic fluid and electrolyte balance, including cholinergic, adrenergic, and serotonergic mediators. Angiotensin and aldosterone also influence colonic absorption, reflecting the common embryologic development of the distal colonic epithelium and the renal tubules.

**SMALL INTESTINAL MOTILITY** During fasting, the motility of the small intestine is characterized by a cyclical event called the migrating motor complex (MMC), which serves to clear nondigestible residue from the small intestine. This organized, propagated series of contractions lasts on average 4 min, occurs every 60 to 90 min, and usually involves the entire small intestine. After food ingestion, the small intestine produces irregular, mixing contractions of relatively low amplitude, except in the distal ileum where more powerful contractions occur intermittently and empty the ileum by bolus transfers.

**ILEOCOLONIC STORAGE AND SALVAGE** The distal ileum acts as a reservoir, emptying intermittently by bolus movements. This action allows time for salvage of fluids, electrolytes, and nutrients. Segmentation by haustra compartmentalizes the colon and facilitates mixing, retention of residue, and formation of solid stools. In health, the ascending and transverse regions of colon function as reservoirs (average transit, 15 h), and the descending colon acts as a conduit (average transit, 3 h). The colon is efficient at conserving sodium and water, a function that is particularly important in sodium-depleted patients in whom the small intestine alone is unable to maintain sodium balance. Diarrhea or constipation may result from alteration in the reservoir function of the small intestine is characterized by an acyclic event called the migrating motor complex (MMC), which serves to clear nondigestible residue from the small intestine. This organized, propagated series of contractions lasts on average 4 min, occurs every 60 to 90 min, and usually involves the entire small intestine. After food ingestion, the small intestine produces irregular, mixing contractions of relatively low amplitude, except in the distal ileum where more powerful contractions occur intermittently and empty the ileum by bolus transfers.

**COLONIC MOTILITY AFTER MEAL INGESTION** After meal ingestion, colonic phasic and tonic contractility increase for a period of approximately 2 h. The initial phase (about 10 min) is mediated by the vagus nerve in response to mechanical distention of the stomach. The subsequent response of the colon requires caloric stimulation and is at least in part mediated by hormones, e.g., gastrin and serotonin.

**DEFECATION** Tonic contraction of the puborectalis muscle, which forms a sling around the rectoanal junction, is important to maintain continence; during defecation, sacral parasympathetic nerves relax this muscle, facilitating the straightening of the rectoanal angle (Fig. 35-1). Distention of the rectum results in transient relaxation of the internal anal sphincter via intrinsic and reflex sympathetic innervation. As sigmoid and rectal contractions increase the pressure within the rectum, the rectosigmoid angle opens by >15°. Voluntary relaxation of the external anal sphincter (striated muscle innervated by the pudendal nerve) permits the evacuation of feces; this evacuation process can be augmented by an increase in intraabdominal pressure created by the Valsalva maneuver.

**DIARRHEA**

**DEFINITION** Diarrhea is loosely defined as passage of abnormally liquid or unformed stools at an increased frequency. For adults on a typical Western diet, stool weight >200 g/d can generally be considered diarrheal. Because of the fundamental importance of duration to diagnostic considerations, diarrhea may be further defined as acute if <2 weeks, persistent if 2 to 4 weeks, and chronic if >4 weeks in duration.

Two common conditions, usually associated with the passage of stool totaling <200 g/d, must be distinguished from diarrhea, as diagnostic and therapeutic algorithms differ. Pseudodiarrhea, or the frequent passage of small volumes of stool, is often associated with rectal urgency and accompanies the irritable bowel syndrome or anorectal disorders such as proctitis. Fecal incontinence is the involuntary discharge of rectal contents and is most often caused by neuromuscular disorders or structural anorectal problems. Diarrhea and urgency, especially if severe, may aggravate or cause incontinence. Pseudodiarrhea and fecal incontinence occur at prevalence rates comparable to or higher than that of chronic diarrhea and should always be considered in patients complaining of “diarrhea.” A careful history and physical examination generally allow these conditions to be discriminated from true diarrhea.

**ACUTE DIARRHEA** More than 90% of cases of acute diarrhea are caused by infectious agents; these cases are often accompanied by vomiting, fever, and abdominal pain. The remaining 10% or so are caused by medications, toxic ingestions, ischemia, and other conditions.

**Infectious Agents** Most infectious diarrheas are acquired by fecal-oral transmission via direct personal contact or, more commonly, via ingestion of food or water contaminated with pathogens from human or animal feces. In the immunologically competent person, the resident fecal microflora, containing >500 taxonomically distinct species, are rarely the source of diarrhea and may actually play a role in suppressing the growth of ingested pathogens. Acute infection or injury occurs when the ingested agent overwhelms the host’s mucosal immune and nonimmune (gastric acid, digestive enzymes, mucus secretion, peristalsis, and suppressive resident flora) defenses. Established clinical associations with specific enteropathogens may offer diagnostic clues.

In the United States, high risk groups are recognized:

1. **Travelers.** Nearly 40% of tourists to endemic regions of Latin America, Africa, and Asia develop so-called traveler’s diarrhea, most commonly due to enterotoxigenic *Escherichia coli* as well as to *Campylobacter*, *Shigella*, and *Salmonella*. Visitors to Russia (especially St. Petersburg) may have increased risk of *Giardia*-associated diarrhea; visitors to Nepal may acquire *Cyclospora*. Campers, backpackers, and swimmers in wilderness areas may become infected with *Giardia*.

2. **Consumers of certain foods.** Diarrhea closely following food consumption at a picnic, banquet, or restaurant may suggest infection with *Salmonella*, *Campylobacter*, or *Shigella* from chicken; enterohemorrhagic *E. coli* (O157:H7) from undercooked hamburger; *Bacillus cereus* from fried rice; *Staphylococcus aureus* or *Salmonella* from mayonnaise or cream; *Salmonella* from eggs; and *Vibrio* species, *Salmonella*, or acute hepatitis A or B from seafood, especially if raw.

3. **Immunodeficient persons.** Individuals at risk for diarrhea include those with primary immunodeficiency (e.g., IgA deficiency, common variable hypogammaglobulinemia, chronic granulomatous disease) or the much more common secondary immunodeficiency states (e.g., AIDS, senescence, pharmacologic suppression). Common enteropathogens often cause a more severe and protracted diarrheal illness, and, particularly in persons with AIDS, opportunistic infections, such as by *Mycobacterium* species, certain viruses (cytomegalovirus, adenovirus, and herpes simplex), and protozoa (*Cryptosporidium*, *Isospora belli*, *Microsporidia*, and *Blastocystis hominis*) may also play a role (Chap. 173). In patients with AIDS, agents transmitted venereally per rectum (e.g., Neisseria gonorrhoeae, Treponema pallidum, Chlamydia) may contribute to proctocolitis.

4. **Daycare participants and their family members.** Infections with *Shigella*, *Giardia*, *Cryptosporidium*, rotavirus, and other agents are very common and should be considered.

5. **Institutionalized persons.** Infectious diarrhea is one of the most frequent categories of nosocomial infections in many hospitals and long-term care facilities; the causes are a variety of microorganisms but most commonly *Clostridium difficile*.

The pathophysiology underlying acute diarrhea by infectious agents produces specific clinical features that may also be helpful in diagnosis (Table 35-2). Profuse watery diarrhea secondary to small bowel hypersecretion occurs with ingestion of preformed bacterial toxins, enterotoxin-producing bacteria, and enteroadherent pathogens. Diarrhea associated with marked vomiting and minimal or no fever may occur abruptly within a few hours after ingestion of the former two types; vomiting is usually less, and abdominal cramping or bloating is greater; fever is higher with the latter. Cytotoxin-producing and invasive microorganisms all cause high fever and abdominal pain. Invasive bacteria and *Entamoeba histolytica* often cause bloody diarrhea (referred to as dysentery). *Yersinia* invades the terminal ileal and proximal colon mucosa and may cause especially severe abdominal pain with tenderness mimicking acute appendicitis.

Finally, infectious diarrhea may be associated with systemic manifestations. Reiter’s syndrome (arthritis, urethritis, and conjunctivitis) may accompany or follow infections by *Salmonella*, *Campylobacter*, *Shigella*, and *Yersinia*. Yersiniosis may also lead to an autoimmune thyroiditis, pericarditis, and glomerulonephritis. Both enterohemorrhagic *E. coli* (O157:H7) and *Shigella* can lead to the hemolyticuremic syndrome with an attendant high mortality rate. Acute diarrhea can also be a major symptom of several systemic infections including viral hepatitis, listeriosis, legionellosis, and toxic shock syndrome.

**Other Causes** Side effects from medications are probably the most common noninfectious cause of acute diarrhea, and etiology may be suggested by a temporal association between use and symptom onset. Although innumerable medications may produce diarrhea, some of the more frequently incriminated include antibiotics, cardiac antiarrhythmic, antihypertensives, nonsteroidal anti-inflammatory drugs (NSAIDs), certain antidepressants, chemotherapy agents, bronchodilators, antacids, and laxatives. Occulsive or nonocclusive *ischemic colitis* typically occurs in persons >50 years, often presents as...
Acute lower abdominal pain preceding watery, then bloody diarrhea, and generally results in acute inflammatory changes in the sigmoid or left colon while sparing the rectum. Acute diarrhea may accompany colonic diverticulitis and graft-versus-host disease. Acute diarrhea, often associated with systemic compromise, can follow ingestion of toxins including organophosphate insecticides, amanita and other mushrooms, arsenic, and preformed environmental toxins in seafoods, such as ciguatera and scombroid. The conditions causing chronic diarrhea can also be confused with acute diarrhea early in their course. This confusion may occur with inflammatory bowel disease and some of the other inflammatory chronic diarrheas that may have an abrupt rather than insidious onset and exhibit features that mimic infection.

**APPROACH TO THE PATIENT**

The decision to evaluate acute diarrhea depends on its severity and duration and on various host factors (Fig. 35-2). Most episodes of acute diarrhea are mild and self-limited and do not justify the cost and potential morbidity of diagnostic or pharmacologic interventions. Indications for evaluation include profuse diarrhea with dehydration, grossly bloody stools, fever ≥38.5°C, duration >48 h without improvement, new community outbreaks, associated severe abdominal pain in patients >50 years, and elderly (≥70 years) or immunocompromised patients. In some cases of moderately severe febrile diarrhea associated with fecal leukocytes (or increased fecal levels of the leukocyte proteins) or gross blood, a diagnostic evaluation might be avoided in favor of an empirical antibiotic trial (see below).

The cornerstone of diagnosis in those suspected of severe acute infectious diarrhea is microbiologic analysis of the stool. Workup includes cultures for bacterial and viral pathogens, direct inspection for ova and parasites, and immunoassays for certain bacterial toxins (C. difficile), viral antigens (rotavirus), and protozoal antigens (Giardia, E. histolytica). The aforementioned clinical and epidemiologic associations may assist in focusing the evaluation. If a particular pathogen or set of possible pathogens is so implicated, then either the whole panel of routine studies may not be necessary or, in some instances, special cultures may be appropriate as for enterohemorrhagic and other types of E. coli, Vibrio species, and Yersinia. Molecular diagnosis of pathogens in stool can be made by identification of unique DNA sequences; and evolving microarray technologies could lead to a more rapid, sensitive, specific, and cost-effective diagnostic approach in the future.

Persistent diarrhea is commonly due to Giardia, but additional causative organisms that should be considered include C. difficile (especially if antibiotics had been administered), E. histolytica, Cryptosporidium, Campylobacter, and others. If stool studies are unrevealing, then flexible sigmoidoscopy with biopsies and upper endoscopy with duodenal aspirates and biopsies may be indicated.

Structural examination by sigmoidoscopy, colonoscopy, or abdominal computed tomographic scanning (or other imaging approaches) may be appropriate in patients with uncharacterized persistent diarrhea to exclude inflammatory bowel disease, or as an initial approach in patients with suspected noninfectious acute diarrhea such as might be caused by ischemic colitis, diverticulitis, or partial bowel obstruction.

**FIGURE 35-2** Algorithm for the management of acute diarrhea. Consider empirical Rx before evaluation with (*) metronidazole and (†) with quinolone.

**TREATMENT**

Fluid and electrolyte replacement are of central importance to all forms of acute diarrhea. Fluid replacement alone may suffice for mild cases. Oral sugar-electrolyte solutions (sport drinks or designed formulations) should be instituted promptly with severe diarrhea to limit dehydration, which is the major cause of death. Profoundly dehydrated patients, especially infants and the elderly, require intravenous rehydration.

In moderately severe nonfebrile and nonbloody diarrhea, antimotility antisecretory agents such as loperamide can be useful adjuncts to control symptoms. Such agents should be avoided with febrile dysentry, which may be exacerbated or prolonged by them. Bismuth subsalicylate may reduce symptoms of vomiting and diarrhea but should not be used to treat immunocompromised patients because of the risk of bismuth encephalopathy.

Judicious use of antibiotics is appropriate in selected instances of acute diarrhea and may reduce its severity and duration (Fig. 35-2). Many physicians treat moderately to severely ill patients with febrile dysentery empirically without diagnostic evaluation using a quinolone, such as ciprofloxacin (500 mg bid for 3 to 5 d). Empirical treatment can also be considered for suspected giardiasis with metronidazole (250 mg qid for 7 d). Selection of antibiotics and dosage regimens are otherwise dictated by specific pathogens and conditions found (Chaps. 113, 134, 137–143). Antibiotic coverage is indicated whether or not a causative organism is discovered in patients who are immunocompromised, have mechanical heart valves or recent vascular grafts, or are elderly. Antibiotic prophylaxis is indicated for certain patients traveling to high-risk countries in whom the likelihood or seriousness of acquired diarrhea would be especially high, including those with immunocompromise, inflammatory bowel disease, or gastric achlorhydria. Use of trimethoprim/sulfamethoxazole or ciprofloxacin may reduce bacterial diarrhea in such travelers by 90%.

**CHRONIC DIARRHEA**

Diarrhea lasting >4 weeks warrants evaluation to exclude serious underlying pathology. In contrast to acute diarrhea, most of the many causes of chronic diarrhea are noninfectious. The classification of chronic diarrhea by pathophysiological mechanism facilitates a rational approach to management (Table 35-3).

**Secretory Causes**

Secretory diarrheas are due to derangements in fluid and electrolyte transport across the enterocytic mucosa. They are char-

Osmotic causes
- Osmotic laxatives (Mg2+, PO43−, SO42−)
- Lactase and other disaccharide deficiencies
- Nonabsorbable carbohydrates (sorbitol, lactulose, polyethylene glycol)

Steatorrhea causes
- Intraluminal malabsorption
- Pancreatic exocrine insufficiency, bacterial overgrowth, liver disease
- Mucosal malabsorption (celiac sprue, Whipple’s disease, infections, abetalipoproteinemia, ischemia)
- Postmucosal obstruction (1st or 2nd lymphatic obstruction)

Medications
Side effects from regular ingestion of drugs and toxins are the most common secretory causes of chronic diarrhea. Hundreds of prescription and over-the-counter medications (see “Other Causes of Acute Diarrhea,” above) may produce unwarranted diarrhea. Spermutinous or habitual use of stimulant laxatives (e.g., senna, cascara, bisacodyl, ricinoleic acid [castor oil]) must also be considered. Chronic ethanol consumption may cause a secretory-type diarrhea due to enterocyte injury with impaired sodium and water absorption as well as rapid transit and other alterations. Inadvertent ingestion of certain environmental toxins (e.g., arsenic) may lead to chronic rather than acute forms of diarrhea. Certain bacterial infections may occasionally persist and be associated with a secretory-type diarrhea.

Bowel resection, mucosal disease, or enterocolic fistula
These conditions may result in a secretory-type diarrhea because of inadequate surface for resorption of secreted fluids and electrolytes. Unlike other secretory diarrheas, this subset of conditions tends to worsen with eating. With disease (e.g., Crohn’s ileitis) or resection of <100 cm of terminal ileum, dihydroxy bile acids may escape absorption and stimulate colonic secretion (choloreheic diarrhea). This mechanism may contribute to so-called idiopathic secretory diarrhea, in which bile acids are functionally malabsorbed from a normal-appearing terminal ileum. Partial bowel obstruction, ostomy stricture, or fecal impaction may paradoxically lead to increased fecal output due to hypersecretion.

Hormones
Although uncommon, the classic examples of secretory diarrhea are those mediated by hormones. Metastatic gastrointestinal carcinoid tumors or, rarely, primary bronchial carcinoids may produce watery diarrhea alone or as part of the carcinoid syndrome that comprises episodic flushing, wheezing, dyspnea, and right-sided valvular heart disease. Diarrhea is due to the release into the circulation of potent intestinal secretagogues including serotonin, histamine, prostaglandins, and various kinins. Pellagra-like skin lesions may rarely occur as the result of serotonin overproduction with niacin depletion. Gastrinoma, one of the most common neuroendocrine tumors, most typically presents with refractory peptic ulcers, but diarrhea occurs in up to one-third of cases and may be the only clinical manifestation in 10%. While various secretagogues released with gastrin may play a role, diarrhea most often results from fat malabsorption owing to pancreatic enzyme inactivation by low intraduodenal pH. The watery diarrhea hypokalemia achlorhydria syndrome, also called pancreatic cholera, is due to a non-beta cell pancreatic adenoma, referred to as a VIPoma, that secretes vasoactive intestinal peptide (VIP) and a host of other peptide hormones including pancreatic polypeptide, secretin, gastrin, gastrin-inhibitory polypeptide, neurotensin, calcitonin, and prostaglandins. The secretory diarrhea is often massive with stool volumes >3 L/d; daily volumes as high as 20 L have been reported. Life-threatening dehydration; neuromuscular dysfunction from associated hypokalemia, hypomagnesemia, or hypercalcemia; flushing; and hyperglycemia may accompany a VIPoma. Medullary carcinoma of the thyroid may present with watery diarrhea caused by calcitonin, other secretory peptides, or prostaglandins. This tumor occurs sporadically or, in 25 to 50% of cases, as a feature of multiple endocrine neoplasia type IIa with pheochromocytomas and hyperparathyroidism. Prominent hypokalemia is often associated with metastatic disease and poor prognosis. Systemic mastocytosis, which may be associated with the skin lesion urticaria pigmentosa, may cause diarrhea that is either secretory and mediated by histamine or inflammatory and due to intestinal filtration by mast cells. Large colorrectal villous adenomas may rarely be associated with a secretory diarrhea that may cause hypokalemia, which can be inhibited by NSAIDs, and is apparently mediated by prostaglandins.

Congenital Defects in Ion Absorption
Rarely, these defects cause watery diarrhea from birth and include defective Cl−/HCO3− exchange (congenital chloridorrhea) with alkalosis and defective Na+/H+ exchange with acidosis. Some hormone deficiencies may be associated with watery diarrhea, such as occurs with adrenocortical insufficiency (Addison’s disease) that may be accompanied by hyperpigmentation.

Osmotic Causes
Osmotic diarrhea occurs when ingested, poorly absorbable, osmotically active solutes draw enough fluid lumenward to exceed the resorptive capacity of the colon. Fecal water output increases in proportion to such a solute load. Osmotic diarrhea characteristically ceases with fasting or with discontinued oral intake of the offending agent.

Osmotic Laxatives
Ingestion of magnesium-containing antacids, health supplements, or laxatives may induce osmotic diarrhea typified by a stool osmotic gap: 2[Na+] + [K+] < 290 mOsm/kg. Anionic laxatives containing sulfates or phosphates produce osmotic diarrhea without an osmotic gap, as sodium accompanies the anionic solutes; direct measurement of stool sulfates and phosphates may be necessary to confirm the cause of diarrhea.

Carbohydrate Malabsorption
Carbohydrate malabsorption due to acquired or congenital defects in brush-border disaccharidases and other enzymes leads to osmotic diarrhea with a low pH. One of the most common causes of chronic diarrhea in adults is lactase deficiency, which affects three-fourths of non-Caucasians worldwide and 5 to 30% of persons in the United States; most learn to avoid milk products without an intervention. Some sugars, such as sorbitol, are universally malabsorbed, and diarrhea ensues with ingestion of ample medications, gum, or candies sweetened with these nonabsorbable sugars.
Lactulose, used to acidify stools in patients with hepatic failure, also causes diarrhea on this basis.

**Steatorrhea**

Fat malabsorption may lead to greasy, foul-smelling, difficult-to-flush diarrhea often associated with weight loss and nutritional deficiencies due to concomitant malabsorption of amino acids and vitamins. Increased fecal output is caused by the osmotic effects of fatty acids, especially after bacterial hydroxylation, and, to a lesser extent, by the burden of neutral fat. Quantitatively, steatorrhea is defined as stool fat exceeding the normal 7 g/d; daily fecal fat averages 15 to 25 g with small intestinal diseases and is often >40 g with pancreatic exocrine insufficiency. Intraluminal malabsorption, mucosal malabsorption, or lymphatic obstruction may produce steatorrhea.

**Intraluminal Malabsorption**

This condition most commonly results from pancreatic exocrine insufficiency, which occurs when >90% of pancreatic secretory function is lost. *Chronic pancreatitis*, usually a sequela of ethanol abuse, most frequently causes pancreatic insufficiency. Other causes include *cystic fibrosis*, pancreatic duct obstruction, and rarely, *somatostatinoma*. Bacterial overgrowth in the small intestine may deconjugate bile acids and alter micelle formation that impairs fat digestion; it occurs with stasis from a blind-loop, small bowel diverticulum or dysmotility and is especially likely in the elderly. Finally, cirrhosis or biliary obstruction may lead to mild steatorrhea due to deficient intraluminal bile acid concentration.

**Mucosal Malabsorption**

Mucosal malabsorption occurs from a variety of enteropathies but most prototypically and perhaps most commonly from celiac sprue. This gluten-sensitive enteropathy characterized by villous atrophy and crypt hyperplasia in the proximal small bowel often presents with fatty diarrhea associated with multiple nutritional deficiencies of varying severity and affects all ages. *Tropical sprue* may produce a similar histologic and clinical syndrome but occurs in residents of or travelers to tropical climates; its often abrupt onset and response to antibiotics suggest an infectious etiology. *Whipple’s disease*, due to the actinomycete *Trepornoma whipplei* and histiocytic infiltration of the small bowel mucosa, is a less common cause of steatorrhea that most typically occurs in young or middle-aged men; it is frequently associated with arthralgias, fever, lymphadenopathy, and extreme fatigue and may affect the central nervous system and endocardium. A similar clinical and histologic picture results from *Mycobacterium avium-intracellulare* infection in patients with AIDS.

**Abetalipoproteinemia**

This rare defect of chylomicron formation and fat malabsorption in children associated with acanthocytic erythrocytes, ataxia, and retinitis pigmentosa. Several other conditions may cause mucosal malabsorption including infections, especially with protozoa such as *Giardia*, numerous medications (e.g., colchicine, cholesterolamine, neomycin), and chronic ischemia.

**Postmucosal Lymphatic Obstruction**

The pathophysiology of this condition, which is due to the rare congenital intestinal lymphangiectasia or to acquired lymphatic obstruction secondary to trauma, tumor, or infection, leads to the unique constellation of fat malabsorption with enteric losses of protein (often causing edema) and lymphocytes (with resultant lymphocytopenia) that enter the portal circulation directly. Carbohydrate and amino acid absorption are preserved.

**Inflammatory Causes**

Inflammatory diarrheas are generally accompanied by pain, fever, bleeding, or other manifestations of inflammation. The mechanism of diarrhea may not only be exudation but, depending on lesion site, may include fat malabsorption, disrupted fluid/electrolyte absorption, and hypersecretion or hypermotility from release of cytokines and other inflammatory mediators. The unifying feature on stool analysis is the presence of leukocytes or leukocyte-derived proteins such as calprotectin. With severe inflammation, exudative protein loss can lead to anasarca (generalized edema). Any middle-aged or older person with chronic inflammatory-type diarrhea, especially with blood, should be carefully evaluated to exclude a colorectal or large enteric tumor.

**35 Diarrhea and Constipation**

**Idiopathic Inflammatory Bowel Disease**

The illnesses in this category, which include *Crohn’s disease* and *chronic ulcerative colitis*, are among the most common organic causes of chronic diarrhea in adults and range in severity from mild to fulminating and life-threatening. They may be associated with uveitis, polyarthralgias, cholestatic liver disease (primary sclerosing cholangitis), and various skin lesions (erythema nodosum, pyoderma gangrenosum). *Microsporidial colitis*, including *collagenous colitis*, is an increasingly recognized cause of chronic watery diarrhea; biopsy of a normal appearing colorectum is required for histologic diagnosis.

**Primary or Secondary Forms of Immunodeficiency**

Immunodeficiency may lead to prolonged infectious diarrhea. With common, variable *hypogammaglobulinemia*, diarrhea is particularly prevalent and often the result of giardiasis.

**Eosinophilic Gastroenteritis**

Eosinophil infiltration of the mucosa, muscularis, or serosa at any level of the gastrointestinal tract may cause diarrhea, pain, vomiting, or ascites. Affected patients often have an atomic history, Charcot-Leyden crystals due to extruded eosinophilic contents may be seen on microscopic inspection of stool, and peripheral eosinophilia is present in 50 to 75% of patients. While hypersensitivity to certain foods occurs in adults, true food allergy causing chronic diarrhea is rare.

**Other Causes**

Chronic inflammatory diarrhea may be caused by radiation enterocolitis, chronic graft-versus-host disease, Behc¸et’s syndrome, and Cronkite-Canada syndrome, among others.

**Dysmotile Causes**

Rapid transit may accompany many diarrheas as a secondary or contributing phenomenon, but primary dysmotility is an unusual etiology of true diarrhea. Stool features often suggest a secretary diarrhea, but mild steatorrhea of up to 14 g of fat per day can be produced by malabsorption from rapid transit alone. *Hyperthyroidism*, *carcinoid syndrome*, and certain drugs (e.g., prostaglandins, prokinetic agents) may produce hypermotility with resultant diarrhea. Primary visceral neuromyopathies or idiopathic acquired intestinal pseudo-obstruction may lead to stasis with secondary bacterial overgrowth causing diarrhea. *Diabetic diarrhea*, often accompanied by peripheral and generalized autonomic neuropathies, may occur in part because of intestinal dysmotility.

The exceedingly common *irritable bowel syndrome* (10% point prevalence, 1 to 2% per year incidence) is characterized by disturbed intestinal and colonic motor and sensory responses to various stimuli. Symptoms of stool frequency typically cease at night, alternate with periods of constipation, are accompanied by abdominal pain relieved with defecation, and rarely result in weight loss or true diarrhea.

**Factual Causes**

Factual diarrhea accounts for up to 15% of unexplained diarrheas referred to tertiary care centers. Either as a form of *Munchausen syndrome* (deception or self-injury for secondary gain) or *bulimia*, some patients covertly self-administer laxatives alone or in combination with other medications (e.g., diuretics) or surreptitiously add water or urine to stool sent for analysis. Such patients are typically women, often with histories of psychiatric illness, and disproportionately from careers in health care. Hypotension and hypokalemia are common co-presenting features. Such patients often deny this possibility when confronted, but they do benefit from psychiatric counseling when they acknowledge their behavior.

**Approach to the Patient**

The laboratory tools available to evaluate the very common problem of chronic diarrhea are extensive, and many are costly and invasive. As such, the diagnostic evaluation must be rationally directed by a careful history and physical examination, and simple triage tests are often warranted before complex investigations are launched (Fig. 35-3). The history, physical examination, and routine blood studies should attempt to characterize the mechanism of diarrhea, identify diagnostically helpful associations, and assess the
In an estimated two-thirds of cases, the cause for chronic diarrhea remains unclear after the initial encounter, and further testing is required. Quantitative stool collection and analyses can yield important objective data that may establish a diagnosis or characterize the type of diarrhea as a triage for focused additional studies (Fig. 35-3). If stool weight is >200 g/d, additional stool analyses should be performed that might include electrolyte concentration, pH, occult blood testing, leukocyte inspection (or leukocyte protein assay), fat quantitation, and laxative screens.

For secretory diarrheas (watery, normal osmotic gap), possible medication-related side effects or surreptitious laxative use should be reconsidered. Microbiologic studies should be done including fecal bacterial cultures (including media for *Aeromonas* and *Plesiomonas*), inspection for ova and parasites, and *Giardia* antigen assay (the most sensitive test for *giardiasis*). Small bowel bacterial overgrowth can be excluded by intestinal aspirates with quantitative cultures or with glucose or xylose breath tests involving measurement of breath hydrogen or other metabolite (e.g., $^{14}$CO$_2$). However, interpretation of these breath tests may be confounded by disturbances of intestinal transit. When suggested by history or other findings, screens for peptide hormones should be pursued (e.g., serum gastrin, VIP, calcitonin, and thyroid hormone/thyroid stimulating hormone, or urinary 5-hydroxyindolacetic acid and histamine). Upper endoscopy and colonoscopy with biopsies and small-bowel barium x-rays are helpful to rule out structural or occult inflammatory disease.

Further evaluation of osmotic diarrhea should include tests for lactose intolerance and magnesium ingestion, the two most common causes. Low fecal pH suggests carbohydrate malabsorption; lactose malabsorption can be confirmed by lactose breath testing or by a therapeutic trial with lactose exclusion and observation of the effect of lactose challenge (e.g., a quart of milk). Lactase determination on small-bowel biopsy is generally not available. If fecal Mg$^{2+}$ or laxative levels are elevated, then inadvertent or surreptitious ingestion should be considered and psychiatric help should be sought.

For those with proven fatty diarrhea, endoscopy with small-
bowl biopsy (including aspiration for *Giardia* and quantitative cultures) should be performed; if this procedure is unrevealing, a small-bowel radiograph is often an appropriate next step. If small-bowel studies are negative or if pancreatic disease is suspected, pancreatic exocrine insufficiency should be excluded with direct tests, such as the secretin-cholecystokinin stimulation test, or by indirect tests, such as assay of fecal chymotrypsin activity or a bentroimide test.

Chronic inflammatory-type diarrheas should be suspected by the presence of blood or leukocytes in the stool. Such findings warrant stool cultures, inspection for ova and parasites, *C. difficile* toxin assay, colonoscopy with biopsies, and, if indicated, small-bowel oral contrast studies.

**TREATMENT**

Treatment of chronic diarrhea depends on the specific etiology and may be curative, suppressive, or empirical. If the cause can be eradicated, treatment is curative as with resection of a colorectal cancer, antibiotic administration for Whipple’s disease, or discontinuation of an offending drug. For many chronic conditions, diarrhea can be controlled by suppression of the underlying mechanism. Examples include elimination of dietary lactose for lactase deficiency or gluten for celiac sprue, use of glucocorticoids or other anti-inflammatory agents for idiopathic inflammatory bowel diseases, adsorptive agents such as cholestyramine for ileal bile acid malabsorption, proton pump inhibitors such as omeprazole for the gastric hypersecretion of gastrinomas, somatostatin analogues such as octreotide for malignant carcinoid, prostaglandin inhibitors such as indomethacin for medullary carcinoma of the thyroid, and pancreatic enzyme replacement for pancreatic insufficiency. When the specific cause or mechanism of chronic diarrhea evades diagnosis, empirical therapy may be beneficial. Mild opiates such as diphenoxylate or loperamide are often helpful in mild or moderate watery diarrhea. For those with more severe diarrhea, codeine or tincture of opium may be beneficial. Such antimotility agents should be avoided with inflammatory bowel disease, as toxic megacolon may be precipitated. Clonidine, an α₂-adrenergic agonist, may allow control of diabetic diarrhea. For all patients with chronic diarrhea, fluid and electrolyte repletion is an important component of management (see “Acute Diarrhea,” above). Replacement of fat-soluble vitamins may also be necessary in patients with chronic steatorrhea.

**CONSTITUTION**

**DEFINITION**

Constipation is a common complaint in clinical practice and usually refers to persistent, difficult, infrequent, or seemingly incomplete defecation. Because of the wide range of normal bowel habits, constipation is difficult to define precisely. Most persons have at least three bowel movements per week; however, stool frequency alone is not a sufficient criterion for the diagnosis of constipation because many constipated patients describe a normal frequency of defecation but subjective complaints of excessive straining, hard stools, lower abdominal fullness, and a sense of incomplete evacuation. The individual patient’s symptoms must be analyzed in detail to ascertain what is meant by “constipation” or “difficulty” with defecation.

Stool form and consistency are well correlated with the time elapsed from the preceding defecation. Hard, pellet stools occur with slow transit, while loose watery stools are associated with rapid transit. Small, pellet stools are more difficult to expel than large ones.

The perception of hard stools or excessive straining is more difficult to assess objectively, and the need for enemas or digital disimpaction is a clinically useful way to corroborate the patient’s perceptions of difficult defecation.

Psychosocial factors may also be important. A person whose parents attached great importance to daily defecation will become greatly concerned when he or she misses a daily bowel movement; some children withhold stool to gain attention; and some adults are simply too busy or too embarrassed to interrupt their work when the call to have a bowel movement is sensed.

**CAUSES**

Pathophysiologically, chronic constipation generally results from inadequate fiber intake or from disordered colonic transit or anorectal function as a result of a neurogastroenterologic disturbance, certain drugs, or in association with a large number of systemic diseases that affect the gastrointestinal tract (Table 35-4). Constipation of recent onset may be a symptom of significant organic disease such as tumor or stricture. In idiopathic constipation, a subset of patients exhibit delayed emptying of the ascending and transverse colon with prolongation of transit (often in the proximal colon) and a reduced frequency of propulsive colonic contractions (HAPCs). Outlet obstruction to defecation (also called evacuation disorders) may cause delayed colonic transit, which is usually corrected by biofeedback retraining of the disordered defecation. Constipation of any cause may be exacerbated by chronic illnesses that lead to physical or mental impairment and result in inactivity or physical immobility.

**APPROACH TO THE PATIENT**

A careful history should explore the patient’s symptoms and confirm whether he or she is indeed constipated based on frequency (e.g., fewer than three bowel movements per week), consistency (lumpy/hard), excessive straining, prolonged defecation time, or need to support the perineum or digitate the anorectum. In the vast majority of cases (probably >90%), there is no underlying cause (e.g., cancer, depression, or hypothyroidism), and constipation responds to ample hydration, exercise, and supplementation of dietary fiber (15 to 25 g/d). A good diet and medication history and attention to psychosocial issues are key. Physical examination and, particularly, a rectal examination should exclude most of the important diseases that present with constipation and possibly indicate features suggesting an evacuation disorder (e.g., high anal sphincter tone).

There is broad consensus on the selection of patients for further investigation. The presence of weight loss, rectal bleeding, or anemia with constipation mandates either sigmoidoscopy plus barium enema or colonoscopy alone, particularly in patients >40 years, to exclude structural diseases such as cancer or strictures. Colonoscopy alone is most cost effective in this setting since it provides an opportunity to biopsy mucosal lesions, perform polypectomy, or dilate strictures. Barium enema has advantages over colonoscopy in the patient with isolated constipation, since it is less costly and identifies colonic dilatation and all significant mucosal lesions or strictures that are likely to present with constipation. Melanosis coli, or pigmentation of the colon mucosa, indicates the use of

anthraquinone laxatives such as cascara or senna; however, this is usually apparent from a careful history. An unexpected disorder such as megacolon or cathartic colon may also be detected by colonic radiographs. Measurement of serum calcium and thyroid stimulating hormone levels will identify rare patients with metabolic disorders.

Patients with more troublesome constipation may not respond to fiber alone and may be helped by a bowel training regimen: taking an osmotic laxative and evacuating with enema or glycerine suppository as needed. After breakfast, a distraction-free 15 to 20 min on the toilet without straining is encouraged. Excessive straining may lead to development of hemorrhoids, and, if there is weakness of the pelvic floor or injury to the pudendal nerve, may result in obstructed defecation from descending perineum syndrome several years later. Those few who do not benefit from the simple measures delineated above or require long-term treatment with stimulant laxatives with the attendant risk of developing laxative abuse syndrome are assumed to have severe or intractable constipation and should have further investigation (Fig. 35-4).

INVESTIGATION OF SEVERE CONSTIPATION A small minority (probably <5%) of all patients with constipation have cases that are considered severe or “intractable”: these are the patients most likely to be seen by gastroenterologists or in referral centers. Further observation of the patient may occasionally reveal a previously unrecognized cause, such as an evacuation disorder, laxative abuse, malingering, or psychiatric disorder. In these patients, recent studies suggest that evaluations of the physiologic function of the colon and pelvic floor and of psychological status aid in the rational choice of treatment. Even among these highly selected patients with severe constipation, a cause can be identified in only about 30% (see below).

Measurement of Colonic Transit Radiopaque marker transit tests are easy, repeatable, generally safe, inexpensive, reliable, and highly applicable in evaluating constipated patients in clinical practice. There are several validated methods that are very simple. For example, radiopaque markers are ingested, and an abdominal flat film taken 5 d later should indicate passage of 80% of the markers out of the colon. This test does not provide useful information about the transit profile of the stomach and small bowel, and avoidance of laxatives or enemas during the testing period is essential.

Radioscintigraphy with a delayed-release capsule containing radiolabeled particles has been used to noninvasively characterize normal, accelerated, or delayed colonic function over 24 to 48 h with low radiation exposure. This approach simultaneously assesses gastric, small-bowel, and colonic transit. The disadvantages are the greater cost and the need for specific materials prepared in a nuclear medicine laboratory.

Anorectal and Pelvic Floor Tests Pelvic floor dysfunction is suggested by the inability to evacuate the rectum, a feeling of persistent rectal fullness, rectal pain, the need to extract stool from the rectum digitally, application of pressure on the posterior wall of the vagina, support of the perineum during straining, and excessive straining. These significant symptoms should be contrasted with the sense of incomplete rectal evacuation, which is common in irritable bowel syndrome.

Patients with clinically suspected obstruction of defecation should also be evaluated by a psychologist to identify eating disorders or a “need to control,” to provide stress management or relaxation training, and to identify depression.

A simple clinical test in the office to document a nonrelaxing puborectalis muscle is to have the patient strain to expel the index finger during a digital rectal examination. Motion of the puborectalis posteriorly during straining indicates proper coordination of the pelvic floor muscles.

Measurement of perineal descent is relatively easy to gauge clinically by placing the patient in the left decubitus position and watching the perineum to assess either paucity or lack of descent (<1.5 cm, a sign of pelvic floor dysfunction) or perineal ballooning during straining relative to bony landmarks (>4 cm, suggesting excessive perineal descent).

A useful overall test of evacuation is the balloon expulsion test. A urinary catheter is placed in the rectum, the balloon is inflated to 50 mL with water, and a determination is made about whether the patient can expel it while seated on a toilet or in the left lateral decubitus position. In the lateral position, the weight needed to facilitate expulsion of the balloon (normal, 0 to 200 g) is determined.

Anorectal manometry is not often contributory in the evaluation of patients presenting with severe constipation, except when an excessively high resting or squeeze anal sphincter tone suggests anismus (anal sphincter spasm). This test also identifies rare syndromes, such as adult Hirschsprung’s disease, by the absence of the rectoanal inhibitory reflex or the presence of occult incontinence.

Defecography (a dynamic barium enema including lateral views obtained during barium expulsion) reveals “soft abnormalities” in many patients; the most relevant findings are the measured changes in rectoanal angle, anatomic defects of the rectum, and enteroceles or rectoceles. In a very small proportion of patients, significant anatomic defects associated with intractable constipation respond best to surgical treatment. These defects include severe intussusception with complete outlet obstruction due to funnel-shaped plugging at the anal canal or an extremely large rectocele that is preferentially filled during attempts at defecation instead of expulsion of the barium through the anus. In summary, defecography requires an interested and experienced radiologist, and abnormalities are not pathognomonic for pelvic floor dysfunction. More commonly, outlet obstruction results from a nonrelaxing puborectalis muscle, which impedes rectal emptying, rather than from defects identified by defecography.

Dynamic imaging studies such as proctography during defecation or scintigraphic expulsion of artificial stool help measure perineal descent and the rectoanal angle during rest, squeezing, and straining, and scintigraphic expulsion quantitates the amount of “artificial stool” emptied. Failure of the rectoanal angle to increase significantly (~15°) during straining confirms pelvic floor dysfunction.
Neurologic testing (electromyography) is more helpful in the evaluation of patients with incontinence than of those with symptoms suggesting obstructed defecation. The absence of neurologic signs in the lower extremities suggests that any documented denervation of the puborectalis results from pelvic (e.g., obstetric) injury or from stretching of the pudendal nerve by chronic, long-standing straining.

Ultrasoundography identifies sphincter or rectal wall defects and may help select patients for surgical correction. Spinal-evoked responses during electrical rectal stimulation or stimulation of external anal sphincter contraction by applying magnetic stimulation over the lumbar-sacral cord identify patients with limited sacral neuropathies with sufficient residual nerve conduction to attempt biofeedback training.

In summary, a balloon expulsion test is an important screening test for anorectal dysfunction. If positive, an anatomic evaluation of the rectum or anal sphincters and an assessment of pelvic floor relaxation are the tools for evaluating patients in whom obstructed defecation is suspected.

### Treatment

After the cause of constipation is characterized, a treatment decision can be made. Slow transit constipation requires aggressive medical or surgical treatment; anismus or pelvic floor dysfunction usually responds to biofeedback management (Fig. 35-4). However, only about 30% of patients with severe constipation are found to have such a physiologic disorder.

Patients with slow transit constipation are treated with bulk, osmotic, and stimulant laxatives, including fiber, psyllium, milk of magnesia, lactulose, polyethylene glycol (colonic lavage solution), and bisacodyl. If a 2- to 3-month trial of medical therapy fails and patients continue to have documented slow transit constipation unassociated with obstructed defecation, colectomy with ileorectostomy is indicated. The decision to resort to surgery is facilitated in the presence of megacolon and megarectum. The complications after surgery include small-bowel obstruction (11%) and fecal soiling, particularly at night during the first postoperative year.

Patients who have a combined disorder should pursue pelvic floor retraining (biofeedback and muscle relaxation), psychological counseling, and dietetic advice first, followed by colectomy and ileorectostomy if colonic transit studies do not normalize with biofeedback alone. In patients with pelvic floor dysfunction alone, biofeedback training has a 70 to 80% success rate; measured by the acquisition of comfortable stool habits. Attempts to manage pelvic floor dysfunction with operations (internal anal sphincter or puborectalis muscle division) have achieved only mediocre success and have been largely abandoned.

### Weight Loss

Significant unintentional weight loss in a previously healthy individual is often a harbinger of underlying systemic disease. During the routine medical history, inquiry should always be made about changes in weight; loss of 5% of body weight over 6 to 12 months should prompt further evaluation.

**Physiology of Weight Regulation**

The normal individual maintains body weight at a remarkably stable “set point,” given the wide variation in daily caloric intake and level of activity. Because of the physiologic importance of maintaining energy stores, voluntary weight loss is difficult to achieve and sustain.

Appetite and metabolism are regulated by an intricate network of neural and hormonal factors. The hypothalamic feeding and satiety centers play a central role in these processes (Chap. 64). Neuropeptides such as corticotropin-releasing hormone (CRH), α-melanocyte stimulating hormone (α-MSH), and cocaine- and amphetamine-related transcript (CART) induce anorexia by acting centrally on satiety centers. The gastrointestinal peptides ghrelin, glucagon, somatostatin, and cholecystokinin signal satiety and thus decrease food intake. Hypoglycemia suppresses insulin, reducing glucose utilization and inhibiting the satiety center.

Leptin is produced by adipose tissue, and it plays a central role in the long-term maintenance of weight homeostasis by acting on the hypothalamus to decrease food intake and increase energy expenditure (Chap. 64). Leptin suppresses expression of hypothalamic neuropeptide Y, a potent appetite stimulatory peptide, and it increases the expression of α-MSH, which acts through the MC4R melanocortin receptor to decrease appetite. Thus, leptin activates a series of downstream neural pathways that alter food-seeking behavior and metabolism. However, leptin deficiency, which occurs in conjunction with the loss of adipose tissue, stimulates appetite and induces adaptive responses including inhibition of hypothalamic thyrotropin-releasing hormone (TRH) and gonadotropin-releasing hormone (GnRH).

A variety of cytokines, including tumor necrosis factor α (TNF-α), interleukin (IL) 6 (IL-6), IL-1, interferon γ (IFN-γ), ciliary neurotrophic factor (CNTF), and leukemia inhibitory factor (LIF), can induce cachexia (Chap. 16). In addition to causing anorexia, these factors may stimulate fever, depress myocardial function, modulate immune and inflammatory responses, and induce a variety of specific metabolic alterations. TNF-α, for example, preferentially mobilizes fat but spares skeletal muscle. Levels of one or more of these cytokines may be increased in patients with cancer, sepsis, chronic inflammatory conditions, AIDS, and congestive heart failure.

Weight loss occurs when energy expenditure exceeds calories available for energy utilization (Chap. 62). In most individuals, approximately half of food energy is utilized for basal processes such as maintenance of body temperature. In a 70-kg person, basal activity consumes about 1800 kcal/d. About 40% of caloric intake is used for physical activity, although athletes may use more than 50% during vigorous exercise. About 10% of caloric intake is used for dietary thermogenesis, the energy expended for digestion, absorption, and metabolism of food.

Mechanisms of weight loss include decreased food intake, malabsorption, loss of calories, and increased energy requirements (Fig. 36-1). Changes in weight may involve loss of tissue mass or body fluid content. A deficit of 3500 kcal generally correlates with the loss of 0.45 kg (1 lb) of body fat, but one must also consider water weight [1 kg/L (2.2 lb/L)] gained or lost. Weight loss that persists over weeks to months reflects the loss of tissue mass.
sufficiency, cholestasis, celiac sprue, intestinal tumors, radiation injury, inflammatory bowel disease, infection, or medication effect. These disease processes may be manifest as changes in stool frequency and consistency. Calories may also be lost due to vomiting or diarrhea, glucosuria in diabetes mellitus, or fistulous drainage. Resting energy expenditure decreases with age and can be affected by thyroid status. Beginning at about age 60, body weight declines by an average of 0.5% per year. Body composition is also affected by aging; adipose tissue increases and lean muscle mass decreases with age.

**SIGNIFICANCE OF WEIGHT LOSS**

Unintentional weight loss, especially in the elderly, is not uncommon and is associated with increased morbidity and mortality rates, even after comorbid conditions have been taken into account. Prospective studies indicate that significant involuntary weight loss is associated with a mortality rate of 25% over the next 18 months. Retrospective studies of significant weight loss in the elderly document mortality rates of 9 to 38% over a 2- to 3-year period.

Cancer patients with weight loss have decreased performance status, impaired responses to chemotherapy, and reduced median survival (Chap. 66). Marked weight loss also predisposes to infection. Patients undergoing elective surgery, who have lost >4.5 kg (>10 lb) in 6 months, have higher surgical mortality rates. Vitamin and nutrient deficiencies also can accompany significant weight loss (Chap. 61).

**CAUSES OF WEIGHT LOSS**

The list of possible causes of weight loss is extensive (Table 36-1). In the elderly, the most common causes of weight loss are depression, cancer, and benign gastrointestinal disease. Lung and gastrointestinal cancer are the most common malignancies in patients presenting with weight loss. In younger individuals, diabetes mellitus, hyperthyroidism, psychiatric disturbances including eating disorders, and infection, especially with HIV, should be considered.

The cause of involuntary weight loss is rarely occult. Careful history and physical examination, in association with directed diagnostic testing, will identify the cause of weight loss in 75% of patients. The etiology of weight loss may not be found in the remaining patients, despite extensive testing. Patients with negative evaluations tend to have lower mortality rates than those found to have organic disease.

Patients with medical causes of weight loss usually have signs or symptoms that suggest involvement of a particular organ system. Gastrointestinal tumors, including those of the pancreas and liver, may affect food intake early in the course of illness, causing weight loss before other symptoms are apparent. Lung cancer may present with post-obstructive pneumonia, dyspnea, or cough and hemoptysis; however, it may be silent and should be considered even in those without a history of cigarette smoking. Depression and isolation can cause profound weight loss, especially in the elderly. Chronic pulmonary disease and congestive heart failure can produce anorexia, and they also increase resting energy expenditure. Weight loss may be the presenting sign of infectious diseases such as HIV infection, tuberculosis, endocarditis, and fungal or parasitic infections. Hyperthyroidism or pheochromocytoma increases metabolism. Elderly patients with apathetic hyperthyroidism may present with weight loss and weakness, with few other manifestations of thyrotoxicosis. New-onset diabetes mellitus is often accompanied by weight loss, reflecting glucosuria and loss of the anabolic actions of insulin. Adrenal insufficiency may be suggested by increased pigmentation, hyponatremia, and hyperkalemia.

**APPROACH TO THE PATIENT**

Before extensive evaluation is undertaken, it is important to confirm weight loss and to determine the time interval over which it has occurred. Almost half of patients who claim significant weight loss have no actual change when body weight is measured objectively. In the absence of documentation, changes in belt notch size or the fit of clothing may be confirmatory. Not infrequently, patients who have actually sustained significant weight loss are unaware that it has occurred. Routine documentation of weight during office visits is therefore important.

The review of systems should focus on signs or symptoms that are associated with disorders that commonly cause weight loss. These include fever, pain, shortness of breath or cough, palpitations, and evidence of neurologic disease. Gastrointestinal disturbances, including difficulty eating, dysphagia, anorexia, nausea, and change in bowel habits, should be sought. Travel history, use of cigarettes and alcohol, and all medications should be reviewed, and patients should be questioned about previous illness or surgery as well as diseases in family members. Risk factors for HIV infection should be assessed. Signs of depression, evidence of dementia, and social factors, including financial issues that might affect food intake, should be considered.

Physical examination should begin with weight determination and documentation of vital signs. The skin should be examined for...
The proportion of patients bleeding from varices varies widely from about 50% of cases. Mallory-Weiss tears account for 5 to 15% of cases.

SOURCES OF GASTROINTESTINAL BLEEDING

UPPER GASTROINTESTINAL SOURCES OF BLEEDING (Table 37-1) The annual incidence of hospital admissions for upper GIB (UGIB) in the United States and Europe is approximately 0.1%, with a mortality rate of 5 to 10%. Patients rarely die from exsanguination; rather, they die due to decomposition from other underlying illnesses. The mortality rate for patients under 60 years of age in the absence of malignancy or organ failure is <1%. The three independent clinical predictors of death in patients hospitalized with UGIB are increasing age, comorbidities, and hemodynamic compromise (tachycardia or hypotension).

Pallor, jaundice, turgor, scars from prior surgery, and stigmata of systemic disease. The search for oral thrush or dental disease, thyroid gland enlargement, adenopathy, and respiratory or cardiac abnormalities and a detailed examination of the abdomen often lead to clues for further evaluation. Rectal examination, including proctate examination and testing of stool for occult blood, should be performed in men; and all women should have a pelvic examination, even if they have had a hysterectomy. Neurologic examination should include mental status assessment and screening for depression.

Laboratory testing should confirm or exclude possible diagnoses elicited from the history and physical examination (Table 36-2). An initial phase of testing should include a complete blood count with differential, serum chemistry tests including glucose, electrolytes, renal and liver tests, calcium, thyroid-stimulating hormone (TSH), urinalysis, and chest x-ray. Patients at risk for HIV infection should have HIV antibody testing. In all cases, recommended cancer screening tests appropriate for the gender and age group, such as mammograms and Pap smears, should be updated (Chap. 67). If gastrointestinal signs or symptoms are present, upper and/or lower endoscopy and abdominal imaging with either computed tomography (CT) or magnetic resonance imaging (MRI) have a relatively high yield, consistent with the high prevalence of gastrointestinal disorders in patients with weight loss. If an etiology of weight loss is not found, careful clinical follow-up, rather than persistent undirected testing, is reasonable.

**INUI A:** Cancer anorexia-cachexia syndrome: Current issues in research and management. Cancer J Clinicians 52:72, 2002

Hemorrhagic and erosive gastropathy (shunt). Probably undergo decompressive surgery (e.g., distal splenorenal shunt). Patients with more severe liver disease and those in whom transplant is required often undergo reinstrumentation. Therefore, TIPS is most appropriate for acute bleeding Mallory-Weiss tears. Angiographic therapy with intraarterial infusion of vasopressin or embolization and operative therapy with oversewing of the tear are rarely required. — MALLORY-WEISS TEARS ARE DISCUSSED IN CHAP. 273.

Esophageal Varices Patients with variceal hemorrhage have poorer outcomes than patients with other sources of UGIB. Endoscopic therapy for acute bleeding and repeated sessions of endoscopic therapy to eradicate esophageal varices significantly reduces rebleeding and mortality. Ligation is the endoscopic therapy of choice for esophageal varices because it has less rebleeding, a lower mortality rate, fewer local complications, and requires fewer treatment sessions to achieve variceal eradication as compared to sclerotherapy.

Acute treatment with octreotide (50–µg bolus and 50–µg/h intravenous infusion for 2 to 5 days) may help in the control of acute bleeding, and this has replaced vasopressin as the medical therapy of choice for acute variceal bleeding in the United States. Agents such as somatostatin and terlipressin, available outside the United States, are also effective. Over the long term, treatment with nonselective beta blockers decreases recurrent bleeding from esophageal varices. Beta blockers are commonly given along with chronic endoscopic therapy. In patients who have persistent or recurrent bleeding despite endoscopic and medical therapy, more invasive therapy is warranted. Transjugular intrahepatic portosystemic shunt (TIPS) decreases rebleeding more effectively than endoscopic therapy, although hepatic encephalopathy is more common and the mortality rates are comparable. Most patients with TIPS have stent stenosis within 1 to 2 years and require reinstrumentation. Therefore, TIPS is most appropriate for patients with more severe liver disease and those in whom transplant is anticipated. Patients with milder, well-compensated cirrhosis should probably undergo decompressive surgery (e.g., distal splenorenal shunt).

Portal hypertension is also responsible for bleeding from gastric varices, varices in the small and large intestine, and portal hypertensive gastropathy and enterocolopathy.

Hemorrhagic and erosive gastropathy (“Gastritis”) Hemorrhagic and erosive gastropathy, or gastritis, refers to endoscopically visualized subepithelial hemmorhages and erosions. These are mucosal lesions and thus do not cause major bleeding. They develop in various clinical settings, the most important of which are NSAID use, alcohol intake, and stress. Half of patients who chronically ingest NSAIDs have erosions (15 to 30% have ulcers), while up to 20% of actively drinking alcoholic patients with symptoms of UGIB have evidence of subepithelial hemorrhages or erosions.

Stress-related gastric mucosal injury occurs only in extremely sick patients: those who have experienced serious trauma, major surgery, burns covering more than one-third of the body surface area, major intracranial disease, and severe medical illness (i.e., ventilator dependence, coagulopathy). Significant bleeding probably does not develop unless ulceration occurs. The mortality rate in these patients is quite high because of their serious underlying illnesses.

The incidence of bleeding from stress-related gastric mucosal injury or ulceration has decreased dramatically in recent years, most likely due to better care of critically ill patients. Pharmacologic prophylaxis for bleeding may be considered in the high-risk patients mentioned above. The best data suggest that intravenous H₂-receptor antagonist therapy is the treatment of choice, although sucralfate is also effective. Prophylactic therapy decreases bleeding but does not lower the mortality rate.

Other Causes Other, less frequent causes of UGIB include erosive duodenitis, neoplasms, aortoenteric fistulas, vascular lesions [including hereditary hemorrhagic telengectasias (Osler-Weber-Rendu) and gastric antral vascular ectasia (“watermelon stomach”), Dieulafoy’s lesion (in which an aberrant vessel in the mucosa bleeds from a pinpoint mucosal defect), prolapse gastropathy (prolapse of proximal stomach into esophagus with retching, especially in alcoholics), and hemobilia and hemosuccus pancreaticus (bleeding from the bile duct or pancreatic duct).

SMALL-INTESTINAL SOURCES OF BLEEDING Small-intestinal sources of bleeding (bleeding from sites beyond the reach of the standard upper endoscope) are difficult to diagnose and are responsible for the majority of cases of obscure GIB. Fortunately, small-intestinal bleeding is uncommon. The most common causes are vascular ectasias and tumors (e.g., adenocarcinoma, leiomyoma, lymphoma, benign polyps, carcinoid, metastases, and lipoma). Other less common causes include Crohn’s disease, infection, ischemia, vasculitis, small-bowel varices, diverticula, Meckel’s diverticulum, duplication cysts, and intussusception. NSAIDs induce small-intestinal erosions and ulcers and may be a relatively common cause of chronic, obscure GIB.

Meckel’s diverticulum is the most common cause of significant lower GIB (LGIB) in children, decreasing in frequency as a cause of bleeding with age. In adults <40 to 50 years, small-bowel tumors often account for obscure GIB; in patients >50 to 60 years, vascular ectasias are usually responsible.

Vascular ectasias should be treated with endoscopic therapy if possible. Surgical therapy can be used for vascular ectasias isolated to a segment of the small intestine when endoscopic therapy is unsuccessful. Although estrogen/progesterone compounds have been used for vascular ectasias, a double-blind trial found no benefit in prevention of recurrent bleeding. Isolated lesions, such as tumors, diverticula, or duplications, are generally treated with surgical resection.

COLONIC SOURCES OF BLEEDING The incidence of hospitalizations for LGIB is about one-fifth that for UGIB. Hemorrhoids are probably the most common cause of LGIB; anal fissures also cause minor bleeding and pain. If these local anal processes, which rarely require hospitalization, are excluded, the most common causes of LGIB in adults are diverticular, vascular ectasias (especially in the proximal colon of patients >70 years), neoplasms (primarily adenocarcinoma), and colitis—most commonly infectious or idiopathic inflammatory bowel disease, but occasionally ischemic or radiation-induced. Uncommon causes include post-polypectomy bleeding, solitary rectal ulcer syndrome, NSAID-induced ulcers or colitis, trauma, varices (most commonly rectal), lymphoid nodular hyperplasia, vasculitis, and aortocolic fistulas. In children and adolescents, the most common colonic causes of significant GIB are inflammatory bowel disease and juvenile polypos.

Diverticular bleeding is abrupt in onset, usually painless, sometimes massive, and often from the right colon; minor and occult bleeding is not characteristic. Clinical reports suggest that bleeding colonic diverticula stop bleeding spontaneously in approximately 80% of patients and rebleed in about 20 to 25% of patients. Intraarterial vasopressin may halt the bleeding, at least temporarily. If bleeding persists or recurs, segmental surgical resection is indicated.

Bleeding from right colonic vascular ectasias in the elderly may be overt or occult; it tends to be chronic and only occasionally is hemodynamically significant. Endoscopic hemostatic therapy may be useful in the treatment of vascular ectasias, as well as discrete bleeding ulcers and post-polypectomy bleeding, while endoscopic polypectomy, if possible, is used for bleeding colonic polyps. Surgical therapy is generally required for major, persistent, or recurrent bleeding from the wide variety of colonic sources of GIB that cannot be treated medically or endoscopically.
Severe bleeding

Intraoperative

Suggested algorithm for patients with acute upper gastrointestinal bleeding. Recommendations on level of care and time of discharge assume patient is stabilized without further bleeding or other concomitant medical problems. PPI, proton pump inhibitor; ICU, intensive care unit.

Approach to the Patient

Measurement of the heart rate and blood pressure is the best way to assess a patient with GIB. Clinically significant bleeding leads to postural changes in heart rate or blood pressure, tachycardia, and, finally, recumbent hypotension. In contrast, the hemoglobin does not fall immediately with acute GIB, due to proportionate reductions in plasma and red cell volumes (i.e., “people bleed whole blood”). Thus, hemoglobin may be normal or only minimally decreased at the initial presentation of a severe bleeding episode. As extravascular fluid enters the vascular space to restore volume, the hemoglobin falls, but this process may take up to 72 h. Patients with slow, chronic GIB may have very low hemoglobin values despite normal blood pressure and heart rate. With the development of iron-deficiency anemia, the mean corpuscular volume will be low and red blood cell distribution width will be increased.

Differentiation of Upper from Lower GIB Hematemesis indicates an upper GI source of bleeding (above the ligament of Treitz). Melena indicates that blood has been present in the GI tract for at least 14 h. Thus, the more proximal the bleeding site, the more likely melena will occur. Hematochezia usually represents a lower GI source of bleeding, although an upper GI lesion may bleed so briskly that blood does not remain in the bowel long enough for melena to develop. When hematochezia is the presenting symptom of UGIB, it is associated with hemodynamic instability and dropping hemoglobin. Bleeding lesions of the small bowel may present as melena or hematochezia. Other clues to UGIB include hyperactive bowel sounds and an elevated blood urea nitrogen level (due to volume depletion and blood proteins absorbed in the small intestine).

A nonbloody nasogastric aspirate may be seen in up to 16% of patients with UGIB—usually from a duodenal source. Even a bile-stained appearance does not exclude a bleeding postpyloric lesion since reports of bile in the aspirate are incorrect in about 50% of cases. Testing of aspirates that are not grossly bloody for occult blood is not useful.

Diagnostic Evaluation of the Patient with GIB UPPER GIB (Fig. 37-1) History and physical examination are not usually diagnostic of the source of GIB. Upper endoscopy is the test of choice in patients with UGIB and should be performed urgently in patients with hemodynamic instability (hypotension, tachycardia, or postural changes in heart rate or blood pressure). Early endoscopy is also beneficial in cases of milder bleeding for management decisions. Patients with major bleeding and high-risk endoscopic findings (e.g., varices, ulcers with active bleeding or a

Acute Upper GI Bleeding

- Ulcer
  - Active bleeding or visible vessel
  - IV PPI therapy + endoscopic therapy
  - ICU for 1 day; ward for 2 days
  - Ward for 3 days
  - Endoscopic therapy
  - ICU for 1-2 days; ward for 2-3 days

- Esophageal varices
  - Ligation (preferred) or sclerotherapy + IV octreotide
  - Endoscopic therapy
  - ICU for 1 day; ward for 2 days

- Mallory-Weiss tear
  - No IV PPI therapy
  - + endoscopic therapy
  - Ward for 3 days
  - Discharge

Acute Lower GI Bleeding

- No hemodynamic instability
  - Age < 40 years
  - Flexible sigmoidoscopy
  - Colonoscopy†
  - Bleeding stops

- Hemodynamic instability
  - Age > 40 years
  - Upper endoscopy
  - Colonoscopy
  - Colonoscopy†
  - Consider enteroscopy, video capsule, enterolysis, angiography if major blood loss

- Severe bleeding persists
  - Angiography (Tc-RBC scan may be done first)
  - Consider intraoperative endoscopy

FIGURE 37-1 Suggested algorithm for patients with acute upper gastrointestinal bleeding. Recommendations on level of care and time of discharge assume patient is stabilized without further bleeding or other concomitant medical problems. PPI, proton pump inhibitor; ICU, intensive care unit.

FIGURE 37-2 Suggested algorithm for patients with acute lower gastrointestinal bleeding. Sequential recommendations under “Hemodynamic instability” assume a test is found to be nondiagnostic before next test is performed. *Some suggest colonoscopy for any degree of rectal bleeding in patients <40 years old as well. †If massive bleeding does not allow time for colonic lavage, proceed to angiography. Tc-RBC, 99mtechnetium-labeled red blood cell.
visible vessel) benefit from endoscopic hemostatic therapy, while patients with low-risk lesions (e.g., clean-based ulcers, nonbleeding Mallory-Weiss tears, erosive or hemorrhagic gastropathy) who have stable vital signs and hemoglobin, and no other medical problems, can be discharged home.

**LOWER GIB (Fig. 37-2)** Patients with hematochezia and hemodynamic instability should have upper endoscopy to rule out an upper GI source before evaluation of the lower GI tract. Patients with presumed LGIB may undergo early sigmoidoscopy for the detection of obvious, low-lying lesions. However, the procedure is difficult with brisk bleeding, and it is usually not possible to identify the area of bleeding. Sigmoidoscopy is useful primarily in patients <40 years with minor bleeding.

Colonoscopy after an oral lavage solution is the procedure of choice in patients admitted with LGIB unless bleeding is too massive or unless sigmoidoscopy has disclosed an obvious actively bleeding lesion. 99mTc-labeled red cell scan allows repeated imaging for up to 24 h and may identify the general location of bleeding. However, radionuclide scans should be interpreted with caution because results, especially from later images, are highly variable. In active LGIB, angiography can detect the site of bleeding (extravasation of contrast into the gut) and permits treatment with intraarterial infusion of vasopressin or embolization. Even after bleeding has stopped, angiography may identify lesions with abnormal vasculature, such as vascular ectasias or tumors.

**GIB OF OBSCURE ORIGIN** Obscure GIB is defined as recurrent acute or chronic bleeding for which no source has been identified by routine endoscopic and contrast x-ray studies. Push enteroscopy, with a specially designed enteroscope or a pediatric colonoscope to inspect the entire duodenum and part of the jejunum, is generally the next step. Push enteroscopy may identify probable bleeding sites in 20 to 40% of patients with obscure GIB. Video capsule endoscopy, which allows endoscopic examination of the entire small intestine, increases diagnostic yield in obscure GIB: bleeding sites are identified in approximately 30 to 65% of cases in the initial published reports. However, lack of control of the capsule prevents its manipulation and full visualization of the intestine; in addition, tissue cannot be sampled and therapy cannot be applied. If enteroscopy and video capsule endoscopy are negative or unavailable, a specialized radiographic examination of the small bowel (e.g., enteroclysis) should be performed.

Patients with continued obscure GIB who require transfusions or repeated hospitalizations warrant further investigations. 99mTc-labeled red blood cell scintigraphy should be employed. Angiography is useful even if bleeding has subsided, since it may disclose vascular anomalies or tumor vessels. 99mTc-pertechnetate scintigraphy for diagnosis of Meckel’s diverticulum should be done, especially in the evaluation of young patients. When all tests are unrevealing, intraoperative endoscopy is indicated in patients with severe recurrent or persistent bleeding requiring repeated transfusions.

**OCCULT GIB** Occult GIB is manifested by a positive test for fecal occult blood or iron-deficiency anemia. Evaluation of a positive test for fecal occult blood generally should begin with colonoscopy, particularly in patients >40 years. If evaluation of the colon is negative, many perform upper endoscopy only if iron-deficiency anemia or upper GI symptoms are present, while others recommend upper endoscopy in all patients since up to 25 to 40% of these patients may have some abnormality noted on upper endoscopy. If standard endoscopic tests are unrevealing, enteroscopy, video capsule endoscopy, and/or enteroclysis may be considered in patients with iron-deficiency anemia.

**JAUNDICE**

Daniel S. Pratt, Marshall M. Kaplan

Jaundice, or icterus, is a yellowish discoloration of tissue resulting from the deposition of bilirubin. Tissue deposition of bilirubin occurs only in the presence of serum hyperbilirubinemia and is a sign of either liver disease or, less often, a hemolytic disorder. The degree of serum bilirubin elevation can be estimated by physical examination. Slight increases in serum bilirubin are best detected by examining the sclerae which have a particular affinity for bilirubin due to their high elastin content. The presence of scleral icterus indicates a serum bilirubin of at least 51 μmol/L (3.0 mg/dL). The ability to detect scleral icterus is made more difficult if the examining room has fluorescent lighting. If the examiner suspects scleral icterus, a second place to examine is underneath the tongue. As serum bilirubin levels rise, the skin will eventually become yellow in light-skinned patients and even green if the process is long-standing; the green color is produced by oxidation of bilirubin to biliverdin.

The differential diagnosis for yellowing of the skin is limited. In addition to jaundice, it includes carotenoderma, the use of the drug quinacrine, and excessive exposure to phenols. Carotenoderma is the yellow color imparted to the skin by the presence of carotene; it occurs in healthy individuals who ingest excessive amounts of vegetables and fruits that contain carotene, such as carrots, leafy vegetables, squash, peaches, and oranges. Unlike jaundice, where the yellow coloration of the skin is uniformly distributed over the body, in carotenodermia the pigment is concentrated on the palms, soles, forehead, and nasolabial folds. Carotenodermia can be distinguished from jaundice by the sparring of the sclerae. Quinacrine causes a yellow discoloration of the skin in 4 to 37% of patients treated with it. Unlike carotene, quinacrine can cause discoloration of the sclerae.

Another sensitive indicator of increased serum bilirubin is darkening of the urine, which is due to the renal excretion of conjugated bilirubin. Patients often describe their urine as tea or cola colored. Bilirubinuria indicates an elevation of the direct serum bilirubin fraction and therefore the presence of liver disease.

Increased serum bilirubin levels occur when an imbalance exists between bilirubin production and clearance. A logical evaluation of the patient who is jaundiced requires an understanding of bilirubin production and metabolism.

**PRODUCTION AND METABOLISM OF BILIRUBIN** (See also Chap. 284) Bilirubin, a tetrapyrrole pigment, is a breakdown product of heme (ferroprotoporphyrin IX). About 70 to 80% of the 250 to 300 mg of bil-
irubin produced each day is derived from the breakdown of hemoglobin in senescent red blood cells. The remainder comes from prematurely destroyed erythroid cells in bone marrow and from the turnover of hemoproteins such as myoglobin and cytochromes found in tissues throughout the body.

The formation of bilirubin occurs in reticuloendothelial cells, primarily in the spleen and liver. The first reaction, catalyzed by the microsomal enzyme heme oxygenase, oxidatively cleaves the α bridge of the porphyrin group and opens the heme ring. The end products of this reaction are biliverdin, carbon monoxide, and iron. The second reaction, catalyzed by the cytosolic enzyme biliverdin reductase, reduces the central methylene bridge of biliverdin and converts it to bilirubin. Bilirubin formed in the reticuloendothelial cells is virtually insoluble in water. This is due to tight internal hydrogen bonding between the water-soluble moieties of bilirubin, propionic acid carboxyl groups of one dipyrrole half of the molecule with the imino and lactam groups of the opposite half. This configuration blocks solvent access to the polar residues of bilirubin and places the hydrophobic residues on the outside. To be transported in blood, bilirubin must be solubilized. This is accomplished by its reversible, noncovalent binding to albumin. Unconjugated bilirubin bound to albumin is transported to the liver, where it, but not the albumin, is taken up by hepatocytes via a process that at least partly involves carrier-mediated membrane transport. No specific bilirubin transporter has yet been identified (Chap. 284, Fig. 284-1).

After entering the hepatocyte, unconjugated bilirubin is bound to the cytosolic protein ligandin, or glutathione S-transferase B. Whereas ligandin was initially thought to be a transport protein, responsible for delivering unconjugated bilirubin from the plasma membrane to the endoplasmic reticulum, it now appears that its role may in fact be to reduce bilirubin efflux back into the plasma. Studies suggest that unconjugated bilirubin may well rapidly diffuse unaided through the aqueous cytosol between membranes. In the endoplasmic reticulum, bilirubin is solubilized by conjugation to glucuronic acid, a process that disrupts the internal hydrogen bonds and yields bilirubin monoglucuronide and diglucuronide. The conjugation of glucuronic acid to bilirubin is catalyzed by bilirubin uridine-diphosphate (UDP) glucuronosyltransferase. The now hydrophilic bilirubin conjugates diffuse from the endoplasmic reticulum to the canalicular membrane, where bilirubin monoglucuronide and diglucuronide are actively transported into biliary bile by an energy-dependent mechanism involving the multiple drug resistance protein 2.

The conjugated bilirubin excreted into bile drains into the duodenum and passes unchanged through the proximal small bowel. Conjugated bilirubin is not taken up by the intestinal mucosa. When the conjugated bilirubin reaches the distal ileum and colon, it is hydrolyzed to unconjugated bilirubin by bacterial β-glucuronidases. The unconjugated bilirubin is reduced by normal gut bacteria to form a group of colorless tetrapyroles called urobilinogens. About 80% to 90% of these products are excreted in feces, either unchanged or oxidized to orange derivatives called urobilins. The remaining 10% to 20% of the urobilinogens are passively absorbed, enter the portal venous blood, and are reexcreted by the liver. A small fraction (usually <3 mg/dL) escapes hepatic uptake, filters across the renal glomerulus, and is excreted in urine.

**MEASUREMENT OF SERUM BILIRUBIN** The terms direct- and indirect-reacting bilirubin are based on the original van den Bergh reaction. This assay, or a variation of it, is still used in most clinical chemistry laboratories to determine the serum bilirubin level. In this assay, bilirubin is exposed to diazotized sulfanilic acid, splitting into two relatively stable dipyrromethene azopigments that absorb maximally at 540 nm, allowing for photometric analysis. The direct fraction is that which reacts with diazotized sulfanilic acid in the absence of an accelerator substance such as alcohol. The direct fraction provides an approximate determination of the conjugated bilirubin. The total serum bilirubin is the amount that reacts after the addition of alcohol. The indirect fraction is the difference between the total and the direct bilirubin and provides an estimate of the unconjugated bilirubin in serum.

With the van den Bergh method, the normal serum bilirubin concentration usually is 17 μmol/L (<1 mg/dL). Up to 30%, or 5.1 μmol/L (0.3 mg/dL), of the total may be direct-reacting (conjugated) bilirubin. Total serum bilirubin concentrations are between 3.4 and 15.4 μmol/L (0.2 and 0.9 mg/dL) in 95% of a normal population.

Several new techniques, although less convenient to perform, have added considerably to our understanding of bilirubin metabolism. First, they demonstrate that in normal persons or those with Gilbert’s syndrome, almost 100% of the serum bilirubin is unconjugated; <3% is monoglucuronated bilirubin. Second, in jaundiced patients with hepato-biliary disease, the total serum bilirubin concentration measured by these new, more accurate methods is lower than the values found with diazo methods. This suggests that there are diazo-positive compounds distinct from bilirubin in the serum of patients with hepatobiliary disease. Third, these studies indicate that in jaundiced patients with hepatobiliary disease, monoglucuronides of bilirubin predominate over the diglucuronides. Fourth, part of the direct-reacting bilirubin fraction includes conjugated bilirubin that is covalently linked to albumin. This albumin-linked bilirubin fraction (delta fraction or biliprotein) represents an important fraction of total serum bilirubin in patients with cholestasis and hepatobiliary disorders. Albumin-bound conjugated bilirubin is formed in serum when hepatic excretion of bilirubin glucuronides is impaired and the glucuronides are present in serum in increasing amounts. By virtue of its tight binding to albumin, the clearance rate of albumin-bound bilirubin from serum approximates the half-life of albumin, 12 to 14 days, rather than the short half-life of bilirubin, about 4 h.

The prolonged half-life of albumin-bound conjugated bilirubin explains two previously unexplained enigmas in jaundiced patients with liver disease: (1) that some patients with conjugated hyperbilirubinemia do not exhibit bilirubinuria during the recovery phase of their disease because the bilirubin is bound to albumin and therefore not filtered by the renal glomeruli and (2) that the elevated serum bilirubin level declines more slowly than expected in some patients who otherwise appear to be recovering satisfactorily. Late in the recovery phase of hepatobiliary disorders, all the conjugated bilirubin may be in the albumin-linked form. Its value in serum falls slowly because of the long half-life of albumin.

**MEASUREMENT OF URINE BILIRUBIN** Unconjugated bilirubin is always bound to albumin in the serum, is not filtered by the kidney, and is not found in the urine. Conjugated bilirubin is filtered at the glomerulus and the majority is reabsorbed by the proximal tubules; a small fraction is excreted in the urine. Any bilirubin found in the urine is conjugated bilirubin. The presence of bilirubinuria implies the presence of liver disease. A urine dipstick test (Ictotest) gives the same information as fractionation of the serum bilirubin. This test is very accurate. A false-negative test is possible in patients with prolonged cholestasis due to the predominance of conjugated bilirubin covalently bound to albumin.

**APPROACH TO THE PATIENT** The bilirubin present in serum represents a balance between input from production of bilirubin and hepatic/biliary removal of the pigment. Hyperbilirubinemia may result from (1) overproduction of bilirubin; (2) impaired uptake, conjugation, or excretion of bilirubin; or (3) regurgitation of unconjugated or conjugated bilirubin from damaged hepatocytes or bile ducts. An increase in unconjugated bilirubin in serum results from either overproduction, impairment of uptake, or conjugation of bilirubin. An increase in conjugated bilirubin is due to decreased excretion into the bile ductules or regurgitation of unconjugated bilirubin from damaged hepatocytes or bile ducts. The initial step in evaluating the patient with jaundice is to determine (1) whether the hyperbilirubinemia is predominantly conjugated or unconjugated in na-
Acquired hemolytic disorders include microangiopathic hemolytic anemia (e.g., hemolytic-uremic syndrome), paroxysmal nocturnal hemoglobinuria, and immune hemolysis. Immune hemolysis occurs in covalamin, folate, and iron deficiencies.

In the absence of hemolysis, the physician should consider a problem with the hepatic uptake or conjugation of bilirubin. Certain drugs, including rifampicin and probenecid, may cause unconjugated hyperbilirubinemia by diminishing hepatic uptake of bilirubin. Impaired bilirubin conjugation occurs in three genetic conditions: Crigler-Najjar syndrome, types I and II, and Gilbert’s syndrome. Crigler-Najjar type I is an exceptionally rare condition found in neonates and characterized by severe jaundice ([bilirubin >342 μmol/L (> 20 mg/dL)] and neurologic impairment due to kernicterus, frequently leading to death in infancy or childhood. These patients have a complete absence of bilirubin UDP glucuronosyltransferase activity, usually due to mutations in the critical 3’ domain of the UDP glucuronosyltransferase gene, and are totally unable to conjugate, hence cannot excrete bilirubin. The only effective treatment is orthotopic liver transplantation. Use of gene therapy and allogeneic hepatocyte infusion are promising for this devastating disease. Crigler-Najjar type II is somewhat more common than type I. Patients live into adulthood with serum bilirubin levels that range from 103 to 428 μmol/L (6 to 25 mg/dL). In these patients, mutations in the bilirubin UDP glucuronosyltransferase gene are associated with decreased UDP glucuronosyltransferase activity.

### Isolated Elevation of Serum Bilirubin

- **UNCONJUGATED HYPERBILIRUBINEMIA**

  The differential diagnosis of an isolated unconjugated hyperbilirubinemia is limited (Table 38-1). The critical determination is whether the patient is suffering from a hemolytic process resulting in an overproduction of bilirubin (hemolytic disorders and ineffective erythropoiesis) or from impaired hepatic uptake/conjugation of bilirubin (drug effect or genetic disorders).

  Hemolytic disorders that cause excessive heme production may be either inherited or acquired. Inherited disorders include spherocytosis, sickle cell anemia, and deficiency of red cell enzymes such as pyruvate kinase and glucose-6-phosphate dehydrogenase. In these conditions, the serum bilirubin rarely exceeds 56 μmol/L (3 mg/dL). Higher levels may occur when there is coexistent renal or hepatocellular dysfunction, or in acute hemolysis such as a sickle cell crisis. In evaluating jaundice in patients with chronic hemolysis, it is important to remember the high incidence of pigmented (calcium bilirubinate) gallstones found in these patients, which increases the likelihood of cholelithiasis as an alternative explanation for hyperbilirubinemia.
Elevated conjugated hyperbilirubinemia is found in two rare inherited conditions: Dubin-Johnson syndrome and Rotor’s syndrome (Table 38-1). Patients with both conditions present with asymptomatic jaundice, typically in the second generation of life. The defect in Dubin-Johnson syndrome is mutations in the gene for multiple drug resistance protein 2. These patients have altered excretion of bilirubin into the bile ducts. Rotor’s syndrome seems to be a problem with the hepatic storage of bilirubin. Differentiating between these syndromes is possible, but clinically unnecessary, due to their benign nature.

**Elevation of Serum Bilirubin with Other Liver Test Abnormalities** The remainder of this chapter will focus on the evaluation of the patient with a conjugated hyperbilirubinemia in the setting of other liver test abnormalities. This group of patients can be divided into those with a primary hepatocellular process and those with intra- or extrahepatic cholestasis. Being able to make this differentiation will guide the physician’s evaluation (Fig. 38-1). This differentiation is made on the basis of the history and physical examination as well as the pattern of liver test abnormalities.

**HISTORY** A complete medical history is perhaps the single most important part of the evaluation of the patient with unexplained jaundice. Important considerations include the use of or exposure to any chemical or medication, either physician-prescribed or over-the-counter, such as herbal and vitamin preparations and other drugs such as anabolic steroids. The patient should be carefully questioned about possible parental exposures, including transfusions, intravenous and intranasal drug use, tattoos, and sexual activity. Other important questions include recent travel history, exposure to people with jaundice, exposure to possibly contaminated foods, occupational exposure to hepatotoxins, alcohol consumption, the duration of jaundice, and the presence of any accompanying symptoms such as arthralgias, myalgias, rash, anorexia, weight loss, abdominal pain, fever, pruritus, and changes in the urine and stool. While none of these latter symptoms are specific for any one condition, they can suggest a particular diagnosis. A history of arthralgias and myalgias predating jaundice suggests hepatitis, either viral or drug-related. Jaundice associated with the sudden onset of severe right upper quadrant pain and shaking chills suggests choledocholithiasis and ascending cholangitis.

**PHYSICAL EXAMINATION** The general assessment should include assessment of the patient’s nutritional status. Temporal and proximal muscle wasting suggests long-standing diseases such as pancreatic cancer or cirrhosis. Stigmata of chronic liver disease, including spider nevi, palmar erythema, gynecomastia, caput medusae, Dupuytren’s contractures, parotid gland enlargement, and testicular atrophy are commonly seen in advanced alcoholic (Laennec’s) cirrhosis and occasionally in other types of cirrhosis. An enlarged left supraclavicular node (Virchow’s node) or periumbilical nodule (Sister Mary Joseph’s nodule) suggests an abdominal malignancy. Jugular venous distention, a sign of right-sided heart failure, suggests hepatic congestion. Right pleural effusion, in the absence of clinically apparent ascites, may be seen in advanced cirrhosis.

The abdominal examination should focus on the size and consistency of the liver, whether the spleen is palpable and hence enlarged, and whether there is ascites present. Patients with cirrhosis may have an enlarged left lobe of the liver which is felt below the xiphoid and an enlarged spleen. A grossly enlarged nodular liver or an obvious abdominal mass suggests malignancy. An enlarged tender liver could be viral or alcoholic hepatitis or, less often, an acutely congested liver secondary to right-sided heart failure. Severe right upper quadrant tenderness with respiratory arrest on inspiration (Murphy’s sign) suggests cholecystitis or, occasionally, ascending cholangitis. Ascites in the presence of jaundice suggests either cirrhosis or malignancy with peritoneal spread.

**Llaboratory Tests** When the physician encounters a patient with unexplained jaundice, there are a battery of tests that are helpful in the initial evaluation. These include total and direct serum bilirubin with fractionation, aminotransferases, alkaline phosphatase, albumin, and prothrombin time tests. Enzyme tests [alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase] are helpful in differentiating between a hepatocellular process and a cholestatic process (Table 283-1; Fig. 38-1), a critical step in determining what additional workup is indicated. Patients with a hepatocellular process generally have a disproportionate rise in the aminotransferases compared to the alkaline phosphatase. Patients with a cholestatic process have a disproportionate rise in the alkaline phosphatase compared to the aminotransferases. The bilirubin can be prominently elevated in both hepatocellular and cholestatic conditions and therefore is not necessarily helpful in differentiating between the two.

In addition to the enzyme tests, all jaundiced patients should have additional blood tests, specifically an albumin level and a prothrombin time, to assess liver function. A low albumin suggests a chronic process such as cirrhosis or cancer. A normal albumin is suggestive of a more acute process such as viral hepatitis or cholelithiasis. An elevated prothrombin time indicates either vitamin K deficiency due to prolonged jaundice and malabsorption of vitamin K or significant hepatocellular dysfunction. The failure of the prothrombin time to correct with parenteral administration of vitamin K indicates severe hepatocellular injury.

The results of the bilirubin, enzyme, albumin, and prothrombin time tests will usually indicate whether a jaundiced patient has a hepatocellular or a cholestatic disease. The causes and evaluation of each of these are quite different.

**Hepatocellular Conditions** Hepatocellular diseases that can cause jaundice include viral hepatitis, drug or environmental toxicity, alcohol, and end-stage cirrhosis from any cause (Table 38-2). Wilson’s disease should be considered in young adults. Autoimmune hepatitis is typically seen in young to middle-aged women but may affect men and women of any age. Alcoholic hepatitis can be differentiated from viral and toxin-related hepatitis by the pattern of the aminotransferases. Patients with alcoholic hepatitis typically have an AST:ALT ratio of at least 2:1. The AST rarely exceeds 300 U/L. Patients with acute viral hepatitis and toxin-related injury severe enough to produce jaundice typically have aminotransferases greater than 500 U/L, with the ALT greater than or equal to the AST. The degree of aminotransferase elevation can occasionally help in differentiating between hepatocellular and cholestatic...
Although ultrasonography may indicate extrahepatic cholestasis, it rarely identifies the site or cause of obstruction. The distal common bile duct is a particularly difficult area to visualize by ultrasound because of overlying bowel gas. Appropriate next tests include computed tomography (CT) and endoscopic retrograde cholangiopancreatography (ERCP). CT scanning is better than ultrasonography for assessing the head of the pancreas and for identifying choledocholithiasis in the distal common bile duct, particularly when the ducts are not dilated. ERCP is the “gold standard” for identifying choledocholithiasis. It is performed by introducing a side-viewing endoscope perorally into the duodenum. The ampulla of Vater is visualized and a catheter is advanced through the ampulla. Injection of dye allows for the visualization of the common bile duct and the pancreatic duct. The success rate for cannulation of the common bile duct ranges from 80 to 95%, depending on the operator’s experience. Beyond its diagnostic capabilities, ERCP allows for therapeutic interventions, including the removal of common bile duct stones and the placement of stents. In patients in whom ERCP is unsuccessful, transhepatic cholangiography can provide the same information. Magnetic resonance cholangiopancreatography is a rapidly developing, noninvasive technique for imaging the bile and pancreatic ducts; this may replace ERCP as the initial diagnostic test in cases where the need for intervention is felt to be small.

In patients with apparent intrahepatic cholestasis, the diagnosis is often made by serologic testing in combination with percutaneous liver biopsy. The list of possible causes of intrahepatic cholestasis is long and varied (Table 38-3). A number of conditions that typically cause a hepatocellular pattern of injury can also present as a cholestatic variant. Both hepatitis B and C can cause a cholestatic hepatitis (fibrosing cholestatic hepatitis) that has histologic features that mimic large duct obstruction. This disease variant has been reported in patients who have undergone solid organ transplantation. Hepatitis A, alcoholic hepatitis, EBV, and CMV may also present as cholestatic liver disease.

Drugs may cause intrahepatic cholestasis, a variant of drug-induced hepatitis. Drug-induced cholestasis is usually reversible after eliminating the offending drug, although it may take many

months for cholestasis to resolve. Drugs most commonly associated with cholestasis are the anabolic and contraceptive steroids. Cholestatic hepatitis has been reported with chlorpromazine, imipramine, tolbutamide, sulindac, cimetidine, and erythromycin estolate. It also occurs in patients taking trimethoprim, sulfamethoxazole, and penicillin-based antibiotics such as ampicillin, dicloxacillin, and clavulanic acid. Rarely, cholestasis may be chronic and associated with progressive fibrosis despite early discontinuation of the drug. Chronic cholestasis has been associated with chlorpromazine and prochlorperazine.

Primary biliary cirrhosis is a disease predominantly of middle-aged women in which there is a progressive destruction of interlobular bile ducts. The diagnosis is made by the presence of the antimitochondrial antibody that is found in 95% of patients. Primary sclerosing cholangitis is characterized by the destruction and fibrosis of larger bile ducts. The disease may involve only the intrahepatic ducts and present as intrahepatic cholestasis. However, in 95% of patients with PSC, both intra- and extrahepatic ducts are involved. The diagnosis of PSC is made by ERCP. The pathognomonic findings are multiple strictures of bile ducts with dilatations proximal to the strictures. Approximately 75% of patients with PSC have inflammatory bowel disease.

The vanishing bile duct syndrome and adult bile ductopenia are rare conditions in which there are a decreased number of bile ducts seen in liver biopsy specimens. The histologic picture is similar to that found in primary biliary cirrhosis. This picture is seen in patients who develop chronic rejection after liver transplantation and in those who develop graft-versus-host disease after bone marrow transplantation. Vanishing bile duct syndrome also occurs in rare cases of sarcoidosis, in patients taking certain drugs including chlorpromazine, and idiopathically. There are also familial forms of intrahepatic cholestasis, including the familial intrahepatic cholestatic syndromes, I–III. Benign recurrent cholestasis is an autosomal recessive disease that appears to be due to mutations in a P type ATPase, which probably acts as a bile acid transporter. The disease is marked by recurrent episodes of jaundice and pruritus; the episodes are self-limited but can be debilitating. Cholestasis of pregnancy occurs in the second and third trimesters and resolves after delivery. Its cause is unknown, but the condition is probably inherited and cholestasis can be triggered by estrogen administration.

Other causes of intrahepatic cholestasis include total parenteral nutrition (TPN), nonhepatobiliary sepsis, benign postoperative cholestasis, and a paraneoplastic syndrome associated with a number of different malignancies, including Hodgkin’s disease, medullary thyroid cancer, hypernephroma, renal sarcoma, T cell lymphoma, prostate cancer, and several gastrointestinal malignancies. In patients developing cholestasis in the intensive care unit, the major considerations should be sepsis, shock liver, and TPN jaundice. Jaundice occurring after bone marrow transplantation is most likely due to venoocclusive disease or graft-versus-host disease.

CAUSES OF EXTRAHEPATIC CHOLESTASIS can be split into malignant and benign (Table 38-3). Malignant causes include pancreatic, gall-bladder, ampullary, and cholangiocarcinoma. The latter is most commonly associated with PSC and is exceptionally difficult to diagnose because its appearance is often identical to PSC. Pancreatic and gallbladder tumors, as well as cholangiocarcinoma, are rarely resectable and have poor prognoses. Ampullary carcinoma has the highest surgical cure rate of all the tumors that present as painless jaundice. Hilar lymphadenopathy due to metastases from other cancers may cause obstruction of the extrahepatic biliary tree.

Choleodocholithiasis is the most common cause of extrahepatic cholestasis. The clinical presentation can range from mild right upper quadrant discomfort with only minimal elevations of the enzyme tests to ascending cholangitis with jaundice, sepsis, and circulatory collapse. PSC may occur with clinically important strictures limited to the extrahepatic biliary tree. In cases where there is a dominant stricture, patients can be effectively managed with serial endoscopic dilatations. Chronic pancreatitis rarely causes strictures of the distal common bile duct, where it passes through the head of the pancreas. AIDS cholangiopathy is a condition, usually due to infection of the bile duct epithelium with CMV or cryptosporidia, which has a cholangiographic appearance similar to that of PSC. These patients usually present with greatly elevated serum alkaline phosphatase levels, mean of 800 IU/L, but the bilirubin is often near normal. These patients do not typically present with jaundice.

SUMMARY The goal of this chapter is not to provide an encyclopedic review of all of the conditions that can cause jaundice. Rather, it is intended to provide a framework that helps a physician to evaluate the patient with jaundice in a logical way (Fig. 38-1).

Simply stated, the initial step is to obtain appropriate blood tests to determine if the patient has an isolated elevation of serum bilirubin. If so, is the bilirubin elevation due to an increased unconjugated or conjugated fraction? If the hyperbilirubinemia is accompanied by other liver test abnormalities, is the disorder hepatocellular or cholestatic? If cholestatic, is it intra- or extrahepatic? All of these questions can be answered with a thoughtful history, physical examination, and interpretation of laboratory and radiologic tests and procedures.

39 Abdominal Swelling and Ascites

Robert M. Glickman

ABDOMINAL SWELLING

Abdominal swelling or distention is a common problem in clinical medicine and may be the initial manifestation of a systemic disease or of otherwise unsuspected abdominal disease. Subjective abdominal enlargement, often described as a sensation of fullness or bloating, is usually transient and is often related to a functional gastrointestinal disorder when it is not accompanied by objective physical findings of increased abdominal girth or local swelling. Obesity and lumbar lordosis, which may be associated with prominence of the abdomen, may usually be distinguished from true increases in the volume of the peritoneal cavity by history and careful physical examination.

CLINICAL HISTORY Abdominal swelling may first be noticed by the patient because of a progressive increase in belt or clothing size, the appearance of abdominal or inguinal hernias, or the development of a localized swelling. Often, considerable abdominal enlargement has gone unnoticed for weeks or months, either because of coexistent obesity or because the ascites formation has been insidious, without pain or localizing symptoms. Progressive abdominal distention may be as-
associated with a sensation of “pulling” or “stretching” of the flanks or groins and vague low back pain. Localized pain usually results from involvement of an abdominal organ (e.g., a passively congested liver, large spleen, or colonic tumor). Pain is uncommon in cirrhosis with ascites, and when it is present, pancreatitis, hepatocellular carcinoma, or peritonitis should be considered. Tense ascites or abdominal tumors may produce increased intraabdominal pressure, resulting in indigestion and heartburn due to gastroesophageal reflux or dyspnea, abdominal wall hernias (inguinal and umbilical) orthopnea, and tachypnea from elevation of the diaphragm. A coexistent pleural effusion, more commonly on the right, presumably due to leakage of ascitic fluid through lymphatic channels in the diaphragm, may also contribute to respiratory embarrassment. A large pleural effusion, obscuring most of the lung is known as a hepatic hydrothorax. The patient with diffuse abdominal swelling should be questioned about increased alcohol intake, a prior episode of jaundice or hematuria, or a change in bowel habits. Such historic information may provide the clues that will lead one to suspect an occult cirrhosis, a colonic tumor with peritoneal seeding, congestive heart failure, or nephrosis.

**Physical Examination** A carefully executed general physical examination can yield valuable clues concerning the etiology of abdominal swelling. Thus palmar erythema and spider angiomata suggest an underlying cirrhosis, while supraclavicular adenopathy (Virchow’s node) should raise the question of an underlying gastrointestinal malignancy.

**Inspection** of the abdomen is important. By noting the abdominal contour, one may be able to distinguish localized from generalized swelling. The tensely distended abdomen with tightly stretched skin, bulging flanks, and everted umbilicus is characteristic of ascites. A prominent abdominal venous pattern with the direction of flow away from the umbilicus is often a reflection of portal hypertension; venous collaterals with flow from the lower part of the abdomen toward the umbilicus suggest obstruction of the inferior vena cava; flow downward toward the umbilicus suggests superior vena cava obstruction. “ Doming” of the abdomen with visible ridges from underlying intestinal loops is usually due to intestinal obstruction or distention. An epigastric mass, with evident peristalsis proceeding from left to right, usually indicates underlying pyloric obstruction. A liver with meta-

**Auscultation** may reveal the high-pitched, rushing sounds of early intestinal obstruction or a succussion sound due to increased fluid and gas in a dilated hollow viscus. Careful auscultation over an enlarged liver occasionally reveals the harsh bruit of a vascular tumor, especially a hepatocellular carcinoma, or the leathery friction rub of a surface nodule. A venous hum at the umbilicus may signify portal hypertension and an increased collateral blood flow around the liver. A fluid wave and flank dullness that shifts with change in position of the patient are important signs that indicate the presence of peritoneal fluid. In obese patients, small amounts of fluid may be difficult to detect by abdominal percussion with patients on their hands and knees. Small amounts of ascites often can only be detected by ultrasound examination of the abdomen, which can detect as little as 100 mL of fluid. Careful percussion should serve to distinguish generalized abdominal enlargement from localized swelling due to an enlarged uterus, ovarian cyst, or distended bladder. Percussion can also outline an abnormally small or large liver. Loss of normal liver dullness may result from massive hepatic necrosis; it also may be a clue to free gas in the peritoneal cavity, as from perforation of a hollow viscus. 

**Palpation** is often difficult with massive ascites, and ballottement of overlying fluid may be the only method of palpating the liver or spleen. A slightly enlarged spleen in association with ascites may be the only evidence of an occult cirrhosis. When there is evidence of portal hypertension, a soft liver suggests that obstruction to portal flow is extrahepatic; a firm liver suggests cirrhosis as the likely cause of the portal hypertension. A very hard or nodular liver is a clue that the liver is infiltrated with tumor, and when accompanied by ascites, it suggests that the latter is due to peritoneal seeding. The presence of a hard peri umbilical nodule (Sister Mary Joseph’s nodule) suggests metastatic disease from a pelvic or gastrointestinal primary tumor. A pulsatile liver and ascites may be found in tricuspid insufficiency.

An attempt should be made to determine whether a mass is solid or cystic, smooth or irregular, and whether it moves with respiration. The liver, spleen, and gallbladder should descend with respiration unless they are fixed by adhesions or extension of tumor beyond the organ. A fixed mass not descending with respiration may indicate that it is retroperitoneal. Tenderness, especially if localized, may indicate an inflammatory process such as an abscess; it also may be due to stretching of the visceral peritoneum or tumor necrosis. Rectal and pelvic examinations are mandatory; they may reveal otherwise undetected masses due to tumor or infection.

**Radiographic and laboratory examinations** are essential for confirming or extending the impressions gained on physical examination. Upright and recumbent films of the abdomen may demonstrate the dilated loops of intestine with fluid levels characteristic of intestinal obstruction or the diffuse abdominal haziness and loss of psoas margins suggestive of ascites. Ultrasonography is often of value in detecting ascites, determining the presence of a mass, or evaluating the size of the liver and spleen. Computed tomography (CT) scanning provides similar information. CT scanning is often necessary to visualize the retroperitoneum, pancreas, and lymph nodes. A plain film of the abdomen may reveal the distended colon of otherwise unsuspected ulcerative colitis and give valuable information as to the size of the liver and spleen. An irregular and elevated right side of the diaphragm may be a clue to a liver abscess or hepatocellular carcinoma. Studies of the gastrointestinal tract with barium or other contrast media are usually necessary in the search for a primary tumor.

**Ascites**

The evaluation of a patient with ascites requires that the cause of the ascites be established. In most cases ascites appears as part of a well-recognized illness, that is, cirrhosis, congestive heart failure, nephrosis, or disseminated carcinomatosis. In these situations, the physician should determine that the development of ascites is indeed a consequence of the basic underlying disease and not due to the presence of a separate or related disease process. This distinction is necessary even when the cause of ascites seems obvious. For example, when the patient with compensated cirrhosis and minimal ascites develops progressive ascites that is increasingly difficult to control with sodium restriction or diuretics, the temptation is to attribute the worsening of the clinical picture to progressive liver disease. However, an occult hepatocellular carcinoma, portal vein thrombosis, spontaneous bacterial peritonitis, or even tuberculosis may be responsible for the decompensation. The disappointingly low success in diagnosing tuberculous peritonitis or hepatocellular carcinoma in the patient with cirrhosis and ascites reflects the too-low index of suspicion for the development of such superimposed conditions. Similarly, the patient with congestive heart failure may develop ascites from a disseminated carcinoma with peritoneal seeding.

Diagnostic paracentesis (50 to 100 mL) should be part of the routine evaluation of the patient with ascites. The fluid should be examined for its gross appearance; protein content, cell count, and differential cell count should be determined; and Gram’s and acid-fast stains and culture should be performed. Cytologic and cell-block examination may disclose an otherwise unsuspected carcinoma. Table 39-1 presents some of the features of ascitic fluid typically found in various disease states. In some disorders, such as cirrhosis, the fluid has the characteristics of a transudate (<25 g protein per liter and a specific gravity of <1.016); in others, such as peritonitis, the features are those of an exudate. Rather than the total protein content of ascites, many clinicians prefer the use of a serum-ascites albumin gradient (SAG) to characterize ascites. The gradient correlates directly with portal pressure. A gradient >1.1 g/dL (high gradient) is characteristic
of uncomplicated cirrhotic ascites and differentiates ascites due to portal hypertension from ascites not due to portal hypertension >95% of the time. A gradient <1.1 g/dL (low gradient) suggests that the ascites is not due to portal hypertension with >95% accuracy and mandates a search for other causes (Table 39-1). Although there is variability of the ascitic fluid in any given disease state, some features are sufficiently characteristic to suggest certain diagnostic possibilities. For example, blood-stained fluid with >25 g protein per liter is unusual in uncomplicated cirrhosis but is consistent with tuberculous peritonitis or neoplasm. Cloudy fluid with a predominance of polymorphonuclear cells and a positive Gram’s stain are characteristic of bacterial peritonitis; if most cells are lymphocytes, tuberculosis should be suspected. The complete examination of each fluid is most important, for occasionally only one finding may be abnormal. For example, if the fluid is a typical transudate but contains >250 white blood cells per microliter, the finding should be recognized as atypical for cirrhosis and should warrant a search for tumor or infection. This is especially true in the evaluation of cirrhotic ascites where occult peritoneal infection may be present with only minor elevations in the white blood cell count of the peritoneal fluid (300 to 500 cells/μL). Since Gram’s stain of the fluid may be negative in a high proportion of such cases, careful culture of the peritoneal fluid is mandatory. Bedside inoculation of blood culture flasks with ascitic fluid results in a dramatically increased incidence of positive cultures when bacterial infection is present (90 versus 40% positivity with conventional cultures done by the laboratory). Direct visualization of the peritoneum (laparoscopy) may disclose peritoneal deposits of tumor, tuberculosis, or metastatic disease of the liver. Biopsies are taken under direct vision, often adding to the diagnostic accuracy of the procedure.

**Chylous ascites** refers to a turbid, milky, or creamy peritoneal fluid due to the presence of thoracic or intestinal lymph. Such a fluid shows Sudan-staining fat globules microscopically and an increased triglyceride content by chemical examination. Opaque milky fluid usually has a triglyceride concentration of >11.3 μmol/L (>1000 mg/dL). A turbid fluid due to leukocytes or tumor cells may be confused with chylous fluid (pseudochylous), and it is often helpful to carry out alkalinization and ether extraction of the specimen. Alkali tend to dissolve cellular proteins and thereby reduce turbidity; ether extraction leads to clearing if the turbidity of the fluid is due to lipid. Chylous ascites is most often the result of lymphatic obstruction from trauma, tumor, tuberculosis, filariasis (Chap. 202), or congenital abnormalities. It may also be seen in the nephrotic syndrome.

Rarely, ascitic fluid may be *necrinos* in character, suggesting either pseudomyxoma peritonei (Chap. 279) or rarely a colloid carcinoma of the stomach or colon with peritoneal implants. On occasion, ascites may develop as a seemingly isolated finding in the absence of a clinically evident underlying disease. Then, a careful analysis of ascitic fluid may indicate the direction the evaluation should take. A useful framework for the workup starts with an analysis of whether the fluid is classified as a high (transudate) or low (exudate) gradient fluid. High gradient (transudative) ascites of unclear etiology is most often due to occult cirrhosis, right-sided venous hypertension raising hepatic sinusoidal pressure, or hypoalbuminemic states such as nephrosis or protein-losing enteropathy. Cirrhosis with well-preserved liver function (normal albumin) resulting in ascites is invariably associated with significant portal hypertension (Chap. 288). Evaluation should include liver function tests, liver-spleen scan, or other hepatic imaging procedure (i.e., CT or ultrasound) to detect nodular changes in the liver or a colloid shift of isotope to suggest portal hypertension.

On occasion, a wedged hepatic venous pressure can be useful to document portal hypertension. Finally, if clinically indicated, a liver biopsy will confirm the diagnosis of cirrhosis and perhaps suggest its etiology. Other etiologies may result in hepatic venous congestion and resultant ascites. Right-sided cardiac valvular disease and particularly constrictive pericarditis should raise a high index of suspicion and may require cardiac imaging and cardiac catheterization for definitive diagnosis. Hepatic vein thrombosis is evaluated by visualizing the hepatic veins with imaging techniques (Doppler ultrasound, angiography, CT scans, magnetic resonance imaging) to demonstrate obliteration, thrombosis, or obstruction by tumor. Uncommonly,

*Because the conditions of examining fluid and selecting patients were not identical in each series, the percentage figures (in parentheses) should be taken as an indication of the order of magnitude rather than as the precise incidence of any abnormal finding.*
transudative ascites may be associated with benign tumors of the ovary, particularly fibroma (Meigs’ syndrome) with ascites and hydrothorax.

Low gradient (exudative) ascites should initiate an evaluation for primary peritoneal processes, most importantly infection and tumor. Routine bacteriologic culture of ascitic fluid often yields a specific organism causing infectious peritonitis. Tuberculous peritonitis (Table 39-1) is best diagnosed by peritoneal biopsy, either percutaneously or via laparoscopy. Histologic examination invariably shows granuloma that may contain acid-fast bacilli. Since cultures of peritoneal fluid and biopsies for tuberculosis may require 6 weeks, characteristic histology with appropriate stains allows antituberculosis therapy to be started promptly. Similarly, the diagnosis of peritoneal seeding by tumor can usually be made by cytologic analysis of peritoneal fluid or by peritoneal biopsy if cytology is negative. Appropriate diagnostic studies can then be undertaken to determine the nature and site of the primary tumor. Pancreatic ascites (Table 39-1) is invariably associated with an extravasation of pancreatic fluid from the pancreatic ductal system, most commonly from a leaking pseudocyst. Ultrasound or CT examination of the pancreas followed by visualization of the pancreatic duct by direct cannulation [viz., endoscopic retrograde cholangiopancreatography (ERCP)] usually discloses the site of leakage and permits resective surgery to be carried out.

An analysis of the physiologic and metabolic factors involved in the production of ascites (detailed in Chap. 288), coupled with a complete evaluation of the nature of the ascitic fluid, invariably discloses the etiology of the ascites and permits appropriate therapy to be instituted.

ACKNOWLEDGMENT

**Section 7 Alterations in Renal and Urinary Tract Function**

**40 AZOTEMIA AND URINARY ABNORMALITIES**
Bradley M. Denker, Barry M. Brenner

Body homeostasis is maintained predominantly through the cellular processes that together comprise normal kidney function. Disturbances to any of these functions can lead to a constellation of abnormalities that may be detrimental to survival. The clinical manifestations of these diseases will depend upon the pathophysiology of the renal injury and will often be initially identified as a complex of symptoms, abnormal physical findings, and laboratory changes that will allow the identification of specific syndromes. These renal syndromes (summarized in Table 40-1) may arise as the consequence of a systemic illness or can occur as a primary renal disease. Nephrologic syndromes usually consist of several elements that reflect the underlying pathologic processes and the duration of the disease and typically include one or more of the following features: (1) disturbances in urine volume (oliguria, anuria, polyuria); (2) abnormalities of urine sediment [red blood cells (RBC); white blood cells, casts, and crystals]; (3) abnormal excretion of serum proteins (proteinuria); (4) reduction in glomerular filtration rate (GFR) (azotemia); (5) presence of hypertension and/or expanded total body volume (edema); (6) electrolyte abnormalities; or (7) in some syndromes, fever/pain. The combination of these findings should permit identification of one of the major nephrologic syndromes (Table 40-1) and will allow the differential diagnoses to be narrowed and the appropriate diagnostic evaluation and therapeutic course to be determined. Each of these syndromes and their associated diseases are discussed in more detail in subsequent chapters. This chapter will focus on several aspects of renal abnormalities that are critically important to distinguishing these processes: (1) reduction in GFR leading to azotemia, (2) alterations of the urinary sediment and/or protein excretion, and (3) abnormalities of urinary volume.

**AZOTEMIA**

**ASSESSMENT OF GLOMERULAR FILTRATION RATE**

Monitoring the GFR is important in both the hospital and outpatient settings, and several different methodologies are available (discussed below). In most acute clinical circumstances a measured GFR is not available, and it is necessary to estimate the GFR from the serum creatinine level in order to provide appropriate doses of drugs that are excreted into the urine. Serum creatinine is the most widely used marker for GFR, and the GFR is related directly to the urine creatinine excretion and inversely to the serum creatinine \( \left( \frac{U_C}{P_C} \right) \). Based upon this relationship and some important caveats (discussed below), the GFR will fall proportionately with the increase in \( P_C \). Failure to account for GFR reductions in drug dosing can lead to significant morbidity and mortality from drug toxicities (e.g., digoxin, aminoglycosides). In the outpatient setting, the serum creatinine is often used as a surrogate for GFR (although much less accurate; see below). In patients with chronic progressive renal failure there is an approximately linear relationship between \( 1/P_C \) and time. The slope of this line will remain constant for an individual patient, and when values are obtained that do not fall on this line, an investigation for a superimposed acute process (e.g., volume depletion, drug reaction) should be initiated. It should be emphasized that the signs and symptoms of uremia will develop at significantly different levels of serum creatinine depending upon the patient (size, age, and sex), the underlying renal disease, existence of concurrent diseases, and true GFR. In general, patients do not develop symptomatic uremia until renal insufficiency is usually quite severe (GFR < 15 mL/min).

A reduced GFR leads to retention of nitrogenous waste products (azotemia) such as serum urea nitrogen and creatinine. Azotemia may result from reduced renal perfusion, intrinsic renal disease, or postrenal processes (ureteral obstruction; see below and Fig. 40-1). Precise determination of GFR is problematic as both commonly used markers (urea and creatinine) have characteristics that affect their accuracy as markers of clearance. Urea clearance is generally an underestimate of GFR because of tubule urea reabsorption and may be as low as one-half of GFR measured by other techniques.

Creatinine is a small, freely filtered solute that varies little from day to day (since it is derived from muscle metabolism of creatine). However, serum creatinine can increase acutely from dietary ingestion of cooked meat. Creatinine can be secreted by the proximal tubule through an organic cation pathway. There are many clinical settings where a creatinine clearance is not available, and decisions concerning
with acute renal failure. Radiographic evidence of renal osteodystrophy (Chap. 261) would be seen only in chronic renal failure but is a very late finding, and these patients are usually on dialysis. The urinalysis and renal ultrasound can occasionally facilitate distinguishing acute from chronic renal failure. An approach to the evaluation of azotemic patients is shown in Fig. 40-1. Patients with advanced chronic renal insufficiency often have some proteinuria, nonconcentrated urine (isosthenuria), and small kidneys on ultrasound characterized by increased echogenicity and cortical thinning. Treatment should be directed toward slowing the progression of renal disease and providing symptomatic relief for edema, acidosis, anemia, and hyperphosphatemia, as discussed in Chap. 261.

### PRERENAL FAILURE
Decreased renal perfusion accounts for 40 to 80% of acute renal failure and, if appropriately treated, is readily reversible. The etiologies of prerenal azotemia include any cause of decreased circulating blood volume such as volume loss (gastrointestinal hemorrhage, burns, diarrhea, diuretics), volume sequestration (pancreatitis, peritonitis, rhabdomyolysis), or decreased effective circulating volume (cardiogenic shock, sepsis). Renal perfusion can also be affected by reductions in cardiac output from peripheral vasodilatation (sepsis, drugs) or profound renal vasoconstriction [severe heart failure, hepatorenal syndrome, drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs)]. True, or “ef-

Hypovolemia leads to a fall in mean arterial pressure, which in turn triggers a series of neural and humoral responses that include activation of the sympathetic nervous and renin-angiotensin-aldosterone systems and ADH release. GFR is maintained by prostaglandin-mediated relaxation of afferent arterioles and angiotensin II–mediated constriction of efferent arterioles. Once the mean arterial pressure falls below 80 mmHg, there is a steep decline in GFR.

Blockade of prostaglandin production by NSAIDs can result in severe vasoconstriction and acute renal failure under these circumstances. Angiotensin-converting enzyme (ACE) inhibitors decrease efferent arteriolar tone and can decrease glomerular capillary perfusion pressure. Patients on NSAIDs and/or ACE inhibitors are most susceptible to hemodynamically mediated acute renal failure when blood volume is reduced for any reason. Patients with renal artery stenosis are dependent upon efferent arteriolar vasocostrictor for maintenance of glomerular filtration pressure and are particularly susceptible to precipitous decline in GFR when given ACE inhibitors.

Prolonged renal hypoperfusion can lead to acute tubular necrosis (ATN; an intrinsic renal disease discussed below). The urinalysis and urinary electrolytes can be useful in distinguishing pre-renal azotemia from ATN (Table 40-2). The urine of patients with prerenal azotemia can be predicted from the stimulatory actions of norepinephrine, angiotensin II, ADH, and low tubule fluid flow on salt and water reabsorption. In prerenal conditions the tubules are intact, leading to a concentrated urine (>500 mosm), avid Na-reabsorption. In prerenal conditions the tubules are particularly susceptible to toxic injury by virtue of its rich blood supply (25% of renal blood flow). Blockade of prostaglandin production by NSAIDs can result in severe vasoconstriction and acute renal failure under these circumstances. Angiotensin-converting enzyme (ACE) inhibitors decrease efferent arteriolar tone and can decrease glomerular capillary perfusion pressure. Patients on NSAIDs and/or ACE inhibitors are most susceptible to hemodynamically mediated acute renal failure when blood volume is reduced for any reason. Patients with renal artery stenosis are dependent upon efferent arteriolar vasocostrictor for maintenance of glomerular filtration pressure and are particularly susceptible to precipitous decline in GFR when given ACE inhibitors.

(especially antibiotics, NSAIDs, and diuretics), severe infections (both bacterial and viral), systemic diseases (e.g., systemic lupus erythematosus), or infiltrative disorders (e.g., sarcoid, lymphoma, or leukemia). A list of drugs associated with allergic interstitial nephritis can be found in Chap. 266. The urinalysis usually shows mild to moderate proteinuria, hematuria, and pyuria (approximately 75% of cases) and occasionally white blood cell casts. The finding of RBC casts in interstitial nephritis has been reported but should prompt a search for glomerular diseases. Occasionally renal biopsy will be needed to distinguish among these possibilities. The finding of eosinophils in the urine is suggestive of allergic interstitial nephritis and is optimally observed by using a Hansel stain. The absence of eosinophiluria, however, does not exclude the possibility of acute interstitial renal nephritis.

Oclusion of large renal vessels including arteries and veins is an uncommon cause of acute renal failure. A significant reduction in GFR by this mechanism suggests bilateral processes or a unilateral process in a patient with a single functioning kidney. Renal arteries can be occluded with atheroemboli, thromboemboli, in situ thrombosis, aortic dissection, or vasculitis. Atherosclerotic renal failure can occur spontaneously but is most often associated with recent aortic instrumentation. The emboli are cholesterol-rich and lodge in medium and small renal arteries, leading to an eosinophil-rich inflammatory reaction. Patients with atherosclerotic acute renal failure often have a normal urinalysis, but the urine may contain eosinophils and casts. The diagnosis can be confirmed by renal biopsy, but this is often unnecessary when other stigmata of atheroemboli are present (livedo reticularis, distal peripheral infarcts, eosinophilia). Renal artery thrombosis may lead to mild proteinuria and hematuria, whereas renal vein thrombosis typically induces heavy proteinuria and hematuria. These vascular complications often require angiography for confirmation and are discussed in Chap. 267.

Diseases of glomeruli (glomerulonephritis or vasculitis) and the renal microvasculature (hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, or malignant hypertension) usually present with various combinations of glomerular injury: proteinuria, hematuria, reduced GFR, and alterations of Na excretion leading to hypertension, edema, and circulatory congestion (acute nephritic syndrome). These findings may occur as primary renal diseases or as renal manifestations of systemic diseases. The clinical setting and other laboratory data will help distinguish primary renal from systemic diseases. The finding of RBC casts in the urine is an indication for early renal biopsy (Fig. 40-1) as the pathologic pattern has important implications for diagnosis, prognosis, and treatment. Hematuria without RBC casts can also be an indication of glomerular disease, and this evaluation is summarized in Fig. 40-2. A detailed discussion of glomerulonephritis and diseases of the microvasculature can be found in Chap. 264.

**POSTRENA L AZOTEMIA** Urinary tract obstruction accounts for fewer than 5% of cases of acute renal failure, but it is usually reversible and must be ruled out early in the evaluation (Fig. 40-1). Since a single kidney is capable of adequate clearance, acute renal failure from obstruction requires obstruction at the urethra or bladder outlet, bilateral ureteral obstruction, or unilateral obstruction in a patient with a single functioning kidney. Obstruction is usually diagnosed by the presence of ureteral dilatation on renal ultrasound. However, early in the course of obstruction or if the ureters are unable to dilate (such as encasement by pelvic tumors), the ultrasound examination may be negative. The specific urologic conditions that cause obstruction are discussed in Chap. 270.

**OLIGURIA AND ANURIA** Oliguria refers to a 24-h urine output of <500 mL, and anuria is the complete absence of urine formation. Anuria can be caused by total urinary tract obstruction, total renal artery or vein occlusion, and shock (manifested by severe hypertension and intense renal vasoconstriction). Cortical necrosis, ATN, and rapidly progressive glomerulonephritis can occasionally cause anuria. Oliguria can accompany any cause of acute renal failure and carries a more serious prognosis for renal recovery in all conditions except prerenal azotemia. Nonoliguria refers to urine output in excess of 500 mL/day in patients with acute or chronic azotemia. With nonoliguric ATN, disturbances of potassium and hydrogen balance are less severe than in oliguric patients and recovery to normal renal function is usually more rapid.

### PROTEINURIA

The evaluation of proteinuria is shown schematically in Fig. 40-3 and is typically initiated after colorimetric detection of proteinuria by dipstick examination. The dipstick measurement detects mostly albumin and gives false-positive results when pH > 7.0 and the urine is very concentrated or contaminated with blood. A very dilute urine may obscure significant proteinuria on dipstick examination, and proteinuria that is not predominantly albumin will be missed. This is particularly important for the detection of Bence Jones proteins in the urine of patients with multiple myeloma. Tests to measure total urine concentration accurately rely on precipitation with sulfosalicylic or trichloracetic acids. Currently, ultrasensitive dipsticks are available to measure microalbuminuria (30 to 300 mg/d), an early marker of glomerular disease that has been shown to predict glomerular injury in early diabetic nephropathy (Fig. 40-3).

The magnitude of proteinuria and the protein composition in the urine depend upon the mechanism of renal injury leading to protein losses. Both charge and size selectivity normally prevent virtually all

of plasma albumin, globulins, and other large-molecular-weight proteins from crossing the glomerular wall. However, if this barrier is disrupted, there can be leakage of plasma proteins into the urine (glomerular proteinuria; Fig. 40-3). Smaller proteins (≤20 kDa) are freely filtered but are readily reabsorbed by the proximal tubule. Normal individuals excrete less than 150 mg/d of total protein and only about 30 mg/d of albumin. The remainder of the protein in the urine is secreted by the tubules (Tamm-Horsfall, IgA, and urokinase) or reabsorbed by the proximal tubule. Normal to 300 mg/d of albumin. The remainder of the protein in the urine is filtered but are readily reabsorbed by the proximal tubule. Normal to 300 mg/d of albumin. However, more exact determination of proteinuria should employ a 24-h urine collection or a spot morning protein/creatinine ratio (mg/g). The pattern of proteinuria on UPEP (urine protein electrophoresis) can be classified as "glomerular," "tubular," or "abnormal" depending upon the origin of the urine proteins. Glomerular proteinuria is due to abnormal glomerular permeability. "Tubular proteins" such as Tamm-Horsfall are normally produced by the renal tubule and shed into the urine. Abnormal circulating proteins such as kappa or lambda light chains are readily filtered because of their small size. RBC, red blood cell; FSGS, focal segmental glomerulosclerosis; MPGN, membranoproliferative glomerulonephritis.

Edema forms from primary renal sodium retention and from reduced plasma oncotic pressure, which favors fluid movement from capillaries to interstitium. The mechanisms designed to correct the decrease in effective intravascular volume contribute to edema formation in some patients. These mechanisms include activation of the renin-angiotensin system, antidiuretic hormone, and the sympathetic nervous system, which contribute to excessive renal salt and water reabsorption.

The severity of edema correlates with the degree of hypoalbuminemia and is modified by other factors such as heart disease or peripheral vascular disease. The diminished plasma oncotic pressure and urinary losses of regulatory proteins appear to stimulate hepatic lipoprotein synthesis. The resulting hyperlipidemia results in lipid bodies (fatty casts, oval fat bodies) in the urine. Other proteins are lost in the urine, leading to a variety of metabolic disturbances. These include thyroxine-binding globulin, cholesterol, and metal-binding proteins. A hypercoagulable state frequently accompanies severe nephrotic syndrome due to urinary losses of antithrombin III, reduced serum levels of proteins S and C, and hypercoagulability, and enhanced platelet aggregation. Some patients develop severe IgG deficiency with resulting defects in immunity. Many diseases (some listed in Fig. 40-3) and drugs can cause the nephrotic syndrome, and a complete list can be found in Chap. 264.

| Approach to the patient with proteinuria. Investigation of proteinuria is often initiated by a positive dipstick on routine urinalysis. Conventional dipsticks detect predominantly albumin and cannot detect urinary albumin levels of 30 to 300 mg/d. However, more exact determination of proteinuria should employ a 24-h urine collection or a spot morning protein/creatinine ratio (mg/g). The pattern of proteinuria on UPEP (urine protein electrophoresis) can be classified as “glomerular,” “tubular,” or “abnormal” depending upon the origin of the urine proteins. Glomerular proteinuria is due to abnormal glomerular permeability. “Tubular proteins” such as Tamm-Horsfall are normally produced by the renal tubule and shed into the urine. Abnormal circulating proteins such as kappa or lambda light chains are readily filtered because of their small size. RBC, red blood cell; FSGS, focal segmental glomerulosclerosis; MPGN, membranoproliferative glomerulonephritis. |

| Normal regulations of glomerular permeability by the glomerular basement membrane trap most large proteins (>100 kDa), while the foot processes of epithelial cells (podocytes) cover the urinary side of the glomerular basement membrane and produce a series of narrow channels (slit diaphragms) to allow molecular passage of small solutes and water. Some glomerular diseases, such as minimal change disease, cause fusion of glomerular epithelial cell foot processes, resulting in predominantly “selective” (Fig. 40-3) loss of albumin. Other glomerular diseases can present with disruption of the basement membrane and slit diaphragms (e.g., by immune complex deposition), resulting in large amounts of protein losses that include albumin and other plasma proteins. The fusion of foot processes causes increased pressure across the capillary basement membrane, resulting in areas with larger pore sizes. The combination of increased pressure and larger pores results in significant proteinuria (“nonselective”; Fig. 40-3). When the total daily excretion of protein exceeds 3.5 g, there is often associated hypoalbuminemia, hyperlipidemia, and edema (nephrotic syndrome; Table 40-1). However, total daily urinary protein excretion greater than 3.5 g can occur without the other features of the nephrotic syndrome in a variety of other renal diseases (Fig. 40-3). Plasma cell dyscrasias (multiple myeloma) can be associated with large amounts of excrated light chains in the urine, which may not be detected by dipstick (which detects mostly albumin). The light chains produced from these disorders are filtered by the glomerulus and overwhelm the reabsorptive capacity of the proximal tubule. A sulfosalicylic acid precipitate that is out of proportion to the dipstick estimate is suggestive of light chains (Bence Jones protein), and light chains typically redissolve upon warming of the precipitate. Renal failure from these disorders occurs through a variety of mechanisms including tubule obstruction (cast nephropathy) and light chain deposition. |

Hypoalbuminemia in nephrotic syndrome occurs through excessive urinary losses, and increased proximal tubule catabolism of filtered albumin. Hepatic rates of albumin synthesis are increased.

two to five RBCs per high-power field (HPF) and can be detected by dipstick. Common causes of isolated hematuria include stones, neoplasms, tuberculosis, trauma, and prostatitis. Gross hematuria with blood clots is almost never indicative of glomerular bleeding; rather, it suggests a postrenal source in the urinary collecting system. Evaluation of patients presenting with microscopic hematuria is outlined in Fig. 40-2. A single urinalysis with hematuria is common and can result from menstruation, viral illness, allergy, exercise, or mild trauma. Annual urinalysis of servicemen over a 10-year period showed an incidence of 38%. However, persistent or significant hematuria (>three RBCs/HPF on three urinalyses, or a single urinalysis with >100 RBCs, or gross hematuria) identified significant renal or urologic lesions in 9.1% of over 1000 patients. Even patients who are chronically anticoagulated should be investigated as outlined in Fig. 40-2. The suspicion for urogenital neoplasms in patients with isolated painless hematuria (nondysmorphic RBCs) increases with age. Neoplasms are rare in the pediatric population, and isolated hematuria is more likely to be “idiopathic” or associated with a congenital anomaly. Hematuria with pyuria and bacteria is typical of infection, and should be treated with antibiotics after appropriate cultures. Acute cystitis or pyelonephritis in women can cause gross hematuria. Hypercalcemia and hyperuricosuria are also risk factors for unexplained isolated hematuria in both children and adults. In some of these patients (50 to 60%), reducing calcium and uric acid excretion through dietary interventions can eliminate the microscopic hematuria.

Isolated microscopic hematuria can be a manifestation of glomerular diseases. The RBCs of glomerular origin are often dysmorphic when examined by phase-contrast microscopy. Irregular shapes of RBCs may also occur due to pH and osmolarity changes found in the distal tubule. There is, however, significant observer variability in detecting dysmorphic RBCs, especially if a phase-contrast microscope is not available. The most common etiologies of isolated glomerular hematuria are IgA nephropathy, hereditary nephritis, and thin basement membrane disease. IgA nephropathy and hereditary nephritis can have episodic gross hematuria. A family history of renal failure is often present in patients with hereditary nephritis, and patients with thin basement membrane disease often have other family members with microscopic hematuria. A renal biopsy is needed for the definitive diagnosis of these disorders, which are discussed in more detail in Chap. 264. Hematuria with dysmorphic RBCs, RBC casts, and protein excretion >500 mg/d is virtually diagnostic of glomerular nephropathy. RBC casts form as RBCs that enter the tubular fluid become trapped in a cylindrical mold of gelled Tamm-Horsfall protein. Even in the absence of azotemia, these patients should undergo serologic evaluation and renal biopsy as outlined in Fig. 40-2.

Isolated pyuria is unusual since inflammatory reactions in the kidney or collecting system are also associated with hematuria. The presence of bacteria suggests infection, and white blood cell casts with bacteria are indicative of pyelonephritis. White blood cells and/or white blood cell casts may also be seen in tubulointerstitial processes such as interstitial nephritis, systemic lupus erythematosus, and transplant rejection. In chronic renal diseases, degenerated cellular casts called waxy casts can be seen in the urine. Broad casts are thought to arise in the dilated tubules of enlarged nephrons that have undergone compensatory hypertrophy in response to reduced renal mass (i.e., chronic renal failure). A mixture of broad casts typically seen with chronic renal failure together with cellular casts and RBCs may be seen in smoldering processes such as chronic glomerulonephritis with active glomerulitis. The volume of urine produced varies depending upon the fluid intake, renal function, and physiologic demands of the individual. See “Azotemia,” above, for discussion of decreased (oliguria) or absent urine production (anuria). The physiology of water formation and renal water conservation are discussed in Chap. 259.

**POLYURIA**

By history, it is often difficult for patients to distinguish urinary frequency (often of small volumes) from polyuria, and a 24-h urine collection is needed for evaluation (Fig. 40-4). It is necessary to determine if the polyuria represents a solute or water diuresis and if the diuresis is appropriate for the clinical circumstances. The average person excretes between 600 and 800 mosmol of solutes per day, primarily as urea and electrolytes. The urine osmolality can help distinguish a solute from water diuresis. If the urine output is >3 L/d (arbitrarily defined as polyuria) and the urine is dilute ( <250 mosmol/L), then total solute excretion is normal and a water diuresis is present. This circumstance could arise from polydipsia, inadequate secretion of vasopressin (central diabetes insipidus), or failure of renal tubules to respond to vasopressin (nephrogenic diabetes insipidus). If the urine volume is >3 L/d and urine osmolality is >300 mosmol/L, then a solute diuresis is clearly present and a search for the responsible solute(s) is mandatory.

Excessive filtration of a poorly reabsorbed solute such as glucose, mannitol, or urea can depress reabsorption of NaCl and water in the proximal tubule and lead to enhanced excretion in the urine. Poorly controlled diabetes mellitus is the most common cause of a solute diuresis, leading to volume depletion and serum hypertonicity. Since the urine Na concentration is less than that of blood, more water than Na is lost, causing hyponatremia and hypertonicity. Common iatrogenic solute diuresis occurs from mannitol administration, radiocontrast media, and high-protein feedings (enterally or parenterally), leading to increased urea production and excretion. Less commonly, excessive Na loss may occur from cystic renal diseases, Barter’s syndrome, or during the course of a tubulointerstitial process (such as

**FIGURE 40-4** Approach to the patient with polyuria. ATN, acute tubular necrosis; ADH, antidiuretic hormone.
resolving ATN). In these so-called salt-wasting disorders, the tubule damage results in direct impairment of Na reabsorption and indirectly reduces the responsiveness of the tubule to aldosterone. Usually, the Na losses are mild, and the obligatory urine output is less than 2 L/d (resolving ATN and postobstructive diuresis are exceptions and may be associated with significant natriuresis and polyuria.)

Formation of large volumes of dilute urine represent polydipsic states or diabetes insipidus. Primary polydipsia can result from habit, psychiatric disorders, neurologic lesions, or medications. During deliberate polydipsia, extracellular fluid volume is normal or expanded and vasopressin levels are reduced because serum osmolality tends to be near the lower limits of normal.

Central diabetes insipidus may be idiopathic in origin or secondary to a variety of hypothalamic conditions including posthypophysectomy or trauma or neoplastic, inflammatory, vascular, or infectious hypothalamic diseases. Idiopathic central diabetes insipidus is associated with selective destruction of the vasopressin-secreting neurons in the supraoptic and paraventricular nuclei and can be inherited as an autosomal dominant trait or occur spontaneously. Nephrogenic diabetes insipidus can occur in a variety of clinical situations as summarized in Fig. 40-4.

A plasma vasopressin level is recommended as the best method for distinguishing between central and nephrogenic diabetes insipidus. Alternatively, a water deprivation test plus exogenous vasopressin may also distinguish primary polydipsia from central and nephrogenic diabetes insipidus. →For a detailed discussion, see Chap. 319.

41 FLUID AND ELECTROLYTE DISTURBANCES

Gary G. Singer, Barry M. Brenner

SODIUM AND WATER

COMPOSITION OF BODY FLUIDS Water is the most abundant constituent in the body, comprising approximately 50% of body weight in women and 60% in men. This difference is attributable to differences in the relative proportions of adipose tissue in men and women. Total body water is distributed in two major compartments—55 to 75% is intracellular (intracellular fluid [ICF]), 25 to 45% is extracellular (extracellular fluid [ECF]). The ECF is further subdivided into intravascular (plasma water) and extravascular (interstitial) spaces in a ratio of 1:3.

The solute or particle concentration of a fluid is known as its osmolality and is expressed as milliosmoles per kilogram of water (mosm/kg). Water crosses cell membranes to achieve osmotic equilibrium (ECF osmolality = ICF osmolality). The extracellular and intracellular solutes or osmoles are markedly different due to disparities in permeability and the presence of transporters and active pumps. The major ECF particles are Na+ and its accompanying anions Cl− and HCO3−, whereas K+ and organic phosphate esters (ATP, creatine phosphate, and phospholipids) are the predominant ICF solutes. Solutes that are restricted to the ECF or the ICF determine the effective osmolality (or tonicity) of that compartment. Since Na+ is largely restricted to the extracellular compartment, total body Na+ content is a reflection of ECF volume. Likewise, K+ and its attendant anions are predominantly limited to the ICF and are necessary for normal cell function. Therefore, the number of intracellular particles is relatively constant, and a change in ICF osmolality is usually due to a change in ECF water content. However, in certain situations, brain cells can vary the number of intracellular solutes in order to defend against large water shifts. This process of osmotic adaptation is important in the defense of cell volume and occurs in chronic hyponatremia and hypernatremia. This response is mediated initially by transcellular shifts of K+ and Na+, followed by synthesis, import, or export of organic solutes (so-called osmoles) such as inositol, betaine, and glutamine. During chronic hyponatremia, brain cells lose solutes, thereby defending cell volume and diminishing neurologic symptoms. The converse occurs during chronic hypernatremia. Certain solutes, such as urea, do not contribute to water shift across cell membranes and are known as ineffective osmoles.

Fluid movement between the intravascular and interstitial spaces occurs across the capillary wall and is determined by the Starling forces—capillary hydraulic pressure and colloid osmotic pressure. The transcapillary hydraulic pressure gradient exceeds the corresponding oncotic pressure gradient, thereby favoring the movement of plasma ultrafiltrate into the extravascular space. The return of fluid into the intravascular compartment occurs via lymphatic flow.

WATER BALANCE (See also Chap. 259) The normal plasma osmolality is 275 to 290 mosmol/kg and is kept within a narrow range by mechanisms capable of sensing a 1 to 2% change in tonicity. To maintain a steady state, water intake must equal water excretion. Disorders of water homeostasis result in hypo- or hypernatremia. Normal individuals have an obligate water loss consisting of urine, stool, and evaporation from the skin and respiratory tract. Gastrointestinal excretion is usually a minor component of total water output, except in patients with vomiting, diarrhea, or high enterostomy output states. Evaporative or insensitive water losses are important in the regulation of core body temperature. Obligatory renal water loss is mandated by the minimum solute excretion required to maintain a steady state. Normally, about 600 mosmols must be excreted per day, and since the maximal urine osmolality is 1200 mosmol/kg a minimum urine output of 500 mL/d is required for neutral solute balance.

Water Intake The primary stimulus for water ingestion is thirst, mediated either by an increase in effective osmolality or a decrease in ECF volume or blood pressure. Osmoreceptors, located in the anterolateral hypothalamus, are stimulated by a rise in tonicity. Ineffective osmoles, such as urea and glucose, do not play a role in stimulating thirst. The average osmotic threshold for thirst is approximately 295 mosmol/kg a minimum urine output of 1200 mosmol/kg a maximum urine output of 500 mL/d is required for neutral solute balance.

Water Intake In contrast to the ingestion of water, its excretion is tightly regulated by physiologic factors. The principal determinant of renal water excretion is arginine vasopressin (AVP; formerly antidiuretic hormone), a polypeptide synthesized in the supraoptic and para-
ventricular nuclei of the hypothalamus and secreted by the posterior pituitary gland. The binding of AVP to V2 receptors on the basolateral membrane of principal cells in the collecting duct activates adenyl cyclase and initiates a sequence of events that leads to the insertion of water channels into the luminal membrane. These water channels that are specifically activated by AVP are encoded by the aquaporin-2 gene (Chap. 319). The net effect is passive water reabsorption along an osmotic gradient from the lumen of the collecting duct to the hypertonic medullary interstitium. The major stimulus for AVP secretion is hypertonicity. Since the major ECF solutes are Na+ salts, effective osmolality is primarily determined by the plasma Na+ concentration. An increase or decrease in tonicity is sensed by hypothalamic osmoreceptors as a decrease or increase in cell volume, respectively, leading to enhancement or suppression of AVP secretion. The osmotic threshold for AVP release is 280 to 290 mosmol/kg, and the system is sufficiently sensitive that plasma osmolality varies by no more than 1 to 2%.

Nonosmotic factors that regulate AVP secretion include effective circulating (arterial) volume, nausea, pain, stress, hypoglycemia, pregnancy, and numerous drugs. The hemodynamic response is mediated by baroreceptors in the carotid sinus. The sensitivity of these receptors is significantly lower than that of the osmoreceptors. In fact, depletion of blood volume sufficient to result in a decreased mean arterial pressure is necessary to stimulate AVP release, whereas small changes in effective circulating volume have little effect.

To maintain homeostasis and a normal plasma Na+ concentration, the ingestion of solute-free water must eventually lead to the loss of the same volume of electrolyte-free water. Three steps are required for the kidney to excrete a water load: (1) filtration and delivery of water (and electrolytes) to the diluting sites of the nephron; (2) active reabsorption of Na+ and Cl− without a gain in the thick ascending limb of the loop of Henle and, to a lesser extent, in the distal nephron; and (3) maintenance of a dilute urine due to impermeability of the collecting duct to water in the absence of AVP. Abnormalities of any of these steps can result in impaired free water excretion, and eventual hypotremia.

**SODIUM BALANCE**  Sodium is actively pumped out of cells by the Na+, K+-ATPase pump. As a result, 85 to 90% of all Na+ is extracellular, and the ECF volume is a reflection of total body Na+ content. Normal volume regulatory mechanisms ensure that Na+ loss balances Na+ gain. If this does not occur, conditions of Na+ excess or deficit ensue and are manifest as edematous or hypovolemic states, respectively. It is important to distinguish between disorders of osmoregulation and disorders of volume regulation since water and Na+ balance are regulated independently. Changes in Na+ concentration generally reflect disturbed water homeostasis, whereas alterations in Na+ content are manifest as ECF volume contraction or expansion and imply abnormal Na+ balance.

**Sodium Intake**  Individuals eating a typical western diet consume approximately 150 mmol of NaCl daily. This normally exceeds basal requirements. As noted above, sodium is the principal extracellular cation. Therefore, dietary intake of Na+ results in ECF volume expansion, which in turn promotes enhanced renal Na+ excretion to maintain steady state Na+ balance.

**Sodium Excretion**  (See also Chap. 259)  The regulation of Na+ excretion is multifactorial and is the major determinant of Na+ balance. A Na+ deficit or excess is manifest as a decreased or increased effective circulating volume, respectively. Changes in effective circulating volume tend to lead to parallel changes in glomerular filtration rate (GFR). However, tubule Na+ reabsorption, and not GFR, is the major regulatory mechanism controlling Na+ excretion. Almost two-thirds of filtered Na+ is reabsorbed in the proximal convoluted tubule—this process is electroneutral and isosmotic. Further reabsorption (25 to 30%) occurs in the thick ascending limb of the loop of Henle via the apical Na+/K+2Cl− cotransporter—this is an active process and is also electroneutral. Distal convoluted tubule reabsorption of Na+ (5%) is mediated by the thiazide-sensitive Na+/Cl− cotransporter. Final Na+ reabsorption occurs in the cortical and medullary collecting ducts, the amount excreted being reasonably equivalent to the amount ingested per day.

**HYPOVOLEMIA**

**ETIOLOGY**  True volume depletion, or hypovolemia, generally refers to a state of combined salt and water loss exceeding intake, leading to ECF volume contraction. The loss of Na+ may be renal or extrarenal (Table 41-1).

**Renal**  Many conditions are associated with excessive urinary NaCl and water losses, including diuretics. Pharmacologic diuretics inhibit specific pathways of Na+ reabsorption along the nephron with a consequent increase in urinary Na+ excretion. Enhanced filtration of non-reabsorbed solutes, such as glucose or urea, can also impair tubular reabsorption of Na+ and water, leading to an osmotic or solute diuresis. This often occurs in poorly controlled diabetes mellitus and in patients receiving high-protein hyperalimentation. Mannitol is a diuretic that produces an osmotic diuresis because the renal tubule is impermeable to mannitol. Many tubule and interstitial renal disorders are associated with Na+ wasting. Excessive renal losses of Na+ and water may also occur during the diuretic phase of acute tubular necrosis (Chap. 260) and following the relief of bilateral urinary tract obstruction. Finally, mineralocorticoid deficiency (pseudoaldosteronism) causes salt wasting in the presence of normal intrinsic renal function.

Massive renal water excretion can also lead to hypovolemia. The ECF volume contraction is usually less severe since two-thirds of the volume lost is intracellular. Conditions associated with excessive urinary water loss include central diabetes insipidus (CDI) and nephrogenic diabetes insipidus (NDI). These two disorders are due to impaired secretion of and renal unresponsiveness to AVP, respectively, and are discussed below.

**Extrarenal**  Nonrenal causes of hypovolemia include fluid loss from the gastrointestinal tract, skin, and respiratory system and third-space accumulations (burns, pancreatitis, peritonitis). Approximately 9 L of fluid enters the gastrointestinal tract daily, 2 L by ingestion and 7 L by secretion. Almost 98% of this volume is reabsorbed so that fecal fluid loss is only 100 to 200 mL/d. Impaired gastrointestinal reabsorption or enhanced secretion leads to volume depletion. Since gastric secretions have a low pH (high H+ concentration) and biliary, pancreatic, and intestinal secretions are alkaline (high HCO3− concentration),

vomiting and diarrhea are often accompanied by metabolic alkalosis and acidosis, respectively.

Water evaporation from the skin and respiratory tract contributes to thermoregulation. These "insensible losses" amount to 300 mL/d. During febrile illnesses, prolonged heat exposure, exercise, or increased salt and water loss from skin, in the form of sweat, can be significant and lead to volume depletion. The Na⁺ concentration of sweat is normally 20 to 50 mmol/L and decreases with profuse sweating due to the action of aldosterone. Since sweat is hypotonic, the loss of water exceeds that of Na⁺. The water deficit is minimized by enhanced thirst. Nevertheless, ongoing Na⁺ loss is manifest as hypovolemia. Enhanced evaporative water loss from the respiratory tract may be associated with hyperventilation, especially in mechanically ventilated patients.

Certain conditions lead to fluid sequestration in a third space. This compartment is extracellular but is not in equilibrium with either the ECF or the ICF. The fluid is effectively lost from the ECF and can result in hypovolemia. Examples include the bowel lumen in gastrointestinal obstruction, subcutaneous tissues in severe burns, retroperitoneal space in acute pancreatitis, and peritoneal cavity in peritonitis. Finally, severe hemorrhage from any source can result in volume depletion.

**PATHOPHYSIOLOGY**

ECF volume contraction is manifest as a decreased plasma volume and hypotension. Hypotension is due to decreased venous return (preload) and diminished cardiac output; it triggers baroreceptors in the carotid sinus and aortic arch and leads to activation of the sympathetic nervous system and the renin-angiotensin system. The net effect is to maintain mean arterial pressure and cerebral and coronary perfusion. In contrast to the cardiovascular response, the renal response is aimed at restoring the ECF volume by decreasing the GFR and filtered load of Na⁺ and, most importantly, by promoting tubular reabsorption of Na⁺. Increased sympathetic tone increases proximal tubular Na⁺ reabsorption and decreases GFR by causing preferential afferent arteriolar vasoconstriction. Sodium is also reabsorbed in the proximal convoluted tubule in response to increased angiotensin II and altered peritubular capillary hemodynamics (decreased hydraulic and increased oncotic pressure). Enhanced reabsorption of Na⁺ by the collecting duct is an important component of the renal adaptation to ECF volume contraction. This occurs in response to increased aldosterone and AVP secretion, and suppressed atrial natriuretic peptide secretion.

**CLINICAL FEATURES**

A careful history is often helpful in determining the etiology of ECF volume contraction (e.g., vomiting, diarrhea, polyuria, diaphoresis). Most symptoms are nonspecific and secondary to electrolyte imbalances and tissue hypoperfusion and include fatigue, weakness, muscle cramps, thirst, and postural dizziness. More severe degrees of volume contraction can lead to end-organ ischemia manifest as oliguria, cyanosis, abdominal and chest pain, and confusion or obtundation. Diminished skin turgor and dry oral mucous membranes are poor markers of decreased intrastitial fluid. Signs of intravascular volume contraction include decreased jugular venous pressure, postural hypotension, and postural tachycardia. Larger and more acute fluid losses lead to hypovolemic shock, manifest as hypotension, tachycardia, peripheral vasoconstriction, and hypoperfusion—cyanosis, cold and clammy extremities, oliguria, and altered mental status.

**DIAGNOSIS**

A thorough history and physical examination are generally sufficient to diagnose the etiology of hypovolemia. Laboratory data usually confirm and support the clinical diagnosis. The blood urea nitrogen (BUN) and plasma creatinine concentrations tend to be elevated, reflecting a decreased GFR. Normally, the BUN:creatinine ratio is about 10:1. However, in prerenal azotemia, hypovolemia leads to increased urea reabsorption and a proportionately greater elevation in BUN than plasma creatinine, and a BUN:creatinine ratio of 20:1 or higher. An increased BUN (relative to creatinine) may also be due to increased urea production that occurs with hyperalimentation (high-protein), glucocorticoid therapy, and gastrointestinal bleeding.

The appropriate response to hypovolemia is enhanced renal Na⁺ and water reabsorption, which is reflected in the urine composition. Therefore, the urine Na⁺ concentration should usually be <20 mmol/L except in conditions associated with impaired Na⁺ reabsorption, as in acute tubular necrosis (Chap. 260). Another exception is hypovolemia due to vomiting, since the associated metabolic alkalosis and increased filtered HCO₃⁻ impair proximal Na⁺ reabsorption. In this case, the urine Cl⁻ is low (<20 mmol/L). The urine osmolality and specific gravity in hypovolemic subjects are generally >450 mosmol/kg and 1.015, respectively, reflecting the presence of enhanced AVP secretion. However, in hypovolemia due to diabetes insipidus, urine osmolality and specific gravity are indicative of inappropriately dilute urine.

**TREATMENT**

The therapeutic goals are to restore normovolemia with fluid similar in composition to that lost and to replace ongoing losses. Symptoms and signs, including weight loss, can help estimate the degree of volume contraction and should also be monitored to assess response to treatment. Mild volume contraction can usually be corrected via the oral route. More severe hypovolemia requires intravenous therapy. Isotonic or normal saline (0.9% NaCl or 154 mmol/L Na⁺) is the solution of choice in normonatremic and mildly hyponatremic individuals and should be administered initially in patients with hypotension or shock. Severe hyponatremia may require hypertonic saline (3.0% NaCl or 513 mmol/L Na⁺). Hyponatremia reflects a proportionally greater deficit of water than Na⁺, and its correction will therefore require a hypertonic solution such as half-normal saline (0.45% NaCl or 77 mmol/L Na⁺) or 5% dextrose in water. Patients with significant hemorrhage, anemia, or intravascular volume depletion may require blood transfusion or colloid-containing solutions (albumin, dextran). Hypokalemia may be present initially or may ensue as a result of increased urinary K⁺ excretion; it should be corrected by adding appropriate amounts of KCl to replacement solutions.

**HYponATREMIA**

**ETIOLOGY**

A plasma Na⁺ concentration less than 135 mmol/L usually reflects a hypotonic state. However, plasma osmolality may be normal or increased in some cases of hyponatremia. Isotonic or slightly hyponatmic hyponatremia may complicate transurethral resection of the prostate or bladder because large volumes of isoosmotic (mannitol) or hypoosmotic (sorbitol or glycine) bladder irrigation solution can be absorbed and result in a dilutional hyponatremia. The metabolism of sorbitol and glycine to CO₂ and water may lead to hypotonicity if the accumulated fluid and solutes are not rapidly excreted. Hypertonic hyponatremia is usually due to hyperglycemia or, occasionally, intra-venous administration of mannitol. Relative insulin deficiency causes myocytes to become impermeable to glucose. Therefore, during poorly controlled diabetes mellitus, glucose is an effective osmole and draws water from muscle cells, resulting in hyponatremia. Plasma Na⁺ concentration falls by 1.4 mmol/L for every 100 mg/dL rise in the plasma glucose concentration.

Most causes of hyponatremia are associated with a low plasma osmolality (Table 41-2). In general, hypertonic hyponatremia is due either to a primary water gain (and secondary Na⁺ loss) or a primary Na⁺ loss (and secondary water gain). In the absence of water intake or hypotonic fluid replacement, hyponatremia is usually associated with hypovolemic shock due to a profound sodium deficit and transcellular water shift. Contraction of the ECF volume stimulates thirst and AVP secretion. The increased water ingestion and impaired renal excretion result in hyponatremia. It is important to note that diuretic-induced hyponatremia is almost always due to thiazide diuretics. Loop diuretics decrease the toxicity of the medullary interstitium and impair maximal urinary concentrating capacity. This limits the ability of AVP to promote water retention. In contrast, thiazide diuretics lead to Na⁺ and K⁺ depletion and AVP-mediated water retention. Hyponatremia can also occur by a process of desalination. This occurs when the urine
proximal fractional reabsorption of Na to increased thirst and increased AVP levels. Additional factors im-
in common a decreased effective circulating arterial volume, leading 
associated with edematous states, such as congestive heart failure, he-
bral salt wasting after neurosurgery.
of administered intravenous fluids (including isotonic saline). This ac-

secretion with increased sensitivity to its actions or secretion of some 
osmolality (incomplete pituitary stalk section); and (4) normal AVP 
response to hypertonicity with failure to suppress completely at low 
set point or reset osmostat 

Hormonal excess or deficiency may cause hyponatremia. Adrenal 
insufficiency (Chap. 321) and hypothyroidism (Chap. 320) may 
present with hyponatremia and should not be confused with SIADH. 
Although decreased mineralocorticoids may contribute to the hypo-
notinism of adrenal insufficiency, it is the cortisol deficiency that leads 
to hypersecretion of AVP both indirectly (secondary to volume deple-
tion) and directly (coresecreted with corticotropin-releasing factor). The 
mechanisms by which hypoaldosteronism leads to hyponatremia include 
decreased cardiac output and GFR and increased AVP secretion in 
response to hemodynamic stimuli.

Finally, hyponatremia may occur in the absence of AVP or renal 
failure if the kidney is unable to excrete the dietary water load. In 
psychogenic or primary polydipsia, compulsive water consumption 
may overwhelm the normally large renal excretory capacity of 12 
L/d (Chap. 319). These patients often have psychiatric illnesses and 
may be taking medications, such as phenothiazines, that enhance the 
sensation of thirst by causing a dry mouth. The maximal urine output is 
a function of the minimum urine osmolality achievable and the 
mandatory solute excretion. Metabolism of a normal diet generates 
about 600 mosmol/d, and the minimum urine osmolality in humans is 
50 mosmol/kg. Therefore, the maximum daily urine output will be 
about 12 L (600 ÷ 50 = 12). A solute excretion rate of greater than 
~750 mosmol/d is, by definition, an osmotic diuresis. A low-protein 
diet may yield as few as 250 mosmol/d, which translates into a maxi-
mal urine output of 5 L/d at a minimum urine toxicity of 50 mosmol/ 
kg. Beer drinkers typically have a poor dietary intake of protein and 
electrolytes and consume large volumes (of beer), which may exceed 
the renal excretory capacity and result in hyponatremia. This phenom-
enon is referred to as beer potomania.

**CLINICAL FEATURES** The clinical manifestations of hyponatremia are re-
lated to osmotic water shift leading to increased ECF volume, specif-
ically brain cell swelling or cerebral edema. Therefore, the symptoms 
are primarily neurologic, and their severity is dependent on the rapidity 
of onset and absolute decrease in plasma Na concentration. Patients 
may be asymptomatic or complain of nausea and malaise. As the 
plasma Na concentration falls, the symptoms progress to include 
headache, lethargy, confusion, and obtundation. Stupor, seizures, and 
coma do not usually occur unless the plasma Na concentration falls 
acutely below 120 mmol/L or decreases rapidly. As described above, 
adaptive mechanisms designed to protect cell volume occur in chronic 
hyponatremia. Loss of Na and K, followed by organic osmolytes, 
from brain cells decreases brain swelling due to secondary transcellular 
water shifts (from ICF to ECF). The net effect is to minimize cerebral 
edema and its symptoms.

**DIAGNOSIS** (Fig. 41-1) Hyponatremia is not a disease but a manifesta-
tion of a variety of disorders. The underlying cause can often be 
ascertained from an accurate history and physical examination, in-
cluding an assessment of ECF volume status and effective circulating 
arterial volume. The differential diagnosis of hyponatremia, an 
expanded ECF volume, and decreased effective circulating volume in-
cludes congestive heart failure, hepatic cirrhosis, and the nephrotic 
syndrome. Hypothyroidism and adrenal insufficiency tend to present 
with a near-normal ECF volume and decreased effective circulating 
arterial volume. All of these diseases have characteristic signs and 
symptoms. Patients with SIADH are usually euvoletic.

Four laboratory findings often provide useful information and can 
narrow the differential diagnosis of hyponatremia: (1) the plasma os-
mosality, (2) the urine osmosality, (3) the urine Na concentration, and 
(4) the urine K concentration. Since ECF toxicity is determined pri-
marily by the Na concentration, most patients with hyponatremia 
have a decreased plasma osmolality. The appropriate renal response to 
hyposalinism is to excrete the maximum volume of dilute urine, i.e., 
urine osmolality and specific gravity of less than 100 mosmol/kg and 
1.003, respectively. This occurs in patients with primary polydip-
sia. If this is not present, it suggests impaired free water excretion due

headache, lethargy, confusion, and obtundation. Stupor, seizures, and
coma do not usually occur unless the plasma Na concentration falls
acutely below 120 mmol/L or decreases rapidly. As described above,
adaptive mechanisms designed to protect cell volume occur in chronic
hyponatremia. Loss of Na and K, followed by organic osmolytes,
from brain cells decreases brain swelling due to secondary transcellular
water shifts (from ICF to ECF). The net effect is to minimize cerebral
edema and its symptoms.

**DIAGNOSIS** (Fig. 41-1) Hyponatremia is not a disease but a manifesta-
tion of a variety of disorders. The underlying cause can often be
ascertained from an accurate history and physical examination, in-
cluding an assessment of ECF volume status and effective circulating
arterial volume. The differential diagnosis of hyponatremia, an
expanded ECF volume, and decreased effective circulating volume in-
cludes congestive heart failure, hepatic cirrhosis, and the nephrotic
syndrome. Hypothyroidism and adrenal insufficiency tend to present
with a near-normal ECF volume and decreased effective circulating
arterial volume. All of these diseases have characteristic signs and
symptoms. Patients with SIADH are usually euvoletic.

Four laboratory findings often provide useful information and can
narrow the differential diagnosis of hyponatremia: (1) the plasma os-
mosality, (2) the urine osmosality, (3) the urine Na concentration, and
(4) the urine K concentration. Since ECF toxicity is determined pri-
marily by the Na concentration, most patients with hyponatremia
have a decreased plasma osmolality. The appropriate renal response to
hyposalinism is to excrete the maximum volume of dilute urine, i.e.,
urine osmolality and specific gravity of less than 100 mosmol/kg and
1.003, respectively. This occurs in patients with primary polydip-
sia. If this is not present, it suggests impaired free water excretion due
Therefore, volume depletion in patients with normal underlying renal function should include Na\(^+\) restriction, generally in the form of isotonic saline. The direct effect of the administered NaCl on the plasma Na\(^+\) concentration is trivial. However, restoration of euvolemia removes the hemodynamic stimulus for AVP release, allowing the excess free water to be excreted. The hyponatremia associated with edematous states tends to reflect the severity of the underlying disease and is usually asymptomatic. These patients have increased total body water that exceeds the increase in total body Na\(^+\) content. Treatment should include restriction of Na\(^+\) and water intake, correction of hypokalemia, and promotion of water loss in excess of Na\(^+\). The latter may require the use of loop diuretics with replacement of a proportion of the urinary Na\(^+\) loss to ensure net free water excretion. Dietary water restriction should be less than the urine output. Correction of the K\(^+\) deficit may raise the plasma Na\(^+\) concentration by favoring a shift of Na\(^+\) out of cells as K\(^+\) moves in. It is also a component of the therapeutic approach to hyponatremia associated with primary polydipsia, renal failure, and SIADH (Chap. 319).

The rate of correction of hyponatremia depends on the absence or presence of neurologic dysfunction. This, in turn, is related to the rapidity of onset and magnitude of the fall in plasma Na\(^+\) concentration. In asymptomatic patients, the plasma Na\(^+\) concentration should be raised by no more than 0.5 to 1.0 mmol/L per h and by less than 10 to 12 mmol/L over the first 24 h. Acute or severe hyponatremia (plasma Na\(^+\) concentration <110 to 115 mmol/L) tends to present with altered mental status and/or seizures and requires more rapid correction. Severe symptomatic hyponatremia should be treated with hypertonic saline, and the plasma Na\(^+\) concentration should be raised by 1 to 2 mmol/L per hour for the first 3 to 4 h or until the seizures subside. Once again, the plasma Na\(^+\) concentration should probably be raised by no more than 12 mmol/L during the first 24 h. The quantity of Na\(^+\) required to increase the plasma Na\(^+\) concentration by a given amount can be estimated by multiplying the deficit in plasma Na\(^+\) concentration by the total body water.

Under normal conditions, total body water is 50 or 60% of lean body weight in women or men, respectively. Therefore, to raise the plasma Na\(^+\) concentration from 105 to 115 mmol/L in a 70-kg man requires 420 mmol \((115 - 105) \times 70 \times 0.6\) of Na\(^+\). The risk of correcting hyponatremia too rapidly is the development of the osmotic demyelination syndrome (ODS). This is a neurologic disorder characterized by flaccid paralysis, dysarthria, and dysphagia. The diagnosis is usually suspected clinically and can be confirmed by appropriate neuroimaging studies. There is no specific treatment for the disorder, which is associated with significant morbidity and mortality. Patients with chronic hyponatremia are most susceptible to the development of ODS, since their brain cell volume has returned to near normal as a result of the osmotic adaptive mechanisms described above. Therefore, administration of hypertonic saline to these individuals can cause sudden osmotic shrinkage of brain cells. In addition to rapid or overcorrection of hyponatremia, risk factors for ODS include prior cerebral anoxic injury, hypokalemia, and malnutrition, especially secondary to alcoholism. Water restriction in primary polydipsia and intravenous saline therapy in ECF volume–contracted patients may also lead to overly rapid correction of hyponatremia as a result of AVP suppression and a brisk water diuresis. This can be prevented by administration of water or use of an AVP analogue to slow down the rate of free water excretion. →For further discussion, see Chap. 319.

**HYPERTONATREMIA**

**ETIOLOGY** Hyponatremia is defined as a plasma Na\(^+\) concentration greater than 145 mmol/L. Since Na\(^+\) and its accompanying anions are the major effective ECF osmoles, hyponatremia is a state of hyperosmolality. As a result of the fixed number of ICF particles, maintenance of osmotic equilibrium in hyponatremia results in ICF volume contraction. Hyponatremia may be due to primary Na\(^+\) gain or water deficit. The two components of an appropriate response to hyponatremia are increased water intake stimulated by thirst and the excretion of maximally concentrated urine reflecting AVP secretion in response to an osmotic stimulus.

In practice, the majority of cases of hyponatremia result from the
loss of water. Since water is distributed between the ICF and the ECF in a 2:1 ratio, a given amount of solute-free water loss will result in a twofold greater reduction in the ICF compartment than the ECF compartment. For example, consider three scenarios: the loss of 1 L of water, isotonic NaCl, or half-isotonic NaCl. If 1 L of water is lost, the ICF volume will decrease by 667 mL, whereas the ECF volume will fall by only 333 mL. Due to the fact that Na⁺ is largely restricted to the ECF, this compartment will decrease by 1 L if the fluid lost is isoosmotic. One liter of half-isotonic NaCl is equivalent to 500 mL of water (one-third ECF, two-thirds ICF) plus 500 mL of isotonic saline (all ECF). Therefore, the loss of 1 L of half-isotonic saline decreases the ECF and ICF volumes by 667 mL and 333 mL, respectively.

The degree of hyperosmolality is typically mild unless the thirst mechanism is abnormal or access to water is limited. It occurs in infants, the physically handicapped, patients with impaired mental status, in the postoperative state, and in intubated patients in the intensive care unit. On rare occasions, impaired thirst may be due to primary hypodipsia. This usually occurs as a result of damage to the hypothalamic osmoreceptors that control thirst and tend to be associated with abnormal osmotic regulation of AVP secretion. Primary hypodipsia may be due to a variety of pathologic changes including granulomatous disease, vascular occlusion, and tumors. A subset of hypodipsic hypernatremia, referred to as essential hypernatremia, does not respond to forced water intake. This appears to be due to a specific osmoreceptor defect resulting in nonosmotic regulation of AVP release. Thus, the hemodynamic effects of water loading lead to AVP suppression and excretion of dilute urine.

The source of free water loss is either renal or extrarenal. Nonrenal loss of water may be due to evaporation from the skin and respiratory tract (insensible losses) or loss from the gastrointestinal tract. Insensible losses are increased with fever, exercise, heat exposure, and severe burns in and mechanically ventilated patients. Furthermore, the Na⁺ concentration of sweat decreases with profuse perspiration, thereby increasing solute-free water loss. Diarrhea is the most common gastrointestinal cause of hypernatremia. Specifically, osmotic diarrheas (induced by lactulose, sorbitol, or malabsorption of carbohydrate) and viral gastroenteritides result in water loss exceeding that of Na⁺ and K⁺. In contrast, secretory diarrheas (e.g., cholera, carcinoid, VIPoma) have a fecal osmolality (twice the sum of the concentrations of Na⁺ and K⁺) similar to that of plasma and present with ECF volume contraction and a normal plasma Na⁺ concentration or hyponatremia.

Renal water loss is the most common cause of hypernatremia and is due to drug-induced or osmotic diuresis or diabetes insipidus (Chap. 319). Loop diuretics interfere with the countercurrent mechanism and produce an isoosmotic solute diuresis. This results in a decreased medullary interstitial tonicity and impaired renal concentrating ability. The presence of non-reabsorbed organic solutes in the tubule lumen impairs the osmotic reabsorption of water. This leads to water loss in excess of Na⁺ and K⁺, known as an osmotic diuresis. The most frequent cause of an osmotic diuresis is hyperglycemia and glucosuria in poorly controlled diabetes mellitus. Intravenous administration of mannitol and increased endogenous production of urea (high-protein diet) can also result in an osmotic diuresis.

Hyponatremia secondary to nonosmotic urinary water loss is usually due to: (1) Central diabetes insipidus (CDI) characterized by impaired AVP secretion, or (2) NDI resulting from end-organ (renal) resistance to the actions of AVP. The most common cause of CDI is destruction of the neurohypophysis. This may occur as a result of trauma, neurosurgery, granulomatous disease, neoplasms, vascular accidents, or infection. In many cases, CDI is idiopathic and may occasionally be hereditary. The familial form of the disease is inherited in an autosomal dominant fashion and has been attributed to mutations in the proopressin (AVP precursor) gene. Nephrogenic diabetes insipidus (NDI) may be either inherited or acquired. Congenital NDI is an X-linked recessive trait due to mutations in the V₂ receptor gene. Mutations in the autosomal aquaporin-2 gene may also result in NDI. The aquaporin-2 gene encodes the water channel protein whose membrane insertion is stimulated by AVP. The causes of sporadic NDI are numerous and include drugs (especially lithium), hypercalcemia, hypokalemia, and conditions that impair medullary hypertonicity (e.g., papillary necrosis or osmotic diuresis). Pregnant women, in the second or third trimester, may develop NDI as a result of excessive elaboration of vasopressinase by the placenta.

Finally, although infrequent, a primary Na⁺ gain may cause hypernatremia. For example, inadvertent administration of hypertonic NaCl or NaHCO₃ or replacing sugar with salt in infant formula can produce this complication.

**CLINICAL FEATURES** As a consequence of hypernatremia, water shifts out of cells, leading to a contracted ICF volume. A decreased brain cell volume is associated with an increased risk of subarachnoid or intracerebral hemorrhage. Hence, the major symptoms of hypernatremia are neurologic and include altered mental status, weakness, neuromuscular irritability, focal neurologic deficits, and occasionally coma or seizures. Patients may also complain of polyuria or thirst. For reasons unknown, patients with polydipsia from CDI tend to prefer ice-cold water. The signs and symptoms of volume depletion are often present in patients with a history of excessive sweating, diarrhea, or an osmotic diuresis. As with hyponatremia, the severity of the clinical manifestations is related to the acuity and magnitude of the rise in plasma Na⁺ concentration. Chronic hypernatremia is generally less symptomatic as a result of adaptive mechanisms designed to defend cell volume. Brain cells initially take up Na⁺ and K⁺ salts, later followed by accumulation of organic osmoles such as inositol. This serves to restore the brain ICF volume towards normal.

**DIAGNOSIS** (Fig. 41-2) A complete history and physical examination will often provide clues as to the underlying cause of hypernatremia. Relevant symptoms and signs include the absence or presence of thirst, diaphoresis, diarrhea, polyuria, and the features of ECF volume contraction. The history should include a list of current and recent medications, and the physical examination is incomplete without a thorough mental status and neurologic assessment. Measurement of urine volume and osmolality are essential in the evaluation of hyperosmolality. The appropriate renal response to hypernatremia is the excretion of the minimum volume (500 mL/d) of maximally concentrated urine (urine osmolality >800 mosmol/kg). These findings suggest extrarenal

---

**FIGURE 41-2** Algorithm depicting clinical approach to hypernatremia.
or remote renal water loss or administration of hypertonic Na\(^+\) salt solutions. The presence of a primary Na\(^+\) excess can be confirmed by the presence of ECF volume expansion and natriuresis (urine Na\(^+\) concentration usually >100 mmol/L).

Many causes of hypernatremia are associated with polyuria and a submaximal urine osmolality. The product of the urine volume and osmolality, i.e., the solute excretion rate, is helpful in determining the basis of the polyuria (see above). To maintain a steady state, total solute excretion must equal solute production. As stated above, individuals eating a normal diet generate ~600 mosmol/d. Therefore, daily solute excretion in excess of 750 mosmol defines an osmotic diuresis. This can be confirmed by measuring the urine glucose and urea. In general, both CDI and NDI present with polyuria and hypotonic urine (urine osmolality <250 mosmol/kg). The degree of hypernatremia is usually mild unless there is an associated thirst abnormality. The clinical history, physical examination, and pertinent laboratory data can often rule out causes of acquired NDI. CDI and NDI can generally be distinguished by administering the AVP analogue desmopressin (10 \(\mu\)g intranasally) after careful water restriction. The urine osmolality should increase by at least 50% in CDI and will not change in NDI. Unfortunately, the diagnosis may sometimes be difficult due to partial defects in AVP secretion and action.

### TREATMENT

The therapeutic goals are to stop ongoing water loss by treating the underlying cause and to correct the water deficit. The ECF volume should be restored in hypovolemic patients. The quantity of water required to correct the deficit can be calculated from the following equation:

\[
\text{Water deficit} = \frac{\text{Plasma Na}\,+\text{ concentration} - 140}{140} \times \text{Total body water}
\]

In hypernatremia due to water loss, total body water is approximately 50 and 40% of lean body weight in men and women, respectively. For example, a 50-kg woman with a plasma Na\(^+\) concentration of 160 mmol/L has an estimated free water deficit of 2.9 L \([((160 - 140) \times 0.4) \times 50]\). As in hypotremia, rapid correction of hypernatremia is potentially dangerous. In this case, a sudden decrease in osmolality could potentially cause a rapid shift of water into cells that have undergone osmotic adaptation. This would result in swollen brain cells and increase the risk of seizures or permanent neurologic damage. Therefore, the water deficit should be corrected slowly over at least 48 to 72 h. When calculating the rate of water replacement, ongoing losses should be taken into account, and the plasma Na\(^+\) concentration should be lowered by 0.5 mmol/L per h and by no more than 12 mmol/L over the first 24 h.

The safest route of administration of water is by mouth or via a nasogastric tube (or other feeding tube). Alternatively, 5% dextrose in water or half-isotonic saline can be given intravenously. The appropriate treatment of CDI consists of administering desmopressin intranasally (Chap. 319). Other options for decreasing urine output include a low-salt diet in combination with low-dose thiazide diuretic therapy. In some patients with partial CDI drugs that either stimulate AVP secretion or enhance its action on the kidney have been useful. These include chlorpropamide, clofibrate, carbamazepine, and nonsteroidal anti-inflammatory drugs (NSAIDs). The concentrating defect in NDI may be reversible by treating the underlying disorder or eliminating the offending drug. Symptomatic polyuria due to NDI can be treated with a low-Na\(^+\) diet and thiazide diuretics as described above. This induces mild volume depletion, which leads to enhanced proximal reabsorption of salt and water and decreased delivery to the site of action of AVP, the collecting duct. By impairing renal prostaglandin synthesis, AVP also facilitates AVP reabsorption and the maintenance of urine osmolality and decrease urine volume. Amiloride may be useful in patients with NDI who need to be on lithium. The nephrotoxicity of lithium requires the drug to be taken up into collecting duct cells via the amiloride-sensitive Na\(^+\) channel.

### POTASSIUM BALANCE

Potassium is the major intracellular cation. The normal plasma K\(^+\) concentration is 3.5 to 5.0 mmol/L, whereas that inside cells is about 150 mmol/L. Therefore, the amount of K\(^+\) in the ECF (30 to 70 mmol) constitutes less than 2% of the total body K\(^+\) content (2500 to 4500 mmol). The ratio of ICF to ECF K\(^+\) concentration (normally 38:1) is the principal result of the resting membrane potential and is crucial for normal neuromuscular function. The basolateral Na\(^+\), K\(^+\)-ATPase pump actively transports K\(^+\) into and Na\(^+\) out of the cell in a 2:3 ratio, and the passive outward diffusion of K\(^+\) is quantitatively the most important factor that generates the resting membrane potential. The activity of the electrogenic Na\(^+\), K\(^+\)-ATPase pump may be stimulated as a result of an increased intracellular Na\(^+\) concentration and inhibited in the setting of digoxin toxicity or chronic illness such as heart failure or renal failure.

The K\(^+\) intake of individuals on an average western diet is 40 to 120 mmol/d or approximately 1 mmol/kg per day, 90% of which is absorbed by the gastrointestinal tract. Maintenance of the steady state necessitates matching K\(^+\) ingestion with excretion. Initially, extrarenal adaptive mechanisms, followed later by urinary excretion, prevent a doubling of the plasma K\(^+\) concentration that would occur if the dietary K\(^+\) load remained in the ECF compartment. Immediately following a meal, most of the absorbed K\(^+\) enters cells as a result of the initial elevation in the plasma K\(^+\) concentration and facilitated by insulin release and basal catecholamine levels. Eventually, however, the excess K\(^+\) is excreted in the urine (see below). The regulation of gastrointestinal K\(^+\) handling is not well understood. The amount of K\(^+\) lost in the stool can increase from 10 to 50 or 60% (of dietary intake) in chronic renal insufficiency. In addition, colonic secretion of K\(^+\) is stimulated in patients with large volumes of diarrhea, resulting in potentially severe K\(^+\) depletion.

### POTASSIUM EXCRETION

(See also Chap. 259) Renal excretion is the major route of elimination of dietary and other sources of excess K\(^+\). The filtered load of K\(^+\) \((\text{GFR} \times \text{plasma K}\,+\text{ concentration} = 180 \text{ L/d} \times 4\text{ mmol/L} = 720 \text{ mmol/d})\) is 10- to 20-fold greater than the ECF K\(^+\) content. Some 90% of filtered K\(^+\) is reabsorbed by the proximal convoluted tubule and loop of Henle. Proximally, K\(^+\) is reabsorbed passively with Na\(^+\) and water, whereas the luminal Na\(^+\)-K\(^+\)-2Cl\(^-\) cotransporter mediates K\(^+\) uptake in the thick ascending limb of the loop of Henle. Therefore, K\(^+\) delivery to the distal nphron (distal convoluted tubule and cortical collecting duct (CCD)) approximates dietary intake. Net distal K\(^+\) secretion or reabsorption occurs in the setting of K\(^+\) excess or depletion, respectively. The cell responsible for K\(^+\) secretion in the late distal convoluted tubule (connecting tubule) and CCD is the principal cell. Virtually all regulation of renal K\(^+\) excretion and total body K\(^+\) balance occurs in the distal nphron. Potassium secretion is regulated by two physiologic stimuli—aldosterone and hyperkalemia. Aldosterone is secreted by the zona glomerulosa cells of the adrenal cortex in response to high renin and angiotensin II or hyperkalemia. The plasma K\(^+\) concentration, independent of aldosterone, can directly affect K\(^+\) secretion. In addition to the K\(^+\) concentration in the lumen of the CCD, renal K\(^+\) loss depends on the urine flow rate, a function of daily solute excretion (see above). Since excretion is equal to the product of concentration and volume, increased distal flow rate can significantly enhance urinary K\(^+\) output. Finally, in severe K\(^+\) depletion, secretion of K\(^+\) is reduced and reabsorption in the cortical and medullary collecting ducts is upregulated.

### HYPOKALEMIA

(See Table 41-3) Hypokalemia, defined as a plasma K\(^+\) concentration <3.5 mmol/L, may result from one (or more) of the following: decreased intake, shift into cells, or increased net loss. Diminished intake is seldom the sole cause of K\(^+\) depletion since urinary excretion can be effectively decreased to less than 15 mmol/d as a
result of net \( K^+ \) reabsorption in the distal nephron. With the exception of the urban poor and certain cultural groups, the amount of \( K^+ \) in the diet almost always exceeds that excreted in the urine. However, dietary \( K^+ \) restriction may exacerbate the hypokalemia secondary to increased gastrointestinal or renal loss. An unusual cause of decreased \( K^+ \) intake is ingestion of clay (geophagia), which binds dietary \( K^+ \) and iron. This custom was previously common among African Americans in the American South.

**Redistribution into Cells** Movement of \( K^+ \) into cells may transiently decrease the plasma \( K^+ \) concentration without altering total body \( K^+ \) content. For any given cause, the magnitude of the change is relatively small, often less than 1 mmol/L. However, a combination of factors may lead to a significant fall in the plasma \( K^+ \) concentration and may amplify the hypokalemia due to \( K^+ \) wasting. Metabolic alkalosis is often associated with hypokalemia. This occurs as a result of \( K^+ \) redistribution as well as excessive renal \( K^+ \) loss. Treatment of diabetic ketoacidosis with insulin may lead to hypokalemia due to stimulation of the \( Na^+-H^+ \) antipporter and (secondarily) the \( Na^+-K^+ \)-ATPase pump. Furthermore, uncontrolled hyperglycemia often leads to \( K^+ \) depletion from an osmotic diuresis (see below). Stress-induced catecholamine release and administration of \( \beta \)-adrenergic agonists directly induce cellular uptake of \( K^+ \) and promote insulin secretion by pancreatic islet \( \beta \) cells. *Hypokalemic periodic paralysis* is a rare condition characterized by recurrent episodic weakness or paralysis (Chap. 367). Since \( K^+ \) is the major ICF cation, anabolic states can potentially result in increased \( K^+ \) release and administration of glucocorticoids directly induce cellular uptake of \( K^+ \). This may occur following rapid cell growth seen in patients with pernicious anemia treated with vitamin \( B_12 \), or with neutropenia after treatment with granulocyte-macrophage colony stimulating factor. Massive transfusion with thawed washed red blood cells (RBCs) could cause hypokalemia since frozen RBCs lose up to half of their \( K^+ \) during storage.

### Nonrenal Loss of Potassium

Excessive sweating may result in \( K^+ \) depletion from increased integumentary and renal \( K^+ \) loss. Hyperaldosteronism, secondary to ECF volume contraction, enhances \( K^+ \) excretion in the urine (Chap. 321). Normally, \( K^+ \) lost in the stool amounts to 5 to 10 mmol/d in a volume of 100 to 200 mL. Hypokalemia subsequent to increased gastrointestinal loss can occur in patients with profuse diarrhea (usually secretory), villous adenomas, VIPomas, or laxative abuse. However, the loss of gastric secretions does not account for the moderate to severe \( K^+ \) depletion often associated with vomiting or nasogastric suction. Since the \( K^+ \) concentration of gastric fluid is 5 to 10 mmol/L, it would take 50 to 80 L of vomitus to achieve a \( K^+ \) deficit of 300 to 400 mmol typically seen in these patients. In fact, the hypokalemia is primarily due to increased renal \( K^+ \) excretion. Loss of gastric contents results in volume depletion and metabolic alkalosis, both of which promote kaliuresis. Hypovolemia stimulates aldosterone release, which augments \( K^+ \) secretion by the principal cells. In addition, the filtered load of \( HC0_3^- \) exceeds the reabsorptive capacity of the proximal convoluted tubule, thereby increasing distal delivery of \( NaHC0_3 \), which enhances the electrochemical gradient favoring \( K^+ \) loss in the urine.

### Renal Loss of Potassium

(See also Chap. 321) In general, most cases of chronic hypokalemia are due to renal \( K^+ \) wasting. This may be due to factors that increase the \( K^+ \) concentration in the lumen of the CCD or augment distal flow rate. Mineralocorticoid excess commonly results in hypokalemia. *Primary hyperaldosteronism* is due to dysregulated aldosterone secretion by an adenral adenoma (Conn’s syndrome) or carcinoma or to adenocortical hyperplasia. In a rare subset of patients, the disorder is familial (autosomal dominant) and aldosterone levels can be suppressed by administering low doses of exogenous glucocorticoid. The molecular defect responsible for glucocorticoid-remediable hyperaldosteronism is a rearranged gene (due to a chromosomal crossover), containing the 5’-regulatory region of the 11\( \beta \)-hydroxylase gene and the coding sequence of the aldosterone synthase gene. Consequently, mineralocorticoid is synthesized in the zona fasciculata and regulated by corticotropin. A number of conditions associated with hyperreninemia result in secondary hyperaldosteronism and renal \( K^+ \) wasting. High renin levels are commonly seen in both renovascular and malignant hypertension. Renin-secreting tumors of the juxtaglomerular apparatus are a rare cause of hypokalemia. Other tumors that have been reported to produce renin include renal cell carcinoma, ovarian carcinoma, and Wilms’ tumor. Hyperreninemia may also occur secondary to decreased effective circulating arterial volume.

In the absence of elevated renin or aldosterone levels, enhanced distal nephron secretion of \( K^+ \) may result from increased production of non-aldosterone mineralocorticoids in congenital adrenal hyperplasia. Glucocorticoid-stimulated kaliuresis does not normally occur due to the conversion of cortisol to cortisone by 11\( \beta \)-hydroxysteroid dehydrogenase (11\( \beta \)-HSDH). Therefore, 11\( \beta \)-HSDH deficiency or suppression allows cortisol to bind to the aldosterone receptor and leads to the syndrome of apparent mineralocorticoid excess. Drugs that inhibit the activity of 11\( \beta \)-HSDH include glucyrrhetinic acid, present in licorice, chewing tobacco, and carbenoxolone. The presentation of Cushing’s syndrome may include hypokalemia if the capacity of 11\( \beta \)-HSDH to inactivate cortisol is overwhelmed by persistently elevated glucocorticoid levels.

*Liddle’s syndrome* is a rare familial (autosomal dominant) disease characterized by hypertension, hypokalemic metabolic alkalosis, renal \( K^+ \) wasting, and suppressed renin and aldosterone secretion. Increased distal delivery of Na\(^+\) with a non-reabsorbable anion (not Cl\(^-\)) enhances \( K^+ \) secretion. Classically, this is seen with proximal (type 2) renal tubular acidosis (RTA) and vomiting, associated with bicarbonaturia. Diabetic ketoacidosis and toluene abuse (glue-sniffing) can lead to increased delivery of \( \beta \)-hydroxybutyrate and hippurate, respectively, to the CCD and to renal \( K^+ \) loss. High doses of penicillin derivatives administered to volume-depleted patients may likewise pro-
remote renal K⁺ secretion as well as an osmotic diuresis. *Classic distal (type 1) RTA* is associated with hypokalemia due to increased renal K⁺ loss, the mechanism of which is uncertain. Amphotericin B causes hypokalemia due to increased distal nephron permeability to Na⁺ and K⁺ and to renal K⁺ wasting.

*Barter’s syndrome* is a disorder characterized by hypokalemia, metabolic alkalosis, hyperreninemic hyperaldosteronism secondary to ECF volume contraction, and juxtapaglomerular apparatus hyperplasia. Finally, diuretic use and abuse are common causes of K⁺ depletion. Carbonic anhydrase inhibitors, loop diuretics, and thiazides are all kaliuretic. The degree of hypokalemia tends to be greater with long-acting agents and is dose-dependent. Increased renal K⁺ excretion is due primarily to increased distal solute delivery and secondary hyperaldosteronism (due to volume depletion).

**CLINICAL FEATURES** The clinical manifestations of K⁺ depletion vary greatly between individual patients, and their severity depends on the degree of hypokalemia. Symptoms seldom occur unless the plasma K⁺ concentration is less than 3 mmol/L. Fatigue, myalgia, and muscular weakness of the lower extremities are common complaints and are due to a lower (more negative) resting membrane potential. More severe hypokalemia may lead to progressive weakness, hyperventilation (due to respiratory muscle involvement), and eventually complete paralysis. Impaired muscle metabolism and the blunted hyperemic response to exercise associated with profound K⁺ depletion increase the risk of rhabdomyolysis. Smooth-muscle function may also be affected and manifest as paralytic ileus.

The electrocardiographic changes of hypokalemia (Fig. 210-17) are due to delayed ventricular repolarization and do not correlate well with the plasma K⁺ concentration. Early changes include flattening or inversion of the T wave, a prominent U wave, ST-segment depression, and a prolonged QU interval. Severe K⁺ depletion may result in a prolonged PR interval, decreased voltage and widening of the QRS complex, and an increased risk of ventricular arrhythmias, especially in patients with myocardial ischemia or left ventricular hypertrophy. Hypokalemia may also predispose to digitalis toxicity. Hypokalemia is often associated with acid-base disturbances related to the underlying disorder. In addition, K⁺ depletion results in intracellular acidification and an increase in net acid excretion or new HCO₃⁻ production. This is a consequence of enhanced proximal HCO₃⁻ reabsorption, increased renal ammoniagenesis, and increased distal H⁺ secretion. This contributes to the generation of metabolic alkalosis frequently present in hypokalemic patients. NDI (see above) is not uncommonly seen in K⁺ depletion and is manifest as polydipsia and polyuria. Glucose intolerance may also occur with hypokalemia and has been attributed to either impaired insulin secretion or peripheral insulin resistance.

**DIAGNOSIS** (Fig. 41-3) In most cases, the etiology of K⁺ depletion can be determined by a careful history. Diuretic and laxative abuse as well as surreptitious vomiting may be difficult to identify but should be excluded. Rarely, patients with a marked leukocytosis (e.g., acute myeloid leukemia) and normokalemia may have a low measured plasma K⁺ concentration due to white blood cell uptake of K⁺ at room temperature. This *pseudohypokalemia* can be avoided by storing the blood sample on ice or rapidly separating the plasma (or serum) from the cells.

After eliminating decreased intake and intracellular shift as potential causes of hypokalemia, examination of the renal response can help to clarify the source of K⁺ loss. The appropriate response to K⁺ depletion is to excrete less than 15 mmol/d of K⁺ in the urine, due to increased reabsorption and decreased distal secretion. Hypokalemia with minimal renal K⁺ excretion suggests that K⁺ was lost via the skin or gastrointestinal tract or that there is a remote history of vomiting or diuretic use. As described above, renal K⁺ wasting may be due to factors that either increase the K⁺ concentration in the CCD or increase the distal flow rate (or both). The ECF volume status, blood pressure, and associated acid-base disorder may help to differentiate the causes of excessive renal K⁺ loss. A rapid and simple test designed to evaluate the driving force for net K⁺ secretion is the *transstubular K⁺ concentration gradient* (TTKG). The TTKG is the ratio of the K⁺ concentration in the lumen of the CCD ([K⁺]₀) to that in peritubular capillaries or plasma ([K⁺]ₚ). The validity of this measurement depends on three assumptions: (1) few solutes are reabsorbed in the medullary collecting duct (MCD), (2) K⁺ is not secreted nor reabsorbed in the MCD, and (3) the osmolality of the fluid in the terminal CCD is known. Significant reabsorption or secretion of K⁺ in the MCD seldom occurs, except in profound K⁺ depletion or excess, respectively. When AVP is acting (OSMₑ ≥ OSMₚ), the osmolality in the terminal CCD is the same as that of plasma, and the K⁺ concentration in the lumen of the distal nephron can be estimated by dividing the urine K⁺ concentration ([K⁺]₀) by the ratio of the urine to plasma osmolality (OSMₑ/OSMₚ):

\[
[K⁺]_{CCD} = [K⁺]_L \times (OSM_p/OSM_e)
\]

\[
TTKG = \frac{[K⁺]_{CCD}}{[K⁺]_p} = \frac{[K⁺]_L \times (OSM_p/OSM_e)}{[K⁺]_p}
\]

Hypokalemia with a TTKG greater than 4 suggests renal K⁺ loss due to increased distal K⁺ secretion. Plasma renin and aldosterone levels are often helpful in differentiating the various causes of hyperaldosteronism. Bicarbonaturia and the presence of other non-reabsorbed anions also increase the TTKG and lead to renal K⁺-wasting.

**TREATMENT**

The therapeutic goals are to correct the K⁺ deficit and to minimize ongoing losses. With the exception of periodic paralysis, hypokalemia resulting from transcellular shifts rarely requires intravenous K⁺ supplementation, which can lead to rebound hyperkalemia. It is generally safer to correct hypokalemia via the oral route. The degree of K⁺ depletion does not correlate well with the plasma K⁺ concentration. A
Hyperkalemia

ETIOLOGY Hyperkalemia, defined as a plasma K⁺ concentration >5.0 mmol/L, occurs as a result of either K⁺ release from cells or decreased renal loss. Increased K⁺ intake is rarely the sole cause of hyperkalemia since the phenomenon of potassium adaptation ensures rapid K⁺ excretion in response to increases in dietary consumption. Iatrogenic hyperkalemia may result from overzealous parenteral K⁺ replacement or in patients with renal insufficiency. Pseudohyperkalemia represents an artificially elevated plasma K⁺ concentration due to K⁺ movement out of cells immediately prior to or following venipuncture. Contributing factors include prolonged use of a tourniquet with or without repeated fist clenching, hemolysis, and marked leukocytosis or thrombocytosis. The latter two result in an elevated serum K⁺ concentration due to K⁺ excretion by the cells of the zona glomerulosa and can lead to increased K⁺ intake or renal dysfunction. Angiotensin-converting enzyme (ACE) inhibitors block the conversion of angiotensin I to angiotensin II. Angiotensin receptor antagonists directly inhibit the actions of angiotensin II on AT1 angiotensin II receptors. The actions of both of these classes of drugs result in impaired aldosterone release. Patients at increased risk of ACE inhibitor or angiotensin receptor antagonist–induced hyperkalemia include those with diabetes mellitus, renal insufficiency, decreased effective circulating arterial volume, bilateral renal artery stenosis, or concurrent use of K⁺-sparring diuretics or NSAIDs.

Decreased aldosterone synthesis may be due to primary adrenal insufficiency (Addison’s disease) or congenital adrenal enzyme deficiency (Chap. 321). Heparin (including low-molecular-weight heparin) inhibits production of aldosterone by the cells of the zona glomerulosa and can lead to severe hyperkalemia in a subset of patients with underlying renal disease, diabetes mellitus, or those receiving K⁺-spparing diuretics. ACE inhibitors, or NSAIDs. Pseudohypoaldosteronism is a rare familial disorder characterized by hyperkalemia, metabolic acidosis, renal Na⁺ wasting, hypotension, high renin and aldosterone levels, and end-organ resistance to aldosterone. The gene encoding the mineralocorticoid receptor is normal in these patients, and the electrolyte abnormalities can be reversed with suprapharmacologic doses of an exogenous mineralocorticoid (e.g., 9α-fludrocortisone) or an inhibitor of 11β-HSDH (e.g., carbexoxoline). The kaliuretic response to aldosterone is impaired by K⁺-sparring diuretics. Spironolactone is a competitive mineralocorticoid antagonist, whereas amiloride and triamterene block the apical Na⁺ channel of the principal cell. Two other drugs that impair K⁺ secretion by blocking distal nephron Na⁺ reabsorption are trimethoprim and pentamidine. These antimicrobial agents may contribute to the hyperkalemia often seen in patients infected with HIV who are being treated for Pneumocystis carinii pneumonia.

TABLE 41-4 Causes of Hyperkalemia

| I. Renal failure |
| II. Decreased distal flow (i.e., decreased effective circulating arterial volume) |
| III. Decreased K⁺ secretion |
| **A. Impaired Na⁺ reabsorption** |
| 1. Primary hypoaldosteronism: adrenal insufficiency, adrenal enzyme deficiency (21-hydroxylase, 3β-hydroxysteroid dehydrogenase, corticosterone methyl oxidase) |
| 2. Secondary hypoaldosteronism: hyperpnea, drugs (ACE inhibitors, NSAIDs, heparin) |
| 3. Resistance to aldosterone: pseudohypoaldosteronism, tubulo-interstitial disease, drugs (K⁺-sparsing diuretics, trimethoprim, pentamidine) |
| **B. Enhanced Cl⁻ reabsorption (chloride shunt)** |
| 1. Gordon’s syndrome |
| 2. Cyclosporine |

Note: ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.
Hyperkalemia frequently complicates acute oliguric renal failure due to increased K⁺ release from cells (acidosis, catabolism) and decreased excretion. Increased distal flow rate and K⁺ secretion per nephron compensate for decreased renal mass in chronic renal insufficiency. However, these adaptive mechanisms eventually fail to maintain K⁺ balance when the GFR falls below 10 to 15 mL/min or oliguria ensues. Otherwise asymptomatic urinary tract obstruction is an often overlooked cause of hyperkalemia. Other nephropathies associated with impaired K⁺ excretion include drug-induced interstitial nephritis, lupus nephritis, sickle cell disease, and diabetic nephropathy. Gordon’s syndrome is a rare condition characterized by hyperkalemia, metabolic acidosis, and a normal GFR. These patients are usually volume-expanded with suppressed renin and aldosterone levels as well as refractory to the kaliuretic effect of exogenous mineralocorticoids. It has been suggested that these findings could all be accounted for by increased distal Cl⁻ reabsorption (electroneutral Na⁺ reabsorption), also referred to as a Cl⁻ shunt. A similar mechanism may be partially responsible for the hyperkalemia associated with cyclosporine nephrotoxicity. Hyperkalemic distal (type 4) RTA may be due to either hypoaldosteronism or a Cl⁻ shunt (aldosterone-resistant).

**CLINICAL FEATURES** Since the resting membrane potential is related to the ratio of the ICF to ECF K⁺ concentration, hyperkalemia partially depolarizes the cell membrane. Prolonged depolarization impairs membrane excitability and is manifest as weakness, which may progress to flaccid paralysis and hypoventilation if the respiratory muscles are involved. Hyperkalemia also inhibits renal ammoniagenesis and reabsorption of NH₄⁺ in the thick ascending limb of the loop of Henle. Thus, net acid excretion is impaired and results in metabolic acidosis, which may further exacerbate the hyperkalemia due to K⁺ movement out of cells.

The most serious effect of hyperkalemia is cardiac toxicity, which does not correlate well with the plasma K⁺ concentration. The earliest electrocardiographic changes include increased T-wave amplitude, or peaked T waves. More severe degrees of hyperkalemia result in a prolonged PR interval and QRS duration, atrioventricular conduction delay, and loss of P waves. Progressive widening of the QRS complex and merging with the T wave produces a sine wave pattern. The terminal event is usually ventricular fibrillation or asystole.

**DIAGNOSIS** (Fig. 41-4) With rare exceptions, chronic hyperkalemia is always due to impaired K⁺ excretion. If the etiology is not readily apparent and the patient is asymptomatic, pseudohyperkalemia should be excluded, as described above. Oliguric acute renal failure and severe chronic renal insufficiency should also be ruled out. The history should focus on medications that impair K⁺ handling and potential sources of K⁺ intake. Evaluation of the ECF compartment, effective circulating volume, and urine output are essential components of the physical examination. The severity of hyperkalemia is determined by the symptoms, plasma K⁺ concentration, and electrocardiographic abnormalities.

The appropriate renal response to hyperkalemia is to excrete at least 200 mmol of K⁺ daily. In most cases, diminished renal K⁺ loss is due to impaired K⁺ secretion, which can be assessed by measuring the transtubular K⁺ concentration gradient (TTKG). A TTKG <10 implies a decreased driving force for K⁺ secretion due to either hypoaldosteronism or resistance to the renal effects of mineralocorticoid. This can be determined by evaluating the kaliuretic response to administration of mineralocorticoid (e.g., 9α-fludrocortisone). Primary adrenal insufficiency can be differentiated from hyporeninemic hypoaldosteronism by examining the renin-aldosterone axis. Renin and aldosterone levels should be measured in the supine and upright positions, following three days of Na⁺ restriction (Na⁺ intake <10 mmol/d) in combination with a loop diuretic to induce mild volume contraction. Aldosterone-resistant hyperkalemia can result from the various causes of impaired distal Na⁺ reabsorption or from a Cl⁻ shunt. The former leads to salt wasting, ECF volume contraction, and high renin and aldosterone levels. In contrast, enhanced distal Cl⁻ reabsorption is associated with volume expansion and suppressed renin and aldosterone secretion. As mentioned above, hypoaldosteronism seldom causes severe hyperkalemia in the absence of increased dietary K⁺ intake, renal insufficiency, transtubular K⁺ shifts, or antikaliuretic drugs.

**TREATMENT**

The approach to therapy depends on the degree of hyperkalemia as determined by the plasma K⁺ concentration, associated muscular weakness, and changes on the electrocardiogram. Potentially fatal hyperkalemia rarely occurs unless the plasma K⁺ concentration exceeds 7.5 mmol/L and is usually associated with profound weakness and absent P waves, QRS widening, or ventricular arrhythmias on the electrocardiogram.

Severe hyperkalemia requires emergent treatment directed at minimizing membrane depolarization, shifting K⁺ into cells, and promoting K⁺ loss. In addition, exogenous K⁺ intake and antikaliuretic drugs should be discontinued. Administration of calcium gluconate decreases membrane excitability. The usual dose is 10 mL of a 10% solution infused over 2 to 3 min. The effect begins within minutes but is short-lived (30 to 60 min), and the dose can be repeated if no change in the electrocardiogram is seen after 5 to 10 min. Insulin causes K⁺ to shift into cells by mechanisms described previously and will temporarily lower the plasma K⁺ concentration. Although glucose alone will stimulate insulin release from normal pancreatic β cells, a more rapid response generally occurs when exogenous insulin is administered (with glucose to prevent hypoglycemia). A commonly recommended combination is 10 to 20 units of regular insulin and 25 to 50 g of glucose. Obviously, hyperglycemic patients should not be given glucose. If effective, the plasma K⁺ concentration will fall by 0.5 to 1.5 mmol/L in 15 to 30 min and the effect will last for several hours. Alkali therapy with intravenous NaHCO₃ can also shift K⁺ into cells. This is safest when administered as an isotonic solution of 3
ACIDOSIS AND ALKALOSIS

Thomas D. DuBose, Jr.

NORMAL ACID-BASE HOMEOSTASIS

Systemic arterial pH is maintained between 7.35 and 7.45 by extracellular and intracellular chemical buffering together with respiratory and renal regulatory mechanisms. The control of arterial CO₂ tension (PₐCO₂) by the central nervous system and respiratory systems and the control of the plasma bicarbonate by the kidneys stabilize the arterial pH by excretion or retention of acid or alkali. The metabolic and respiratory components that regulate systemic pH are described by the Henderson-Hasselbalch equation:

\[ \text{pH} = 6.1 + \log \frac{\text{HCO}_3^-}{\text{P}_{\text{aCO}_2} \times 0.0301} \]

Under most circumstances, CO₂ production and excretion are matched, and the usual steady-state PₐCO₂ is maintained at 40 mmHg. Underexcretion of CO₂ produces hypercapnia, and overexcretion causes hypocapnia. Nevertheless, production and excretion are again matched at a new steady-state PₐCO₂. Therefore, the PₐCO₂ is regulated primarily by neural respiratory factors (Chap. 246) and is not subject to regulation by the rate of CO₂ production. Hypercapnia is usually the result of hypoventilation rather than of increased CO₂ production. Increases or decreases in PₐCO₂ represent derangements of neural respiratory control or are due to compensatory changes in response to a primary alteration in the plasma [HCO₃⁻].

Primary changes in PₐCO₂ can cause acidosis or alkalosis, depending on whether PₐCO₂ is above or below the normal value of 40 mmHg (respiratory acidosis or alkalosis, respectively). Primary alteration of PₐCO₂ evokes cellular buffering and renal adaptation, a slow process that becomes more efficient with time. A primary change in the plasma [HCO₃⁻] as a result of metabolic or renal factors results in compensatory changes in ventilation that blunt the changes in blood pH that would occur otherwise. Such respiratory alterations are referred to as secondary, or compensatory, changes, since they occur in response to primary metabolic changes.

The kidneys regulate plasma [HCO₃⁻] through three main processes: (1) “reabsorption” of filtered HCO₃⁻, (2) formation of titratable acid, and (3) excretion of NH₄⁺ in the urine. The kidney filters approximately 4000 mmol of HCO₃⁻ per day. To reabsorb the filtered load of HCO₃⁻, the renal tubules must therefore secrete 4000 mmol of hydrogen ions. Between 80 and 90% of HCO₃⁻ is reabsorbed in the proximal tubule. The distal nephron reabsorbs the remainder and secretes protons, as generated from metabolism, to defend systemic pH. While this quantity of protons, 40 to 60 mmol/d, is small, it must be secreted to prevent chronic positive H⁺ balance and metabolic acidosis. This quantity of secreted protons is represented in the urine as titratable acid and NH₄⁺. Metabolic acidosis in the face of normal renal function increases NH₄⁺ production and excretion. NH₄⁺ production and excretion are impaired in chronic renal failure, hyperkalemia, and renal tubular acidosis.

In sum, these regulatory responses, including chemical buffering, the regulation of PₐCO₂ by the respiratory system, and the regulation of [HCO₃⁻] by the kidneys, act in concert to maintain a systemic arterial pH between 7.35 and 7.45.

DIAGNOSIS OF GENERAL TYPES OF DISTURBANCES

The most common clinical disturbances are simple acid-base disorders, i.e., metabolic acidosis or alkalosis or respiratory acidosis or alkalosis. Since compensation is not complete, the pH is abnormal in simple disturbances. More complicated clinical situations can give rise to mixed acid-base disturbances.

SIMPLE ACID-BASE DISORDERS

Primary respiratory disturbances (primary changes in PₐCO₂) invoke compensatory metabolic responses (secondary changes in [HCO₃⁻]), and primary metabolic disturbances elicit predictable compensatory respiratory responses. Physiologic compensation can be predicted from the relationships displayed in Table 42-1. Primary changes in PₐCO₂ or [HCO₃⁻] alter systemic pH and cause acidosis or alkalosis. To illustrate, metabolic acidosis due to an increase in endogenous acids (e.g., ketoacidosis) lowers extracellular fluid [HCO₃⁻] and decreases extracellular pH. This stimulates the medullary chemoreceptors to increase ventilation and to return the ratio of [HCO₃⁻] to PₐCO₂, and thus pH, toward normal, although not to normal. The degree of respiratory compensation expected in a simple form of metabolic acidosis can be predicted from the relationship: PₐCO₂ = (1.5 × [HCO₃⁻]) + 8, i.e., the PₐCO₂ is expected to decrease 1.25 mmHg for each mmol per liter decrease in [HCO₃⁻]. Thus, a patient
Mixed Acid-Base Disorders

Mixed acid-base disorders—defined as independently coexisting disorders, not merely compensatory responses—are often seen in patients in critical care units and can lead to dangerous extremes of pH. A patient with diabetic ketoacidosis (metabolic acidosis) may develop an independent respiratory problem leading to respiratory acidosis or alkalosis. Patients with underlying pulmonary disease may not respond to metabolic acidosis with an appropriate ventilatory response because of insufficient respiratory reserve. Such imposition of respiratory acidosis on metabolic acidosis can lead to severe acidemia and a poor outcome. When metabolic acidosis and metabolic alkalosis coexist in the same patient, the pH may be normal or near normal. When the pH is normal, an elevated anion gap (see below) denotes the presence of a metabolic acidosis. A diabetic patient with ketoacidosis may have renal dysfunction resulting in simultaneous metabolic acidosis. Patients who have ingested an overdose of drug combinations such as sedatives and salicylates may have mixed disturbances as a result of the acid-base response to the individual drugs (metabolic acidosis mixed with respiratory acidosis or respiratory alkalosis, respectively). Even more complex are triple acid-base disturbances. For example, patients with metabolic acidosis due to alcoholic ketoacidosis may develop metabolic alkalosis due to vomiting and superimposed respiratory alkalosis due to the hyperventilation of hepatic dysfunction or alcohol withdrawal.

**DIAGNOSIS OF ACID-BASE DISORDERS** A stepwise approach to the diagnosis of acid-base disorders follows and is summarized in Table 42-2. Care should be taken when measuring blood gases to obtain the arterial blood sample without using excessive heparin. In the determination of arterial blood gases by the clinical laboratory, both pH and PaCO_2 are measured, and the [HCO_3] is calculated from the Henderson-Hasselbalch equation. This calculated value should be compared with the measured [HCO_3] (total CO_2) on the electrolyte panel. These two values should agree within 2 mmol/L. If they do not, the values may not have been drawn simultaneously, a laboratory error may be present, or an error could have been made in calculating the [HCO_3]. After verifying the blood acid-base values, one can then identify the precise acid-base disorder.

The most common causes of acid-base disorders should be kept in mind while probing the history for clues about the etiology. For example, established chronic renal failure is expected to cause a metabolic acidosis, and chronic vomiting frequently causes metabolic alkalosis. Patients with pneumonia, sepsis, or cardiac failure frequently have respiratory acidosis, and patients with chronic obstructive pulmonary disease or a sedative drug overdose often display a respiratory acidosis. The drug history is important since loop or thiazide diuretics may cause metabolic alkalosis, and the carbonic anhydrase inhibitor acetazolamide can result in metabolic acidosis.

Blood for electrolytes and arterial blood gases should be drawn simultaneously prior to therapy, since an increase in [HCO_3] occurs with metabolic alkalosis and respiratory acidosis. Conversely, a decrease in [HCO_3] occurs in metabolic acidosis and respiratory alkalosis.

Metabolic acidosis leads to hyperkalemia as a result of cellular shifts in which H⁺ is exchanged for K⁺ or Na⁺. For each decrease in blood pH of 0.10, the plasma [K⁺] should rise by 0.6 mmol/L. This relationship is not invariable. Diabetic ketoacidosis, lactic acidosis, diarrhea, and renal tubular acidosis (RTA) are often associated with potassium depletion because of urinary K⁺ wasting.

**Anion Gap** All evaluations of acid-base disorders should include a simple calculation of the anion gap (AG); it represents those unmeasured anions in plasma (normally 10 to 12 mmol/L) and is calculated as

![Figure 42-1](https://example.com/image.png)

**TABLE 42-2 Steps in Acid-Base Diagnosis**

1. Obtain arterial blood gases (ABGs) and electrolytes (lytes) simultaneously.
2. Compare [HCO_3] on ABG and lytes to verify accuracy.
3. Calculate anion gap (AG).
4. Know four causes of high AG acidosis (ketoacidosis, lactic acid acidosis, renal failure, and toxins).
5. Know two causes of high hyperchloremic or nongap acidosis (bicarbonate loss from GI tract, renal tubular acidosis).
6. Estimate compensatory response (Table 42-1).
7. Compare ΔAG and ΔHCO_3.
8. Compare change in [Cl⁻] with change in [Na⁺].
follows: \[ AG = Na^+ - (Cl^- + HCO_3^-) \]. The unmeasured anions include anionic proteins, phosphate, sulfate, and organic anions. When acid anions, such as acetooacetate and lactate, accumulate in extracellular fluid, the AG increases, causing a high-AG acidosis. An increase in the AG is most often due to an increase in unmeasured anions and less commonly is due to a decrease in unmeasured cations (calcium, magnesium, potassium). In addition, the AG may increase with an increase in anionic albumin, either because of increased albumin concentration or alkalosis, which alters albumin charge. A decrease in the AG can be due to (1) an increase in unmeasured cations; (2) the addition to the blood of abnormal cations, such as lithium (lithium intoxication) or cationic immunoglobulins (plasma cell dyscrasias); (3) a reduction in the major plasma anion albumin concentration (nephrotic syndrome); (4) a decrease in the effective anionic charge on albumin by acidosis; or (5) hyperviscosity and severe hyperlipidemia, which can lead to an underestimation of sodium and chloride concentrations. A fall in serum albumin by 1 g/dL from the normal value (4.5 g/dL) decreases the anion gap by 2.5 meq/L.

In the face of a normal serum albumin, a high AG is usually due to non-chloride-containing acids that contain inorganic (phosphate, sulfate), organic (ketocids, lactate, uremic organic anions), exogenous (salicylate or ingested toxins with organic acid production), or unidentified anions. By definition, therefore, a high-AG acidosis has two identifying features: a low \([HCO_3^-]\) and an elevated AG. The latter is present even if an additional acid-base disorder is superimposed to modify the \([HCO_3^-]\) independently. Simultaneous metabolic acidosis of the high-AG variety plus either chronic respiratory acidosis or metabolic alkalosis represents such a situation in which \([HCO_3^-]\) may be normal or even high. However, the AG is elevated, and \([Cl^-]\) is depressed.

Similarly, normal values for \([HCO_3^-], PaCO_2,\) and pH do not ensure the absence of an acid-base disturbance. For instance, an alcoholic who has been vomiting may develop a metabolic acidosis with a pH of 7.55, \(PaCO_2\) of 48 mmHg, \([HCO_3^-]\) of 40 mmol/L, \([Na^+]\) of 135, \([Cl^-]\) of 80, and \([K^+]\) of 2.8. If such a patient were then to develop a superimposed alcoholic ketoacidosis with a \(\beta\)-hydroxybutyrate concentration of 15 mM, arterial pH would fall to 7.40, \([HCO_3^-]\) to 25 mmol/L, and the \(PaCO_2\) to 40 mmHg. Although these blood gases are normal, the AG is elevated at 30 mmol/L, indicating a mixed metabolic acidosis and metabolic acidosis.

**METABOLIC ACIDOSIS**

Metabolic acidosis can occur because of an increase in endogenous acid production (such as lactate and ketocids), loss of bicarbonate (as in diarrhea), or accumulation of endogenous acids (as in renal failure). Metabolic acidosis has profound effects on the respiratory, cardiac, and nervous systems. The fall in blood pH is accompanied by a characteristic increase in ventilation, especially the tidal volume (Kussmaul respiration). Intrinsic cardiac contractility may be depressed, but inotropic function can be normal because of catecholamine release. Both peripheral arterial vasodilation and central venoconstriction can be present; the decrease in central and pulmonary vascular compliance predisposes to pulmonary edema with even minimal volume overload. Central nervous system function is depressed, with headache, lethargy, stupor, and, in some cases, even coma. Glucose intolerance may also occur.

There are two major categories of clinical metabolic acidosis: high-anion-gap (AG) and normal-AG, or hyperchloremic acidosis (Table 42-3 and Table 42-4).

**TREATMENT**

Treatment of metabolic acidosis with alkali should be reserved for severe acidemia except when the patient has no “potential \([HCO_3^-]\)” in plasma. Potential \([HCO_3^-]\) can be estimated from the increment (\(\Delta\)) in the AG (\(\Delta AG = patient’s AG - 10\)). It must be determined if the acid anion in plasma is metabolizable (i.e., \(\beta\)-hydroxybutyrate, acetooacetate, and lactate) or nonmetabolizable (anions that accumulate in chronic renal failure and after toxin ingestion). The latter requires return of renal function to replenish the \([HCO_3^-]\) deficit, a slow and often unpredictable process. Consequently, patients with a normal AG acidosis (hyperchloremic acidosis), a slightly elevated AG (mixed hyperchloremic and AG acidosis), or an AG attributable to a nonmetabolizable anion in the face of renal failure should receive alkali therapy, either orally (NaHCO_3 or Shohl’s solution) or intravenously (NaHCO_3), in an amount necessary to slowly increase the plasma \([HCO_3^-]\) into the 20 to 22 mmol/L range.

Controversy exists, however, in regard to the use of alkali in patients with a pure AG acidosis owing to accumulation of a metabolizable organic acid anion (ketoacidosis or lactic acidosis). In general, severe acidosis (pH < 7.20) warrants the intravenous administration of 50 to 100 meq of NaHCO_3 over 30 to 45 min, during the initial 1 to 2 h of therapy. Provision of such modest quantities of alkali in this situation seems to provide an added measure of safety, but it is essential to monitor plasma electrolytes during the course of therapy, since the \([K^+]\) may decline as pH rises. The goal is to increase the \([HCO_3^-]\) to 10 meq/L and the pH to 7.15, not to increase these values to normal.

**HIGH-ANION-GAP ACIDOSES** There are four principal causes of a high-AG acidosis: (1) lactic acidosis, (2) ketoacidosis, (3) ingested toxins, and (4) acute and chronic renal failure (Table 42-3). Initial screening to differentiate the high-AG acidoses should include (1) a probe of the

history for evidence of drug and toxin ingestion and measurement of arterial blood gas to detect coexistent respiratory alkalosis (salicylates); (2) determination of whether diabetes mellitus is present (diabetic ketoacidosis); (3) a search for evidence of alcoholism or increased levels of β-hydroxybutyrate (alcoholic ketoacidosis); (4) observation for clinical signs of uremia and determination of the blood urea nitrogen (BUN) and creatinine (uremic acidosis); (5) inspection of the urine for oxalate crystals (ethyleneglycol); and (6) recognition of the numerous clinical settings in which lactate levels may be increased (hypotension, shock, cardiac failure, leukemia, cancer, and drug or toxin ingestion).

**Lactic Acidosis** An increase in plasma L-lactate may be secondary to poor tissue perfusion (type A)—circulatory insufficiency (shock, circulatory failure), severe anemia, mitochondrial enzyme defects, and inhibitors (carbon monoxide, cyanide)—or to aerobic disorders (type B)—malignancies, diabetes mellitus, renal or hepatic failure, severe infections (cholera, malaria), seizures, AIDS, or drugs/toxins (biganides, ethanol, methanol, isoniazid, AZT analogues, and fructose). Unrecognized bowel ischemia or infarction in a patient with severe atherosclerosis or cardiac decompensation receiving vasopressors is a common cause of lactic acidosis. D-Lactic acidosis, which may be associated with jejunal bypass or intestinal obstruction and is due to formation of D-lactate by gut bacteria, may cause both an increased AG and hyperchloremia.

**TREATMENT**

The underlying condition that disrupts lactate metabolism must first be corrected; tissue perfusion must be restored when it is inadequate. Vasocostrictors should be avoided, if possible, since they may worsen tissue perfusion. Alkali therapy is generally advocated for acute, severe acidemia (pH <7.15) to improve cardiac function and lactate utilization. However, NaHCO3 therapy may paradoxically depress cardiac performance and exacerbate acidosis by enhancing lactate production (HCO3− stimulates phosphofructokinase). While the use of alkali in moderate lactic acidosis is controversial, it is generally agreed that attempts to return the pH or [HCO3−] to normal by administration of exogenous NaHCO3 are deleterious. A reasonable approach is to infuse sufficient NaHCO3 to raise the arterial pH to no more than 7.2 over 30 to 40 min.

NaHCO3 therapy can cause fluid overload and hypertension because the amount required can be massive when accumulation of lactic acid is relentless. Fluid administration is poorly tolerated because of central venocination, especially in the oliguric patient. If the underlying cause of the lactic acidosis can be remedied, blood lactate will be converted to HCO3− and may result in an overshoot alkalosis.

**Ketoacidosis**

**DIABETIC KETOACIDOSIS** This condition is caused by increased fatty acid metabolism and the accumulation of ketocids (acetacetate and β-hydroxybutyrate). Diabetic ketoacidosis usually occurs in insulin-dependent diabetes mellitus in association with cessation of insulin or an intercurrent illness, such as an infection, gastroenteritis, pancreatitis, or myocardial infarction, which increases insulin requirements temporarily and acutely. The accumulation of ketocids accounts for the increment in the AG and is accompanied most often by hyperglycemia [glucose >17 mmol/L (300 mg/dL)]. It should be noted that since insulin prevents production of ketones, bicarbonate therapy is rarely needed except with extreme acidemia (pH <7.1), and then in only limited amounts (see “Treatment” for lactic acidosis). →The management of this condition is described in Chap. 323.

**ALCOHOLIC KETOACIDOSIS** Chronic alcoholics can develop ketoacidosis when alcohol consumption is abruptly curtailed; it is usually associated with binge drinking, vomiting, abdominal pain, starvation, and volume depletion. The glucose concentration is low or normal, and acidosis may be severe because of elevated ketones, predominantly β-hydroxybutyrate. Mild lactic acidosis may coexist because of alteration in the redox state. The nitropusslide ketone reaction (Acetest) can detect acetocetic acid but not β-hydroxybutyrate, so that the degree of ketosis and ketonuria can be underestimated. Typically, insulin levels are low, and concentrations of triglyceride, cortisol, glucagon, and growth hormone are increased.

**TREATMENT**

Extracellular fluid deficits should be replaced by intravenous administration of saline and glucose (5% dextrose in 0.9% NaCl). Hypophosphatemia, hypokalemia, and hypomagnesemia may coexist and should be corrected. Hypophosphatemia usually emerges 12 to 24 h after admission, may be exacerbated by glucose infusion, and, if severe, may induce rhabdomyolysis. Upper gastrointestinal hemorrhage, pancreatitis, and pneumonia may accompany this disorder.

**Drug- and Toxin-Induced Acidosis**

**SALICYLATES** (See also Chap. 377.) Salicylate intoxication in adults usually causes respiratory alkalosis, mixed metabolic acidosis—respiratory alkalosis, or a pure high-AG metabolic acidosis. In the latter example, which is less common, only a portion of the AG is due to the salicylates. Lactic acid production is also often increased.
an osmolar gap in serum, and a high-AG acidosis. Treatment should not be delayed while awaiting measurement of ethylene glycol levels in this setting.

**TREATMENT**

This includes the prompt institution of a saline or osmotic diuresis, thiamine and pyridoxine supplements, fomepizole or ethanol, and hemodialysis. The intravenous administration of the alcohol dehydrogenase inhibitor fomepizole (4-methylpyrazole; 7 mg/kg as a loading dose) or ethanol intravenously to achieve a level of 22 mmol/L (100 mg/dL) serves to lessen toxicity because they compete with ethylene glycol for metabolism by alcohol dehydrogenase. Fomepizole, although expensive, offers the advantages of a predictable decline in ethylene glycol levels without the adverse effects, such as excessive obtundation, associated with ethanol infusion.

**METHANOL** (See also Chap. 377.) The ingestion of methanol (wood alcohol) causes metabolic acidosis, and its metabolites formaldelyde and formic acid cause severe optic nerve and central nervous system damage. Lactic acid, ketoacids, and other unidentified organic acids may contribute to the acidosis. Due to its low molecular weight (32 Da), an osmolar gap is usually present.

**RENAL FAILURE** (See also Chaps. 260 and 261) The hyperchloremic acidosis of moderate renal insufficiency is eventually converted to the high-AG acidosis of advanced renal failure. Poor filtration and reabsorption of organic anions contribute to the pathogenesis. As renal disease progresses, the number of functioning nephrons eventually becomes insufficient to keep pace with net acid production. Uremic acidosis is characterized, therefore, by a reduced rate of NH$_4^+$ production and excretion, primarily due to decreased renal mass. [HCO$_3^-$] rarely falls below 15 mmol/L, and the AG rarely exceeds 20 mmol/L. The acid retained in chronic renal disease is buffered by alkaline salts from bone. Despite significant retention of acid (up to 20 mmol/d), the serum [HCO$_3^-$] does not decrease further, indicating participation of buffers outside the extracellular compartment. Chronic metabolic acidosis results in significant loss of bone mass due to reduction in bone calcium carbonate. Chronic acidosis also increases urinary calcium excretion, proportional to cumulative acid retention.

**TREATMENT**

Both uremic acidosis and the hyperchloremic acidosis of renal failure require oral alkali replacement to maintain the [HCO$_3^-$] between 20 and 24 mmol/L. This can be accomplished with relatively modest amounts of alkali (1.0 to 1.5 mmol/kg body weight per day). It is assumed that alkali replacement prevents the harmful effects of H$^+$ balance on bone and prevents or retards muscle catabolism. Sodium citrate (Shohl’s solution) or NaHCO$_3$ tablets are equally effective alkalinizing salts. Citrate enhances the absorption of aluminum from the gastrointestinal tract and should never be given together with aluminum-containing antacids because of the risk of aluminum intoxication. When hyperkalemia is present, furosemide (60 to 80 mg/d) should be added.

**HYPERCHLOREMIC (NON GAP) METABOLIC ACIDOSIS** Alkali can be lost from the gastrointestinal tract in diarrhea or from the kidneys (renal tubular acidosis, RTA). In these disorders (Table 42-4), reciprocal changes in [Cl$^-$] and [HCO$_3^-$] result in a normal AG. In pure hyperchloremic acidosis, therefore, the increase in [Cl$^-$] above the normal value approximates the decrease in [HCO$_3^-$]. The absence of such a relationship suggests a mixed disturbance.

In diarrhea, stools contain a higher [HCO$_3^-$] and decomposed HCO$_3^-$ than plasma so that metabolic acidosis develops along with volume depletion. Instead of an acute urine pH (as anticipated with systemic acidosis), urine pH is usually around 6 because metabolic acidosis and hypokalemia increase renal synthesis and excretion of NH$_4^+$, thus providing a urinary buffer that increases urine pH. Metabolic acidosis due to gastrointestinal losses with a high urine pH can be differentiated from RTA (Chap. 265) because urinary NH$_4^+$ excretion is typically low in RTA and high with diarrhea. Urinary NH$_4^+$ levels can be estimated by calculating the urine anion gap (UAG): UAG = [Na$^+$ + K$^+$] - [Cl$^-$]. When [Cl$^-$] > [Na$^+$ + K$^+$], and the urine gap is negative, the urine ammonium level is appropriately increased, suggesting an extrarenal cause of the acidosis. Conversely, when the urine anion gap is positive, the urine ammonium level is low, suggesting a renal cause of the acidosis.

Loss of functioning renal parenchyma by progressive renal disease leads to hyperchloremic acidosis when the glomerular filtration rate (GFR) is between 20 and 50 mL/min and to uremic acidosis with a high AG when the GFR falls to <20 mL/min. Such a progression occurs commonly with tubulointerstitial forms of renal disease, but hyperchloremic metabolic acidosis can persist with advanced glomerular disease. In advanced renal failure, ammoniagenesis is reduced in proportion to the loss of functional renal mass, and ammonium accumulation and trapping in the outer medullary collecting tubule may also be impaired. Because of adaptive increases in K$^+$ secretion by the collecting duct and colon, the acidosis of chronic renal insufficiency is typically normokalemic.

Proximal RTA (type 2 RTA) (Chap. 265) is most often due to generalized proximal tubular dysfunction manifested by glycosuria, generalized aminoaciduria, and phosphaturia (Fanconi syndrome). With a low plasma [HCO$_3^-$], the urine pH is acid (pH <5.5). The fractional excretion of [HCO$_3^-$] may exceed 10 to 15% when the serum HCO$_3^-$ > 20 mmol/L. Since HCO$_3^-$ is not reabsorbed normally in the proximal tubule, therapy with NaHCO$_3$ will enhance renal potassium wasting and hypokalemia.

The typical findings in classic distal RTA (type 1 RTA) include hypokalemia, hyperchloremic acidosis, low urinary NH$_4^+$ excretion (positive UAG, low urine [NH$_4^+$]), and inappropriately high urine pH (pH >5.5). Such patients are unable to acidify the urine below a pH of 5.5. Most patients have hypopituitarism and hypercalciuria, so nephrolithiasis, nephrocalcinosis, and bone disease are common. In type 4 RTA, hyperkalemia is disproportionate to the reduction in GFR because of coexisting dysfunction of potassium and acid secretion. Urinary ammonium excretion is invariably depressed, and renal function may be compromised, for example, due to diabetic nephropathy, amyloidosis, or tubulointerstitial disease. -->See Chap. 265 for the pathophysiology, diagnosis, and treatment of RTA.

**Hyperoxenemin Hypoaldosteronism** (See also Chap. 321) This condition typically causes hyperchloremic metabolic acidosis, most commonly in older adults with diabetes mellitus or tubulointerstitial disease and renal insufficiency. Patients usually have mild to moderate renal insufficiency and acidosis, with elevation in serum [K$^+$] (5.2 to 6.0 mmol/L), concurrent hypertension, and congestive heart failure. Both the metabolic acidosis and the hyperkalemia are out of proportion to impairment in GFR. Nonsteroidal anti-inflammatory drugs trimethoprim, pentamidine, and angiotensin-converting enzyme (ACE) inhibitors can also cause hyperkalemia with hyperchloremic metabolic acidosis in patients with renal insufficiency (Table 42-4).

**METABOLIC ALKALOSIS**

Metabolic alkalosis is manifested by an elevated arterial pH, an increase in the serum [HCO$_3^-$], and an increase in Pa$_{CO_2}$, as a result of compensatory alveolar hypoventilation. It is often accompanied by hypochloremia and hypokalemia. The patient with a high [HCO$_3^-$] and a low [Cl$^-$] has either metabolic alkalosis or chronic respiratory acidosis. As shown in Table 42-1, the Pa$_{CO_2}$ increases 6 mmHg for each 10-mmol/L increase in the [HCO$_3^-$] above normal. Stated differently, in the range of [HCO$_3^-$] from 10 to 40 mmol/L, the predicted Pa$_{CO_2}$...
is approximately equal to the $[\text{HCO}_3^-] + 15$. The arterial pH establishes the diagnosis, since it is increased in metabolic alkalosis and decreased or normal in respiratory acidosis. Metabolic alkalosis frequently occurs in association with other disorders such as respiratory acidosis or alkalosis or metabolic acidosis.

**PATHOGENESIS** Metabolic alkalosis occurs as a result of net gain of $[\text{HCO}_3^-]$ or loss of nonvolatile acid (usually HCl by vomiting) from the extracellular fluid. Since it is unusual for alkali to be added to the body, the disorder involves a generative stage, in which the loss of acid usually causes alkalosis, and a maintenance stage, in which the kidneys fail to compensate by excreting $\text{HCO}_3^-$ because of volume contraction, a low GFR, or depletion of $\text{K}^+$.

Under normal circumstances, the kidneys have an impressive capacity to excrete $\text{HCO}_3^-$. Continuation of metabolic alkalosis represents a failure of the kidneys to eliminate $\text{HCO}_3^-$ in the usual manner. For $\text{HCO}_3^-$ to be added to the extracellular fluid, it must be administered exogenously or synthesized endogenously, in part or entirely by the kidneys. The kidneys will retain, rather than excrete, the excess alkali and maintain the alkalosis if (1) volume deficiency, chloride deficiency, and $\text{K}^+$ deficiency exist in combination with a reduced GFR, which augments distal tubule $\text{H}^+$ secretion; or (2) hypokalemia exists because of autonomous hyperaldosteronism. In the first example, alkalosis is corrected by administration of NaCl and KCl, whereas in the latter it is necessary to repair the alkalosis by pharmacologic or surgical intervention, not with saline administration.

**DIFFERENTIAL DIAGNOSIS** To establish the cause of metabolic alkalosis (Table 42-5), it is necessary to assess the status of the extracellular fluid volume (ECFV), the recumbent and upright blood pressure, the serum $[\text{K}^+]$, and the renin-aldosterone system. For example, the presence of chronic hypertension and chronic hypokalemia in an alkalotic patient suggests either mineralocorticoid excess or that the hypertensive patient is receiving diuretics. Low plasma renin activity and normal urine [Na+] and [Cl⁻] in a patient who is not taking diuretics indicate a primary mineralocorticoid excess syndrome. The combination of hypokalemia and alkalosis in a normotensive, nonendematosus patient can be due to Bartter’s or Gitelman’s syndrome, magnesium deficiency, vomiting, exogenous alkali, or diuretic ingestion. Determination of urine electrolytes (especially the urine [Cl⁻]) and screening of the urine for diuretics may be helpful. If the urine is alkaline, with an elevated [Na⁺] and [K⁺] but low [Cl⁻], the diagnosis is usually either vomiting (overt or surreptitious) or alkali ingestion. If the urine is relatively acid and has low concentrations of Na⁺, K⁺, and Cl⁻, the most likely possibilities are prior vomiting, the posthypercapnic state, or prior diuretic ingestion. If, on the other hand, neither the urine sodium, potassium, nor chloride concentrations are depressed, magnesium deficiency, Bartter’s or Gitelman’s syndrome, or current diuretic ingestion should be considered. Bartter’s syndrome is distinguished from Gitelman’s syndrome because of hypocalciuria and hypomagnesemia in the latter disorder. The genetic and molecular basis of these two disorders has been elucidated recently (Chap. 265).

**Alkali Administration** Chronic administration of alkali to individuals with normal renal function rarely, if ever causes alkalosis. However, in patients with coexistent hemodynamic disturbances, alkalosis can develop because the normal capacity to excrete $\text{HCO}_3^-$ may be exceeded or there may be enhanced reabsorption of $\text{HCO}_3^-$. Such patients include those who receive oral or intravenous $\text{HCO}_3^-$, acetate loads (parenteral hyperalimentation solutions), citrate loads (transfusions), or antacids plus cation-exchange resins (aluminum hydroxide and sodium polystyrene sulfonate).

**METABOLIC ALKALOSIS ASSOCIATED WITH ECFV CONTRACTION, K⁺ DEPLETION, AND SECONDARY HYPERRENINEMIC HYPERALDOSTERONISM**

**Gastrointestinal Origin** Gastrointestinal loss of $\text{H}^+$ from vomiting or gastric aspiration results in retention of $\text{HCO}_3^-$. The loss of fluid and NaCl in vomitus or nasogastric suction results in contraction of the ECFV and an increase in the secretion of renin and aldosterone. Volume contraction causes a reduction in GFR and an enhanced capacity of the renal tubule to reabsorb $\text{HCO}_3^-$. During active vomiting, there is continued addition of $\text{HCO}_3^-$ to plasma in exchange for Cl⁻, and the plasma $[\text{HCO}_3^-]$ exceeds the reabsorptive capacity of the proximal tubule. The excess NaHCO₃ reaches the distal tubule, where secretion is enhanced by an aldosterone and the delivery of the poorly reabsorbed anion, $\text{HCO}_3^-$. Because of contraction of the ECFV and hypochloremia, Cl⁻ is avidly conserved by the kidney. Correction of the contracted ECFV with NaCl and repair of K⁺ deficits corrects the acid-base disorder.

**Renal Origin** **DIURETICS** (See also Chap. 216) Drugs that induce diuresis, such as thiazides and loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid), acutely diminish the ECFV without altering the total body bicarbonate content. The serum $[\text{HCO}_3^-]$ increases. The chronic administration of diuretics tends to generate an alkalosis by increasing distal salt delivery, so that $\text{K}^+$ and $\text{H}^+$ secretion are stimulated. The alkalosis is maintained by persistence of the contraction of the ECFV, secondary hyperaldosteronism, $\text{K}^+$ deficiency, and the direct effect of the diuretic (as long as diuretic administration...

continues). Repair of the alkalosis is achieved by providing isotonic saline to correct the ECFV deficit.

**Bartter’s Syndrome and Gitelman’s Syndrome** See Chap. 265.

**Nonreabsorbable Anions and Magnesium Deficiency** Administration of large quantities of nonreabsorbable anions, such as penicillin or carbencillin, can enhance distal acidification and K⁺ secretion by increasing the transepithelial potential difference (lumen negative). Mg²⁺ deficiency results in hypokalemic alkalosis by enhancing distal acidification through stimulation of renin and hence aldosterone secretion.

**Potassium Depletion** Chronic K⁺ depletion may cause metabolic alkalosis by increasing urinary acid excretion. Both NH₄⁺ production and absorption are enhanced and HCO₃⁻ reabsorption is stimulated. Chronic K⁺ deficiency upregulates the renal H⁺ / K⁺-ATPase to increase K⁺ absorption at the expense of enhanced H⁺ secretion. Alkalosis associated with severe K⁺ depletion is resistant to salt administration, but repair of the K⁺ deficiency corrects the alkalosis.

**After Treatment of Lactic Acidosis or Ketoadidosis** When an underlying stimulus for the generation of lactic acid or ketoadidosis is removed rapidly, as with repair of circulatory insufficiency or with insulin therapy, the lactate or ketones are metabolized to yield an equivalent amount of HCO₃⁻. Other sources of new HCO₃⁻ are additive with the original amount generated by organic anion metabolism to create a surge of HCO₃⁻. Such sources include (1) new HCO₃⁻ added to the blood by the kidneys as a result of enhanced acid excretion during the pre-existing period of acidosis, and (2) alkali therapy during the treatment phase of the acidosis. Acidosis-induced contraction of the ECFV and K⁺ deficiency act to sustain the alkalosis.

**Posthypercapnia** Prolonged CO₂ retention with chronic respiratory acidosis enhances renal HCO₃⁻ absorption and the generation of new HCO₃⁻ (increased net acid excretion). If the PaCO₂ is returned to normal, metabolic alkalosis results from the persistently elevated [HCO₃⁻]. Alkalosis develops if the elevated PaCO₂ is abruptly returned toward normal by a change in mechanically controlled ventilation. Associated ECFV contraction does not allow complete repair of the alkalosis by correction of the PaCO₂ alone, and alkalosis persists until Cl⁻ supplementation is provided.

**Metabolic Alkalosis Associated with ECFV Expansion, Hypertension, and Hyperaldosteronism** Mineralocorticoid administration or excess production (primary aldosteronism of Cushion’s syndrome and adrenal cortical enzyme defects (Chap. 321)) increases net acid excretion and may result in metabolic alkalosis, which may be worsened by associated K⁺ deficiency. ECFV expansion from salt retention causes hypertension and antagonizes the reduction in GFR and/or increases tubular acidification induced by aldosterone and by K⁺ deficiency. The kaliuresis persists and causes continued K⁺ depletion with polydipsia, inability to concentrate the urine, and polyuria. Increased aldosterone levels may be the result of autonomous primary adrenal overproduction or of secondary aldosterone release due to renal overproduction of renin. In both situations, the normal feedback of ECFV on net aldosterone production is disrupted, and hypertension from volume retention can result.

Liddle’s syndrome (Chap. 265) results from increased activity of the collecting duct Na⁺ channel (ENaC) and is a rare inherited disorder associated with hypertension due to volume expansion manifested as hypokalemic alkalosis and normal aldosterone levels.

**Symptoms** With metabolic alkalosis, changes in central and peripheral nervous system function are similar to those of hypokalemia (Chap. 331); symptoms include mental confusion, obtundation, and a predisposition to seizures, paresthesia, muscular cramping, tetany, aggravation of arrhythmias, and hypoxemia in chronic obstructive pulmonary disease. Related electrolyte abnormalities include hypokalemia and hypophosphatemia.
accompanying hypoxemia. A rapid increase in $P_aCO_2$ may cause anxiety, dyspnea, confusion, psychosis, and hallucinations and may progress to coma. Lesser degrees of dysfunction in chronic hypcapnia include sleep disturbances, loss of memory, daytime somnolence, personality changes, impairment of coordination, and motor disturbances such as tremor, myoclonic jerks, and asterixis. Headaches and other signs that mimic intracranial pressure, such as papilledema, abnormal reflexes, and focal muscle weakness, are due to vasoconstriction secondary to loss of the vasodilator effects of $CO_2$.

Depression of the respiratory center by a variety of drugs, injury, or disease can produce respiratory acidosis. This may occur acutely with general anesthetics, sedatives, and head trauma or chronically with sedatives, alcohol, intracranial tumors, and the syndromes of sleep-disordered breathing, including the primary alveolar and obesity-hypoventilation syndromes (Chaps. 246 and 247). Abnormalities or disease in the motor neurons, neuromuscular junction, and skeletal muscle can cause hypoventilation via respiratory muscle fatigue. Mechanical ventilation, when not properly adjusted and supervised, may result in respiratory acidosis, particularly if $CO_2$ production suddenly rises (because of fever, agitation, sepsis, or overfeeding) or alveolar ventilation falls because of worsening pulmonary function. High levels of positive end-expiratory pressure in the presence of reduced cardiac output may cause hypercapnia as a result of large increases in alveolar dead space (Chap. 234). Permissive hypercapnia is being used with increasing frequency because of studies suggesting lower mortality rates than with conventional mechanical ventilation, especially with severe central nervous system or heart disease. Although the potential beneficial effects of permissive hypercapnia may be mitigated by correction of the acidemia, it seems prudent, nevertheless, to keep the pH in the range of 7.2 to 7.3 by administration of $NaHCO_3$.

Acute hypercapnia follows sudden occlusion of the upper airway or generalized bronchospasms as in severe asthma, anaphylaxis, inhalational burn, or toxin injury. Chronic hypercapnia and respiratory acidosis occur in end-stage obstructive lung disease. Restrictive disorders involving both the chest wall and the lungs can cause respiratory acidosis because the high metabolic cost of respiration causes ventilatory muscle fatigue. Advanced stages of intrapulmonary and extrapulmonary restrictive defects present as chronic respiratory acidosis.

The diagnosis of respiratory acidosis requires, by definition, the measurement of $P_aCO_2$ and arterial pH. A detailed history and physical examination often indicate the cause. Pulmonary function studies (Chap. 234), including spirometry, diffusion capacity for carbon monoxide, lung volumes, and arterial $P_aCO_2$ and $O_2$ saturation, usually make it possible to determine if respiratory acidosis is secondary to lung disease. The workup for nonpulmonary causes should include a detailed drug history, measurement of hematocrit, and assessment of upper airway, chest wall, pleura, and neuromuscular function.

**TREATMENT**

The management of respiratory acidosis depends on its severity and rate of onset. Acute respiratory acidosis can be life-threatening, and measures to reverse the underlying cause should be undertaken simultaneously with restoration of adequate alveolar ventilation. This may necessitate tracheal intubation and assisted mechanical ventilation. Oxygen administration should be titrated carefully in patients with severe obstructive pulmonary disease and chronic $CO_2$ retention who are breathing spontaneously (Chap. 242). When oxygen is used judiciously, these patients may experience progression of the respiratory acidosis. Aggressive and rapid correction of hypercapnia should be avoided, because the falling $P_aCO_2$ may provoke the same complications noted with acute respiratory alkalosis (i.e., cardiac arrhythmias, reduced cerebral perfusion, and seizures). The $P_aCO_2$ should be lowered gradually in chronic respiratory acidosis, aiming to restore the $P_aCO_2$ to baseline levels and to provide sufficient Cl⁻ and K⁺ to enhance the renal excretion of $HCO_3^-$.

Chronic respiratory acidosis is frequently difficult to correct, but measures aimed at improving lung function (Chap. 242) can help some patients and forestall further deterioration in most.

**RESPIRATORY ALKALOSIS**

Alveolar hyperventilation decreases $P_aCO_2$, and increases the $HCO_3^- / P_aCO_2$ ratio, thus increasing pH (Table 42-6). Nonbicarbonate cellular buffers respond by consuming $HCO_3^-$. Hypocapnia develops when a sufficiently strong ventilatory stimulus causes $CO_2$ output in the lungs to exceed its metabolic production by tissues. Plasma pH and [$HCO_3^-$] appear to vary proportionately with $P_aCO_2$ over a range from 40 to 15 mmHg. The relationship between arterial ([$H^+$]) concentration and $P_aCO_2$ is about 0.7 mmol/L per mmHg (or 0.01 pH unit/mmHg), and that for plasma [$HCO_3^-$] is 0.2 mmol/L per mmHg. Hypocapnia sustained longer than 2 to 6 h is further compensated by a decrease in renal ammonium and titratable acid excretion and a reduction in filtered $HCO_3^-$ reabsorption. Full renal adaptation to respiratory alkalosis may take several days and requires normal volume status and renal function. The kidneys appear to respond directly to the lowered $P_aCO_2$, rather than to alkalosis per se. In chronic respiratory alkalosis a 1-mmHg fall in $P_aCO_2$ causes a 0.4- to 0.5-mmol/L drop in [$HCO_3^-$] and a 0.3-mmol/L fall (or 0.003 rise in pH) in [$H^+$].

The effects of respiratory alkalosis vary according to duration and severity but are primarily those of the underlying disease. Reduced cerebral blood flow as a consequence of a rapid decline in $P_aCO_2$ may cause dizziness, mental confusion, and seizures, even in the absence of hypoxemia. The cardiovascular effects of acute hypocapnia in the conscious human are generally minimal, but in the anesthetized or mechanically ventilated patient, cardiac output and blood pressure may fall because of the depressant effects of anesthesia and positive-pressure ventilation on heart rate, systemic resistance, and venous return. Cardiac arrhythmias may occur in patients with heart disease as a result of changes in oxygen unloading by blood from a left shift in the hemoglobin-oxygen dissociation curve (Bohr effect). Acute respiratory alkalosis causes intracellular shifts of $Na^+$, $K^+$, and $PO_4^{3-}$ and reduces free [Ca²⁺] by increasing the protein-bound fraction. Hypocapnia-induced hypokalemia is usually minor.

Chronic respiratory alkalosis is the most common acid-base disturbance in critically ill patients and, when severe, portends a poor prognosis. Many cardiopulmonary disorders manifest respiratory alkalosis in their early to intermediate stages, and the finding of normocapnia and hypoxemia in a patient with hyperventilation may herald the onset of rapid respiratory failure and should prompt an assessment to determine if the patient is becoming fatigued. Respiratory alkalosis is common during mechanical ventilation.

The hyperventilation syndrome may be disabling. Paresthesia, circumoral numbness, chest wall tightness or pain, dizziness, inability to take an adequate breath, and, rarely, tetany may themselves be sufficiently stressful to perpetuate the disorder. Arterial blood-gas analysis demonstrates an acute or chronic respiratory alkalosis, often with hypocapnia in the range of 15 to 30 mmHg and no hypoxemia. Central nervous system diseases or injury can produce several patterns of hyperventilation and sustained $P_aCO_2$ levels of 20 to 30 mmHg. Hyperthyroidism, high caloric loads, and exercise raise the basal metabolic rate, but ventilation usually rises in proportion so that arterial blood gases are unchanged and respiratory alkalosis does not develop. Salicylates are the most common cause of drug-induced respiratory alkalosis as a result of direct stimulation of the medullary chemoreceptor (Chap. 377). The methylxanthines, theophylline, and aminophylline stimulate ventilation and increase the ventilatory response to $CO_2$. Progesterone increases ventilation and lowers arterial $P_aCO_2$ by as much as 5 to 10 mmHg. Therefore, chronic respiratory alkalosis is a common feature of pregnancy. Respiratory alkalosis is also prominent in liver failure, and the severity correlates with the degree of hepatic insufficiency. Respiratory alkalosis is an early finding in gram-negative sepsis, before fever, hypoxemia, or hypotension develop.

The diagnosis of respiratory alkalosis depends on measurement of...
arterial pH and \( \text{PaCO}_2 \). The plasma [K\(^+\)] is often reduced and the [Cl\(^-\)] increased. In the acute phase, respiratory alkalosis is not associated with increased renal \( \text{HCO}_3^- \) excretion, but within hours net acid excretion is reduced. In general, the \( \text{HCO}_3^- \) concentration falls by 2.0 mmol/L for each 10-mmHg decrease in \( \text{PaCO}_2 \). Chronic hypocapnia reduces the serum [HCO\(_3^-\)] by 5.0 mmol/L for each 10-mmHg decrease in \( \text{PaCO}_2 \). It is unusual to observe a plasma \( \text{HCO}_3^- <12 \) mmol/L as a result of a pure respiratory alkalosis.

When a diagnosis of respiratory alkalosis is made, its cause should be investigated. The diagnosis of hyperventilation syndrome is made by exclusion. In difficult cases, it may be important to rule out other conditions such as pulmonary embolism, coronary artery disease, and hyperthyroidism.

**TREATMENT**

The management of respiratory alkalosis is directed toward alleviation of the underlying disorder. If respiratory alkalosis complicates ventilator management, changes in dead space, tidal volume, and frequency can minimize the hypocapnia. Patients with the hyperventilation syndrome may benefit from reassurance, rebreathing from a paper bag during symptomatic attacks, and attention to underlying psychological stress. Antidepressants and sedatives are not recommended. \( \beta \)-Adrenergic blockers may ameliorate peripheral manifestations of the hyperadrenergic state.

**FURTHER READING**

**Sexual Dysfunction**

Male sexual dysfunction affects 10 to 25% of middle-aged and elderly men. Female sexual dysfunction occurs with a similar frequency. Demographic changes, the popularity of newer treatments, and greater awareness of sexual dysfunction by patients and society have led to increased diagnosis and associated health care expenditures for the management of this common disorder. Because many patients are reluctant to initiate discussion of their sex lives, the physician should address this topic directly to elicit a history of sexual dysfunction.

**PHYSIOLOGY OF MALE SEXUAL RESPONSE**

Normal male sexual function requires (1) an intact libido; (2) the ability to achieve and maintain penile erection; (3) ejaculation; and (4) detumescence. Libido refers to sexual desire and is influenced by a variety of visual, olfactory, tactile, auditory, imaginative, and hormonal stimuli. Sex steroids, particularly testosterone, act to increase libido. Libido can be diminished by hormonal or psychiatric disorders or by medications.

Penile turgence leading to erection depends on the increased flow of blood into the lacunar network after complete relaxation of the arteries and corporal smooth muscle. The microarchitecture of the corpora is composed of a mass of smooth muscle (trabecula) which contains a network of endothelial-lined vessels (lacunar spaces). Subsequent compression of the trabecular smooth muscle against the fibroelastic tunica albuginea causes a passive closure of the emissary veins and accumulation of blood in the corpora. In the presence of a full erection and a competent valve mechanism, the corpora become noncompressible cylinders from which blood does not escape.

The central nervous system exerts an important influence by either stimulating or antagonizing spinal pathways that mediate erectile function and ejaculation. The erectile response is mediated by a combination of central (psychogenic) and peripheral (reflexogenic) innervation. Sensory nerves that originate from receptors in the penile skin and glans converge to form the dorsal nerve of the penis, which travels to the S2-S4 dorsal root ganglia via the pudendal nerve. Parasympathetic nerve fibers to the penis arise from neurons in the intermediolateral columns of S2-S4 sacral spinal segments. Sympathetic inner-
**Synthesis; iCa2**
erectile function by inhibiting phosphodiesterase type 5 (PDE-5), thereby maintaining
contraction.

**Employment or other causes.**

**Logical causes of ED include depression, anger, or stress from unem-
ployment or other causes.**

**Pathophysiology** ED may result from three basic mechanisms: (1) failure to initiate (psychogenic, endocrinologic, or neurogenic); (2) failure to fill (arteriogenic); or (3) failure to store (venoocclusive dys-
fuction) adequate blood volume within the lacunar network. These
categories are not mutually exclusive, and multiple factors contribute
to ED in many patients. For example, diminished filling pressure can lead
secondarily to venous leak. Psychogenic factor frequently coexist
with other etiologic factors and should be considered in all cases. Di-
abetic, atherosclerotic, and drug-related causes account for >80% of
cases of ED in older men.

**Vascularogenic** The most frequent organic cause of ED is a disturbance
of blood flow to and from the penis. Atherosclerotic or traumatic ar-
terial disease can decrease flow to the lacunar spaces, resulting in
decreased rigidity and an increased time to full erection. Excessive out-
flow through the veins, despite adequate inflow, may also contribute
to ED. This situation may be due to insufficient relaxation of trabecular
smooth muscle and may occur in anxious individuals with excessive
adrenergic tone or in those with damaged parasympathetic outflow.
Structural alterations to the fibroelastic components of the corpora may
cause a loss of compliance and an inability to compress the tunical
veins. This condition may result from aging, increased cross-linking
of collagen fibers induced by nonenzymatic glycosylation, hypoxia, or
altered synthesis of collagen associated with hypercholesterolemia.

**Neurogenic** Disorders that affect the sacral spinal cord or the auto-
nomic fibers to the penis preclude nervous system relaxation of penile
smooth muscle, thus leading to ED. In patients with spinal cord injury,
the degree of ED depends on the completeness and level of the lesion.
Patients with incomplete lesions or injuries to the upper part of the
spinal cord are more likely to retain erectile capabilities than those
with complete lesions or injuries to the lower part. Although 75% of
patients with spinal cord injuries have some erectile capability, only
25% have erections sufficient for penetration. Other neurologic dis-
orders commonly associated with ED include multiple sclerosis and
peripheral neuropathy. The latter is often due to either diabetes or
alcoholism. Pelvic surgery may cause ED through disruption of the
autonomic nerve supply.

**Endocrinologic** Androgens increase libido, but their exact role in erec-
tile function remains unclear. Individuals with castrate levels of tes-
tosterone can achieve erections from visual or sexual stimuli. None-
theless, normal levels of testosterone appear to be important for erectile
function, particularly in older males. Androgen replacement therapy
can improve depressed erectile function when it is secondary to hy-
pogonadism; it is not useful for ED when endogenous testosterone
levels are normal. Increased prolactin may decrease libido by sup-
pressing gonadotropin-releasing hormone (GnRH), and it also leads to
decreased testosterone levels. Treatment of hyperprolactinemia with
dopamine agonists can restore libido and testosterone.

**Diabetic** ED occurs in 35 to 75% of men with diabetes mellitus. Path-
ologic mechanisms are primarily related to diabetes-associated vas-
cular and neurologic complications. Diabetic macrovascular compli-
cations are mainly related to age, whereas microvascular complications
correlate with the duration of diabetes and the degree of glycemic
control (Chap. 323). Individuals with diabetes also have reduced
amounts of nitric oxide synthase in both endothelial and neural tissues.

**Psychogenic** Two mechanisms contribute to the inhibition of erections
in psychogenic ED. First, psychogenic stimuli to the sacral cord may
inhibit reflexogenic responses, thereby blocking activation of vasodi-
lator outflow to the penis. Second, excess sympathetic stimulation in
an anxious man may increase penile smooth muscle tone. The most
common causes of psychogenic ED are performance anxiety, depres-
sion, relationship conflict, loss of attraction, sexual inhibition, conflicts
over sexual preference, sexual abuse in childhood, and fear of preg-
nancy or sexually transmitted disease. Almost all patients with ED,
even when it has a clear-cut organic basis, develop a psychogenic
component as a reaction to ED.

**Figure 43-1** Pathways that control erection and detumescence. A. Erection is me-
diated by cholinergic parasympathetic pathways, and nonadrenergic, noncholinergic
(NANC) pathways, which release nitric oxide (NO). Endothelial cells also release NO,
which induces vascular smooth muscle cell relaxation, allowing enhanced blood flow,
and leading to erection. Detumescence is mediated by sympathetic pathways that re-
lease norepinephrine and stimulate α-adrenergic pathways, leading to contraction of
vascular smooth muscle cells. Endothelin, released from endothelial cells, also induces
contraction. B. Biochemical pathways of NO synthesis and action. Sildenafil enhances
erectile function by inhibiting phosphodiesterase type 5 (PDE-5), thereby maintaining
high levels of cyclic 3’,5’-guanosine monophosphate (cyclic GMP). NOS, nitric oxide
synthase; iCa2++, intracellular calcium.

*pism refers to a persistent and painful erection and may be associated
with sickle cell anemia, hypercoagulable states, spinal cord injury, or
injection of vasodilator agents into the penis.

**Erectile Dysfunction**

**Epidemiology** Erectile dysfunction (ED) is not considered a normal
part of the aging process. Nonetheless, it is associated with certain
physiologic and psychological changes related to age. In the Massa-
chusetts Male Aging Study (MMAS), a community-based survey of
men between the ages of 40 and 70, 52% of respondents reported some
degree of ED. Complete ED occurred in 10% of respondents, moderate
ED occurred in 25%, and minimal ED in 17%. The incidence of mod-
erate or severe ED more than doubled between the ages of 40 and 70.
In the National Health and Social Life Survey (NHSLS), which was a
nationally representative sample of men and women age 18 to 59 years,
10% of men reported being unable to maintain an erection (corre-
sponding to the proportion of men in the MMAS reporting severe ED).
Incidence was highest among men in the 50 to 59 age group (21%) and
among men who were poor (14%), divorced (14%), and less edu-
cated (13%).

The incidence of ED is also higher among men with certain medical
disorders such as diabetes mellitus, heart disease, hypertension,
and decreased HDL levels. Smoking is a significant risk factor in the
development of ED. Medications used to treat diabetes or cardiovascular
disease are additional risk factors (see below). There is a higher inci-
dence of ED among men who have undergone radiation or surgery for
prostate cancer and in those with a lower spinal cord injury. Psycholo-
gical causes of ED include depression, anger, or stress from unem-
ployment or other causes.
Medication-induced ED (Table 43-1) is estimated to occur in 25% of men seen in general medical outpatient clinics. Among the antihypertensive agents, the thiazide diuretics and beta blockers have been implicated most frequently. Calcium channel blockers and angiotensin-converting enzyme inhibitors are less frequently cited. These drugs may act directly at the corporal level (e.g., calcium channel blockers) or indirectly by reducing pelvic blood pressure, which is important in the development of penile rigidity. Alpha-adrenergic blockers are less likely to cause ED. Estrogens, GnRH agonists, H2 antagonists, and spironolactone cause ED by suppressing gonadotropin production or by blocking androgen action. Antidepressants and antipsychotic agents—particularly neuroleptics, tricyclics, and SSRIs—are associated with erectile, ejaculatory, orgasmic, and sexual desire difficulties.

Although many medications can cause ED, patients frequently have concomitant risk factors that confound the clinical picture. If there is a strong association between the institution of a drug and the onset of ED, alternative medications should be considered. Otherwise, it is often practical to treat the ED without attempting multiple changes in medications, as it may be difficult to establish a causal role for the drug.

**CLINICAL EVALUATION**

A good physician-patient relationship helps to unravel the possible causes of ED, many of which require discussion of personal and sometimes embarrassing topics. For this reason, a primary care provider is often ideally suited to initiate the evaluation. A complete medical and sexual history should be taken in an effort to assess whether the cause of ED is organic, psychogenic, or multifactorial (Fig. 43-2). Initial questions should focus on the onset of symptoms, the presence and duration of partial erections, and the progression of ED. A history of nocturnal or early morning erections is useful for distinguishing physiologic from psychogenic ED. Nocturnal erections occur during rapid eye movement (REM) sleep and require intact neurologic and circulatory systems. Organic causes of ED are generally characterized by a gradual and persistent change in rigidity or the inability to sustain nocturnal, coital, or self-stimulated erections. The patient should also be questioned about the presence of penile curvature or pain with coitus. It is also important to address libido, as decreased sexual drive and ED are sometimes the earliest signs of endocrine abnormalities (e.g., increased prolactin, decreased testosterone levels). It is useful to ask whether the problem is confined to coitus with one or other partners; ED arises not uncommonly in association with new or extramarital sexual relationships. Situational ED, as opposed to consistent ED, suggests psychogenic causes. Ejaculation is much less commonly affected than erection, but questions should be asked about whether ejaculation is normal, premature, delayed, or absent. Relevant risk factors should be identified, such as diabetes mellitus, coronary artery disease, lipid disorders, hypertension, peripheral vascular disease, smoking, alcoholism, and endocrine or neurologic disorders. The patient’s surgical history should be explored with an emphasis on bowel, bladder, prostate, or vascular procedures. A complete drug history is also important. Social changes that may precipitate ED are also crucial to the evaluation, including health worries, spousal death, divorce, relationship difficulties, and financial concerns.

The physical examination is an essential element in the assessment of ED. Signs of hypertension as well as evidence of thyroid, hepatic, hematologic, cardiovascular, or renal diseases should be sought. An assessment should be made of the endocrine and vascular systems, the external genitalia, and the prostate gland. The penis should be carefully palpated along the corpora to detect fibrotic plaques. Reduced testicular size and loss of secondary sexual characteristics are suggestive of hypogonadism. Neurologic examination should include assessment of anal sphincter tone, the bulbocavernous reflex, and testing for peripheral neuropathy.

Although hyperprolactinemia is uncommon, a serum prolactin level should be measured, as decreased libido and/or erectile dysfunction may be the presenting symptoms of a prolactinoma or other mass lesions of the sella (Chap. 318). The serum testosterone level should be measured and, if low, gonadotropins should be measured to determine whether hypogonadism is primary (testicular) or secondary (hypothalamic-pituitary) in origin (Chap. 325). Serum chemistries, CBC, and lipid profiles may be of value, if not performed recently, as they can yield evidence of anemia, diabetes, hyperlipidemia, or other systemic diseases associated with ED. Determination of serum PSA should be conducted according to recommended clinical guidelines (Chap. 81).

Additional diagnostic testing is rarely necessary in the evaluation of ED. However, in selected patients, specialized testing may provide insight into pathologic mechanisms of ED and aid in the selection of

**FIGURE 43-2** Algorithm for the evaluation and management of patients with ED.
treatment options. Optional specialized testing includes: (1) studies of nocturnal penile tumescence and rigidity; (2) vascular testing (in-office injection of vasoactive substances, penile Doppler ultrasound, penile angiography, dynamic infusion cavernosography/cavernosometry); (3) neurologic testing (biothesiometry-graded vibratory perception; somatosensory evoked potentials); and (4) psychological diagnostic tests. The information potentially gained from these procedures must be balanced against their invasiveness and cost.

**Patient Education** Patient and partner education is essential in the treatment of ED. In goal-directed therapy, education facilitates understanding of the disease, results of the tests, and selection of treatment. Discussion of treatment options helps to clarify how treatment is best offered, and to stratify first- and second-line therapies. Patients with high-risk lifestyle issues, such as smoking, alcohol abuse, or recreational drug use, should be counseled on the role these factors play in the development of ED.

**Oral Agents** Sildenafil is the only approved and effective oral agent for the treatment of ED. Sildenafil has markedly improved the management of ED because it is effective for the treatment of a broad range of causes of ED, including psychogenic, diabetic, vasculogenic, post-radical prostatectomy (nerve-sparing procedures), and spinal cord injury. Sildenafil is a selective and potent inhibitor of PDE-5, the predominant phosphodiesterase isofrom found in the penis. It is administered in doses of 25, 50, or 100 mg, and enhances erections after sexual stimulation. The onset of action is approximately 60 to 90 min. Reduced initial doses should be considered for patients who are elderly, have renal insufficiency, or are taking medications that inhibit the CYP3A4 metabolic pathway in the liver (e.g., erythromycin, cimetidine, ketoconazole, and, possibly, itraconazole and mibefradil), as they may increase the serum concentration of sildenafil. The drug does not affect ejaculation, orgasm, or sexual drive. Side effects associated with sildenafil include headaches (19%), facial flushing (9%), dyspepsia (6%) and nasal congestion (4%). Approximately 7% of men may experience transient altered color vision (blue halo effect). Sildenafil is contraindicated in men receiving nitrate therapy for cardiovascular disease, including agents delivered by oral, sublingual, transnasal, or topical routes. These agents can potentiate its hypotensive effect and may result in profound shock. Likewise, amyl/butyl nitrates “poppers” may have a fatal synergistic effect on blood pressure. Sildenafil should also be avoided in patients with congestive heart failure and cardiomyopathy because of the risk of vascular collapse. Because sexual activity leads to an increase in physiologic expenditure [5 to 6 metabolic equivalents (METs)], physicians have been advised to exercise caution in prescribing any drug for sexual activity to those with active coronary disease, heart failure, borderline hypotension, hypovolemia, and to those on complex antihypertensive regimens.

**Androgen Therapy** Testosterone replacement is used to treat both primary and secondary causes of hypogonadism (Chap. 325). Androgen supplementation in the setting of normal testosterone is rarely efficacious and is discouraged. Methods of androgen replacement include parenteral administration of long-acting testosterone esters (enanthate and cypionate), oral preparations (17 α-alkylated derivatives), and transdermal patches, and gels (Chap. 325). The long-acting 17 β-hydroxy esters of testosterone are the safest, most cost-effective, and practical preparations available. The administration of 200 to 300 mg intramuscularly every 2 to 3 weeks provides a practical option but is far from an ideal physiologic replacement. Oral androgen preparations have the potential for hepatotoxicity and should be avoided. Transdermal delivery of testosterone using patches or gels more closely mimics physiologic testosterone levels, but it is unclear whether this translates into improved sexual function. Testosterone therapy is contraindicated in men with androgen-sensitive cancers and may be inappropriate for men with bladder neck obstruction. It is generally advisable to measure PSA before giving androgen. Hepatic function should be tested before and during testosterone therapy.

**Vacuum Constriction Devices** Vacuum constriction devices (VCD) are a well-established, noninvasive therapy. They are a reasonable treatment alternative for select patients who cannot take sildenafil or do not desire other interventions. VCD draw venous blood into the penis and use a constriction ring to restrict venous return and maintain tumescence. Adverse events with VCD include pain, numbness, bruising, and altered ejaculation. Additionally, many patients complain that the devices are cumbersome and that the induced erections have a non-physiologic appearance.

**Intraurethral Alprostadil** If a patient fails to respond to oral agents, a reasonable next choice is intraurethral or self-injection of vasoactive substances. Intraurethral prostaglandin E1 (alprostadil), in the form of a semisolid pellet (doses of 125 to 1000 µg), is delivered with an applicator. Approximately 65% of men receiving intraurethral alprostadil respond with an erection when tested in the office, but only 50% of those achieve successful coitus at home. Intraurethral insertion is associated with a markedly reduced incidence of priapism in comparison to intracavernosal injection.

**Intracavernosal Self-Injection** Injection of synthetic formulations of alprostadil is effective in 70 to 80% of patients with ED, but discontinuation rates are high because of the invasive nature of administration. Doses range between 1 and 40 µg. Injection therapy is contraindicated in men with a history of hypersensitivity to the drug and in men at risk for priapism (hypercoagulable states, sickle cell disease). Side effects include local adverse events, prolonged erections, pain, and fibrosis with chronic use. Various combinations of alprostadil, phentolamine, and/or papaverine are sometimes used.

**Surgery** A less frequently used form of therapy for ED involves the surgical implantation of a semi-rigid or inflatable penile prosthesis. These surgical treatments are invasive, associated with potential complications, and generally reserved for treatment of refractory ED. Despite their high cost and invasiveness, penile prostheses are associated with high rates of patient satisfaction.

**SEX THERAPY** A course of sex therapy may be useful for addressing specific interpersonal factors that may affect sexual functioning. Sex therapy generally consists of in-session discussion and at-home exercises specific to the person and the relationship. It is preferable if therapy includes both partners, provided the patient is involved in an ongoing relationship.

**FEMALE SEXUAL DYSFUNCTION**

Female sexual dysfunction (FSD) has traditionally included disorders of desire, arousal, pain, and muted orgasm. The associated risk factors for FSD are similar to those in males: cardiovascular disease, endocrine disorders, hypertension, neurologic disorders, and smoking (Table 43-2).

**TABLE 43-2 Risk Factors for Female Sexual Dysfunction**

| Neurologic disease: stroke, spinal cord injury, Parkinsonism |
| Trauma, genital surgery, radiation |
| Endocrinopathies: diabetes, hyperprolactinemia |
| Liver and/or renal failure |
| Cardiovascular disease |
| Psychological factors and interpersonal relationship disorders: sexual abuse, life stressors |
| Medications |
| Antiandrogens: Cimetidine, spironolactone |
| Antidepressants, Alcohol, hypnotics, sedatives |
| Antiandrogens or GnRH antagonists |
| Antihistamines, sympathomimetic amines |
| Antihypertensives: Diuretics, calcium channel blockers |
| Alkylating agents |
| Anticholinergics |
EPIDEMIOLOGY  Epidemiologic data are limited but the available estimates suggest that as many as 43% of women complain of at least one sexual problem. Despite the recent interest in organic causes of FSD, desire and arousal phase disorders (including lubrication complaints) remain the most common presenting problems when surveyed in a community-based population.

PHYSIOLOGY OF THE FEMALE SEXUAL RESPONSE  Although there are the obvious anatomic differences as well as variation in the density of vascular and neural beds in males and females, the primary effectors of sexual response are strikingly similar. Intact sensation is important for arousal. Thus, reduced levels of sexual functioning are more common in women with peripheral neuropathies (e.g., diabetes). Vaginal lubrication is a transudate of serum that results from the increased pelvic blood flow associated with arousal. Vascular insufficiency from a variety of causes may compromise adequate lubrication and result in dyspareunia. Similar to the male response, cavernosal and arteriole smooth muscle relaxation occurs via increased NOS activity and produces engorgement in the clitoris and surrounding vestibule. Orgasm requires an intact sympathetic outflow tract; hence, orgasmic disorders are common in female patients with spinal cord injuries.

CLINICAL EVALUATION  The evaluation of FSD previously occurred mainly in a psychosocial context. However, inconsistencies between diagnostic categories based on only psychosocial considerations, and the emerging recognition of organic etiologies, has led to a new classification of FSD. This diagnostic scheme is based on four components that are not mutually exclusive: (1) **Hyposexual desire**—the persistent or recurrent lack of sexual thoughts and/or receptivity to sexual activity, which causes personal distress. Hyposexual sexual desire may result from endocrine failure or may be associated with psychological or emotional disorders; (2) **Sexual arousal disorder**—the persistent or recurrent inability to attain or maintain sexual excitement, which causes personal distress; (3) **Orgasmic disorder**—the persistent or recurrent loss of orgasmic potential after sufficient sexual stimulation and arousal, which causes personal distress; (4) **Sexual pain disorder**—persistent or recurrent genital pain associated with noncoital sexual stimulation, which causes personal distress. This newer classification emphasizes “personal distress” as a requirement for dysfunction and provides clinicians an organized framework for evaluation prior to or in conjunction with more traditional counseling methods.

44  HIRSUTISM AND VIRILIZATION
David A. Ehrmann

**Hirsutism**, defined as excessive male-pattern hair growth, affects approximately 10% of women. If often represents a variation of normal hair growth, but rarely it is a harbinger of a serious underlying condition. Hirsutism is often idiopathic but may be caused by conditions associated with androgen excess, such as polycystic ovarian syndrome (PCOS) or congenital adrenal hyperplasia (CAH) (Table 44-1). Cutaneous manifestations commonly associated with hirsutism include acne and male-pattern balding (androgenic alopecia). **Virilization** refers to the state in which androgen levels are sufficiently high to cause additional signs and symptoms such as deepening of the voice, breast atrophy, increased muscle bulk, clitoromegaly, and increased libido; virilization is an ominous sign that suggests the possibility of an ovarian or adrenal neoplasm.

**HAIR FOLLCLE GROWTH AND DIFFERENTIATION**

Hair can be categorized as either **vellus** (fine, soft, and not pigmented) or **terminal** (long, coarse, and pigmented). The number of hair follicles does not change over an individual’s lifetime, but the follicle size and type of hair can change in response to numerous factors, particularly androgens. Androgens are necessary for terminal hair and sebaceous gland development and mediate differentiation of pilosebaceous units (PSUs) into either a terminal hair follicle or a sebaceous gland. In the former case, androgens transform the vellus hair into a terminal hair; in the latter, the sebaceous component proliferates and the hair remains vellus.

There are three phases in the cycle of hair growth: (1) **anagen** (growth phase), (2) **catagen** (involution phase), and (3) **telogen** (rest phase). Depending on the body site, hormonal regulation may play an important role in the hair growth cycle. For example, the eyebrows, eyelashes, and vellus hairs are androgen-insensitive, whereas the axillary and pubic areas are sensitive to low levels of androgens. Hair growth on the face, chest, upper abdomen, and back requires greater levels of androgens and is therefore more characteristic of the pattern typically seen in males. Androgen excess in women leads to increased hair growth in most androgen-sensitive sites except in the scalp region, where hair loss occurs because androgens cause scalp hairs to spend less time in the anagen phase.

Although androgen excess underlies most cases of hirsutism, there is only a modest correlation between androgen levels and the quantity of hair growth. This is due to the fact that hair growth from the follicle also depends on local growth factors, and there is variability in end-

organ sensitivity. Genetic factors and ethnic background also influence hair growth. In general, dark-haired individuals tend to be more hirsute than blonde or fair individuals. Asians and Native Americans have relatively sparse hair in regions sensitive to high androgen levels, whereas people of Mediterranean descent are more hirsute.

CLINICAL ASSESSMENT

Historic elements relevant to the assessment of hirsutism include the age of onset and rate of progression of hair growth and associated symptoms or signs (e.g., acne). Depending on the cause, excess hair growth is typically first noted during the second and third decades. The growth is usually slow but progressive. Sudden development and rapid progression of hirsutism suggests the possibility of an androgen-secreting neoplasm, in which case virilization may also be present.

The age of onset of menstrual cycles (menarche) and the pattern of the menstrual cycle should be ascertained; irregular cycles from the time of menarche onward are more likely to result from ovarian rather than adrenal androgen excess. Associated symptoms such as galactorrhea should prompt evaluation for hyperprolactinemia (Chap. 318) and possibly hypothyroidism (Chap. 320). Hypertension, striae, easy bruising, centripetal weight gain, and weakness suggest hypercortisolism (Cushing’s syndrome; Chap. 321). Rarely, patients with growth hormone excess (i.e., acromegaly) will present with hirsutism.

Use of medications such as phenytoin, minoxidil, or cyclosporine may be associated with androgen-independent causes of excess hair growth (i.e., hypertrichosis). A family history of infertility and/or hirsutism may indicate disorders such as nonclassic CAH (Chap. 321).

Physical examination should include measurement of height, weight, and calculation of body mass index (BMI). A BMI >25 kg/m² is indicative of excess weight for height, and values >30 kg/m² are often seen in association with hirsutism. Notation should be made of blood pressure, as adrenal causes may be associated with hypertension. Cutaneous signs sometimes associated with androgen excess and insulin resistance include acanthosis nigricans and skin tags.

An objective clinical assessment of hair distribution and quantity is central to the evaluation in any woman presenting with hirsutism. This assessment permits the distinction between hirsutism and hypertrichosis and provides a baseline reference point to gauge the response to treatment. A simple and commonly used method to grade hair growth is the modified scale of Ferriman and Gallwey (Fig. 44-1), where each of nine androgen-sensitive sites is graded from 0 to 4. Approximately 95% of Caucasian women have a score below 8 on this scale; thus, it is normal for most women to have some hair growth in androgen-sensitive sites. Scores above 8 suggest excess androgen-mediated hair growth, a finding that should be assessed further by hormonal evaluation (see below). In racial/ethnic groups that are less likely to manifest hirsutism (e.g., Asian women), additional cutaneous

FIGURE 44-1 Hirsutism scoring scale of Ferriman and Gallwey. The nine body areas possessing androgen-sensitive areas are graded from 0 (no terminal hair) to 4 (frankly virile) to obtain a total score. A normal hirsutism score is less than 8. [Reproduced from DA Ehrmann et al: Hyperandrogenism, hirsutism, and polycystic ovarian syndrome, in LJ DeGroot et al (eds), Endocrinology, 4th ed. Philadelphia, Saunders, 2000; with permission.]
Hormonal Evaluation

Androgens are secreted by the ovaries and adrenal glands in response to their respective trophic hormones, luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH). The principal circulating steroids involved in the etiology of hirsutism are testosterone, androstenedione, dehydroepiandrosterone (DHEA) and its sulfated form (DHEAS). The ovaries and adrenal glands normally contribute about equally to testosterone production. Approximately half of the total testosterone originates from direct glandular secretion, and the remainder is derived from the peripheral conversion of androstenedione and DHEA (Chap. 325).

Although it is the most important circulating androgen, testosterone is, in effect, the penultimate androgen in mediating hirsutism; it is converted to the more potent dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is located in the PSU. DHT has a higher affinity for, and slower dissociation from, the androgen receptor. The local production of DHT allows it to serve as the primary mediator of androgen action at the level of the pilosebaceous unit. There are two isoenzymes of 5α-reductase: type 2 is found in the prostate gland and in hair follicles, whereas type 1 is found primarily in sebaceous glands.

One approach to testing for hyperandrogenemia is depicted in Fig. 44-2. In addition to measuring blood levels of testosterone and DHEAS, it is also important to measure the level of free (or unbound) testosterone. The fraction of testosterone that is not bound to its carrier protein, sex-hormone binding globulin (SHBG), is biologically available for conversion to DHT and for binding to androgen receptors. Hyperinsulinemia and/or androgen excess decrease hepatic production of SHBG, resulting in levels of total testosterone within the high-normal range, whereas the unbound hormone is more substantially elevated. Although there is a decline in ovarian testosterone production after menopause, ovarian estrogen production decreases to an even greater extent, and the concentration of SHBG is reduced. Consequently, there is an increase in the relative proportion of unbound testosterone, and it may exacerbate hirsutism after menopause.

Because adrenal androgens are readily suppressed by low doses of glucocorticoids, the dexamethasone androgen-suppression test may broadly distinguish ovarian from adrenal androgen overproduction. A blood sample is obtained before and after administering dexamethasone (0.5 mg orally every 6 h for 4 days). An adrenal source is suggested by suppression of unbound testosterone into the normal range; incomplete suppression suggests ovarian androgen excess.

A baseline plasma total testosterone level >12 nmol/L (>3.5 ng/mL) usually indicates a virilizing tumor, whereas a level >7 nmol/L (>2 ng/mL) is suggestive. A basal DHEAS level >18.5 μmol/L (>7000 μg/L) suggests an adrenal tumor. Although DHEAS has been proposed as a “marker” of predominant adrenal androgen excess, it is not unusual to find modest elevations in DHEAS among women with PCOS. Computed tomography (CT) or magnetic resonance imaging (MRI) should be used to localize an adrenal mass, and ultrasound will usually suffice to identify an ovarian mass, if clinical evaluation and hormonal levels suggest these possibilities.

PCOS is the most common cause of ovarian androgen excess (Chap. 326). However, the increased ratio of LH to follicle-stimulating hormone that is characteristic of carefully studied patients with PCOS is not seen in up to half of these women due to the pulsatility of gonadotropins. If performed, ultrasound shows enlarged ovaries and increased stroma in many women with PCOS. However, polycystic ovaries may also be found in women without clinical or laboratory features of PCOS. Therefore, polycystic ovaries are a relatively insensitive and nonspecific finding for the diagnosis of ovarian hyperandrogenism. Gonadotropin-releasing hormone agonist testing can be used to make a specific diagnosis of ovarian hyperandrogenism. A peak 17-hydroxyprogesterone level ≥7.8 nmol/L (≥2.6 μg/L), after the administration of 100 μg nafarelin (or 10 μg/kg leuprolide) subcutaneously, is virtually diagnostic of ovarian hyperandrogenism.

Nonclassic CAH is most commonly due to 21-hydroxylase deficiency but can also be caused by autosomal recessive defects in other steroidogenic enzymes necessary for adrenal corticosteroid synthesis (Chap. 321). Because of the enzyme defect, the adrenal gland cannot secrete glucocorticoids efficiently (especially cortisol). This results in diminished negative feedback inhibition of ACTH, leading to compensatory adrenal hyperplasia and the accumulation of steroid precursors that are subsequently converted to androgen.
Deficiency of 21-hydroxylase can be reliably excluded by determining a morning 17-hydroxyprogesterone level <6 nmol/L (<=2 μg/L) (drawn in the follicular phase). Alternatively, 21-hydroxylase deficiency can be diagnosed by measurement of 17-hydroxyprogesterone 1 h after administration of 250 μg of synthetic ACTH (cosyntropin) intravenously.

TREATMENT

Treatment of hirsutism may be accomplished pharmacologically or by mechanical means of hair removal. Nonpharmacologic treatments should be considered in all patients, either as the only treatment or as an adjunct to drug therapy.

Nonpharmacologic treatments include (1) bleaching; (2) depilatory (removal from the skin surface) such as shaving and chemical treatments; or (3) epilatory (removal of the hair including the root) such as plucking, waxing, electrolysis, and laser therapy. Despite perceptions to the contrary, shaving does not increase the rate or density of hair growth. Chemical depilatory treatments may be useful for mild hirsutism that affects only limited skin areas, though they can cause skin irritation. Wax treatment removes hair temporarily but is uncomfortable. Electrolysis is effective for more permanent hair removal, particularly in the hands of a skilled electrolgist. Laser phototherapy appears to be efficacious for hair removal. It delays hair regrowth and causes permanent hair removal in most patients. The long-term effects and complications associated with laser treatment are being evaluated.

Pharmacologic therapy is directed at interrupting one or more of the steps in the pathway of androgen synthesis and action: (1) suppression of adrenal and/or ovarian androgen production; (2) enhancement of androgen-binding to plasma-binding proteins, particularly SHBG; (3) impairment of the peripheral conversion of androgen precursors to active androgens; and (4) inhibition of androgen action at the target tissue level. Attenuation of hair growth is typically not evident until 4 to 6 months after initiation of medical treatment and, in most cases, leads to only a modest reduction in hair growth.

Combination estrogen-progestin therapy, in the form of an oral contraceptive, is usually the first-line endocrine treatment for hirsutism and acne, after cosmetic and dermatologic management. The estrogen component of most oral contraceptives currently in use is either ethinyl estradiol or mestranol. The suppression of LH leads to reduced production of ovarian androgens. The reduced androgen levels also result in a dose-related increase in SHBG, thereby lowering the fraction of unbound plasma testosterone. Combination therapy has also been demonstrated to decrease DHEAS, perhaps by reducing ACTH levels. Estrogens also have a direct, dose-dependent suppressive effect on sebaceous cell function.

The choice of a specific oral contraceptive should be predicated on the progestational component, as progestins vary in their suppressive effect on SHBG levels and in their androgenic potential. Ethynodiol diacetate has relatively low androgenic potential, whereas progestins such as norgestrel and levonorgestrel are androgenic, as judged from their attenuation of the estrogen-induced increase in SHBG. Norgestimate exemplifies the newer generation of progestins that are virtually non-androgenic. Drospirenone, an analogue of spironolactone that has both antimineralocorticoid and antiandrogenic activities, has been approved for use as a progestational agent in combination with ethinyl estradiol. Its properties suggest that it should be the preferred choice for the treatment of hirsutism.

Oral contraceptives are contraindicated in women with a history of thromboembolic disease or in women with increased risk of breast or other estrogen-dependent cancers (Chap. 327). There is a relative contraindication to the use of oral contraceptives in smokers or in those with hypertension or a history of migraine headaches. In most trials, estrogen-progestin therapy alone improves the extent of acne by a maximum of 50 to 70%. The effect on hair growth may not be evident for 6 months, and the maximum effect may require 9 to 12 months owing to the length of the hair growth cycle. Improvements in hirsutism are typically in the range of 20%, but there may be an arrest of further progression of hair growth.

Adrenal androgens are more sensitive than cortisol to the suppressive effects of glucocorticoids. Therefore, glucocorticoids are the mainstay of treatment in patients with CAH. Although glucocorticoids have been reported to restore ovulatory function in some women with PCOS, this effect is highly variable. Because of side effects from excessive glucocorticoids, low doses should be used. Dexamethasone (0.2 to 0.5 mg) or prednisone (5 to 10 mg) should be taken at bedtime to achieve maximal suppression by inhibiting the nocturnal surge of ACTH.

Cyproterone acetate is the prototypic antiandrogen. It acts mainly by competitive inhibition of the binding of testosterone and DHT to the androgen receptor. In addition, it may act to enhance the metabolic clearance of testosterone by inducing hepatic enzymes. Although not available for use in the United States, cyproterone acetate is widely used in Canada, Mexico, and Europe. Cyproterone (50 to 100 mg) is given on days 1 to 15 and ethinyl estradiol (50 μg) is given on days 5 to 26 of the menstrual cycle. Side effects include irregular uterine bleeding, nausea, headache, fatigue, weight gain, and decreased libido.

Spironolactone, usually used as a mineralocorticoid antagonist, is also a weak antiandrogen. It is almost as effective as cyproterone acetate when used at high enough doses (100 to 200 mg daily). Patients should be monitored intermittently for hyperkalemia or hypotension, though these side effects are uncommon. Pregnancy should be avoided because of the risk of feminization of a male fetus. Spironolactone can also cause menstrual irregularity. It is often used in combination with an oral contraceptive, which suppresses ovarian androgen production and helps prevent pregnancy.

Flutamide is a potent nonsteroidal antiandrogen that is effective in treating hirsutism, but concerns about the induction of hepatocellular dysfunction have limited its use. Finasteride is a competitive inhibitor of 5α-reductase type 2. Beneficial effects on hirsutism have been reported, but the predominance of 5α-reductase type 1 in the PSU appears to account for its limited efficacy. Finasteride would also be expected to impair sexual differentiation in a male fetus, and it should not be used in women who may become pregnant.

Eflornithine cream (Vaniqa) has been approved as a novel treatment for unwanted facial hair in women, but long-term efficacy remains to be established. It can cause skin irritation under exaggerated conditions of use. Ultimately, the choice of any specific agent(s) must be tailored to the unique needs of the patient being treated. As noted previously, pharmacologic treatments for hirsutism should be used in conjunction with nonpharmacologic approaches. It is also helpful to review the pattern of female hair distribution in the normal population to dispel unrealistic expectations.

INFERTILITY AND FERTILITY CONTROL
Janet E. Hall

The concept of reproductive choice is now firmly entrenched in developed countries and has dramatically altered reproductive behavior. The availability of effective contraceptive methods prevents unintended pregnancies and has important economic and social implications. Infertility, on the other hand, can be accompanied by substantial stress and disappointment. Fortunately, the ability to diagnose and to treat various causes of infertility now provides an array of effective new approaches to this condition.

INFERTILITY

DEFINITION AND PREVALENCE  Infertility is defined as the inability to conceive after 12 months of unprotected sexual intercourse. In a study of 5574 English and American women who ultimately conceived, pregnancy occurred in 50% within 3 months, 72% within 6 months, and 85% within 12 months. These findings are consistent with predictions based on fecundability, the probability of achieving pregnancy in one menstrual cycle (approximately 20 to 25% in healthy young couples). Assuming a fecundability of 0.25, 98% of couples should conceive within 13 months. Based on this definition, the National Survey of Family Growth reports a 14% rate of infertility in the United States in married women aged 15 to 44. The infertility rate has remained relatively stable over the past 30 years, although the proportion of couples without children has risen, reflecting a trend to delay childbearing. This trend has important implications because of an age-related decrease in fecundability, which begins at age 35 and is exacerbated after age 40.

CAUSES OF INFERTILITY  The spectrum of infertility ranges from reduced conception rates or the need for medical intervention to irreversible causes of infertility (sterility). Infertility can be attributed primarily to male factors in 25%, female factors in 58%, and is unexplained in about 17% of couples (Fig. 45-1). Not uncommonly, both male and female factors contribute to infertility.

APPROACH TO THE PATIENT

Initial Evaluation  In all couples presenting with infertility, the initial evaluation includes discussion of the appropriate timing of intercourse and discussion of modifiable risk factors such as smoking, alcohol, caffeine, and obesity. A description of the range of investigations that may be required and a brief description of infertility treatment options, including adoption, should be reviewed. Initial investigations are focused on determining whether the primary cause of the infertility is male, female, or both. These investigations include a semen analysis in the male, confirmation of ovulation in the female, and, in the majority of situations, documentation of tubal patency in the female. Although frequently used in the past, recent studies have not supported the efficacy of postcoital testing of sperm interaction with cervical mucus as a routine component of initial testing. Strategies for further evaluation are described below and in Chaps. 325 and 326. In some cases, after an extensive evaluation has excluded identifiable male or female causes of infertility, the disorder is classified as unexplained infertility.

Psychological Aspects of Infertility  Infertility is invariably associated with psychological stress. In addition to the diagnostic and therapeutic procedures, stress may result from repeated cycles of hope and loss associated with each new procedure or cycle of treatment that does not result in the birth of a child. These feelings are often combined with a sense of isolation from friends and family. Counseling and stress-management techniques should be introduced early in the evaluation of infertility. When extreme, stress can contribute to infertility; for example, stress may impair hypothalamic control of ovulation. Infertility and its treatment do not appear to be associated with long-term psychological sequelae.

Female Causes  Abnormalities in menstrual function constitute the most common cause of female infertility. These disorders, which include ovulatory dysfunction and abnormalities of the uterus or outflow tract, may present as amenorrhea (absence of menses) or as irregular or short menstrual cycles. A careful history and physical examination and a limited number of laboratory tests will help to determine whether the abnormality is (1) hypothalamic or pituitary [low follicle-stimulating hormone (FSH), luteinizing hormone (LH), and estradiol with or without an increase in prolactin]; (2) polycystic ovarian syndrome (PCOS); (3) ovarian (low estradiol with increased FSH); or (4) uterine or outflow tract abnormality. The frequency of these diagnoses depends on whether the amenorrhea is primary or occurs after normal puberty and menarche (Fig. 45-1).

Ovulatory Dysfunction  In women with a history of regular menstrual cycles, evidence of ovulation should be sought by using urinary ovulation predictor kits (they reflect the preovulatory gonadotropin surge but do not confirm ovulation), basal body temperature charts, or a mid-luteal phase progesterone level. The mid-luteal phase progesterone increase (usually >3 ng/mL) confirms ovulation and corpus luteum function and is responsible for the rise in basal body temperature [>0.3°C (>0.6°F) for 10 days]. An endometrial biopsy to exclude luteal phase insufficiency is no longer considered an essential part of the infertility workup for most patients. Even in the presence of ovulatory cycles, evaluation of ovarian reserve is recommended for women over 35 by measurement of FSH on day 3 of the cycle or in response to clomiphene, an estrogen antagonist (see below). An FSH level <10 IU/mL on cycle day 3 predicts adequate ovarian oocyte reserve. Inhibin B, an ovarian hormone that selectively suppresses FSH, is not of additional benefit in assessment of ovarian reserve.

Tubal Disease  Tubal disease may result from pelvic inflammatory disease (PID), appendicitis, endometriosis, pelvic adhesions, tubal surgery, and previous use of an intrauterine device (IUD). How-
ever, a specific cause is not identified in up to 50% of patients with documented tubal factor infertility. Because of the high prevalence of tubal disease, evaluation of tubal patency by hysterosalpingogram or laparoscopy should occur early in the majority of couples with infertility. Subclinical infection with *Chlamydia trachomatis* may be an underdiagnosed cause of tubal infertility and requires the treatment of both partners.

**Endometriosis** Endometriosis is defined as the presence of endometrial glands or stroma outside the endometrial cavity and uterine musculature. Its presence is suggested by a history of dyspareunia (painful intercourse), worsening dysmenorrhea that often begins before menses, or by a thickened rectovaginal septum or deviation of the cervix on pelvic examination. The pathogenesis of the infertility associated with endometriosis is unclear but may involve cytokine effects on the normal endometrium as well as adhesions. Endometriosis is often clinically silent, however, and can only be excluded definitively by laparoscopy.

**Male Causes** Known causes of male infertility include primary testicular dysfunction, disorders of sperm transport, and hypothalamic-pituitary disease resulting in secondary hypogonadism. However, the etiology is not ascertained in up to half of men with suspected male factor infertility (Fig. 45-1). The key initial diagnostic test is a *semen analysis*. Although 95% confidence limits can be used to define normal semen parameters, data relating sperm counts to fecundability are more useful. Such studies suggest that normal fertility is associated with sperm counts of >48 million/mL, with a motility of >63%, with >12% exhibiting normal morphology, whereas subfertility is seen with sperm counts of <13 million/mL, motility of <32%, and <9% normal morphology. Abnormalities of spermatogenesis may have a genetic component. Y chromosome microdeletions and POLG variants are increasingly recognized as a cause of azoospermia (absence of sperm) or oligospermia (low sperm count). Y chromosome microdeletions have also been identified in a subset of men with elevated FSH levels and idiopathic infertility. Testosterone levels should be measured if the sperm count is low on repeated examination or if there is clinical evidence of hypogonadism. A low testosterone level may result from primary gonadal deficiency; in this condition, levels of LH and FSH will be elevated. Less commonly, low testosterone and decreased spermatogenesis result from hypothalamic or pituitary disease, in which case the LH and FSH levels will be low (Chap. 325).

Acquired disorders of the testes are often associated with impaired spermatogenesis with relatively preserved Leydig cell function; thus, testosterone levels may be normal. Such abnormalities include viral orchitis (especially mumps) and other infectious causes such as tuberculosis or sexually transmitted diseases (STDs), chemotherapy (especially the alkylating agents cyclophosphamide and chlorambucil), ionizing radiation, and drugs that may impair fertility directly or through inhibition of testicular androgen production or action. Anabolic androgen abuse should be considered in a well-androgenized man with low gonadotropins and testosterone but a suppressed sperm count. Prolonged elevation of testicular temperature may impair spermatogenesis, e.g., cryptorchidism, after an acute febrile illness or in association with varicocele. A potential role for environmental toxins as a cause of impaired spermatogenesis has been suggested based on an apparent decrease in sperm counts over the past several decades, but a direct cause-and-effect relationship has not been established.

**Secondary Hypogonadism** Low gonadotropin levels, associated with low testosterone, may signal the presence of a pituitary macroadenoma or hypothalamic tumor (in both cases prolactin levels may be elevated; Chap. 316) or may be the first presentation of hemochromatosis (Chap. 336) or other systemic illness. Recent studies have identified several genetic causes of gonadotropin-releasing hormone (GnRH) deficiency (*KAL* and *DAX-1*), as well as mutations that lead to isolated gonadotropin deficiency (GnRH receptor, LHRβ, FSHβ mutations) (Chap. 316).

**Disordered Sperm Transport** Patients with low sperm counts and normal hormonal levels may be found to have obstructive abnormalities of the vas deferens or epididymis. The most common causes of vas deferens obstruction are previous vasectomy or accidental ligation during inguinal surgery. Congenital absence of the vas deferens can be diagnosed by a deficiency of fructose in the ejaculate and is often associated with an abnormality of the cystic fibrosis transmembrane regulator (*CFTR*) gene. Young's syndrome, characterized by inspissated secretions, can also preclude normal sperm transport.

**TREATMENT**

The treatment of infertility should be tailored to the problems unique to each couple. In many situations, including unexplained infertility, mild to moderate endometriosis, and/or borderline semen parameters, a stepwise approach to infertility is optimal, beginning with low-risk interventions and moving to more invasive, higher risk interventions only if necessary. After determination of all infertility factors and their correction, if possible, this approach might include, in increasing order of complexity: (1) expectant management, (2) clomiphene citrate (see below) with or without intrauterine insemination (IUI), (3) gonadotropins with or without IUI, and (4) in vitro fertilization (IVF). The time used to complete the evaluation, correction, and expectant management can be longer in women <30, but this process should be advanced rapidly in women >35. In some situations, expectant management will not be appropriate.

**Ovulatory Dysfunction** Treatment of ovulatory dysfunction should first be directed at identification of the etiology of the disorder to allow specific management when possible. Dopamine agonists, for example, may be indicated in patients with hyperprolactinemia (Chap. 316); lifestyle modification may be successful in women with low body weight or a history of intensive exercise (Chap. 65).

Medications used for ovulation induction include clomiphene citrate, gonadotropins, and pulsatile GnRH. Clomiphene citrate is a non-steroidal estrogen antagonist that increases FSH and LH levels by blocking estrogen negative feedback at the hypothalamus. The efficacy of clomiphene for ovulation induction is highly dependent on patient selection. It induces ovulation in 70 to 80% of women with PCOS and is the initial treatment of choice in these patients, particularly in conjunction with the use of insulin-sensitizing agents, such as metformin. Clomiphene citrate is less successful in patients with hypogonadotropic hypogonadism.

**Gonadotropins** are highly effective for ovulation induction in women with hypogonadotropic hypogonadism and PCOS and are used to induce multiple follicular recruitment in unexplained infertility and in older reproductive-aged women. Disadvantages include a significant risk of multiple gestation and the risk of ovarian hyperstimulation, but careful monitoring and a conservative approach to ovarian stimulation reduce these risks. Currently available gonadotropins include urinary preparations of LH and FSH, highly purified FSH, and recombinant FSH. Though FSH is the key component, the addition of some LH (or human chorionic gonadotropin) may improve results, particularly in hypogonadotropic patients.

**Pulsatile GnRH** is highly effective for restoring ovulation in patients with hypothalamic amenorrhea but is not widely available in the United States. Pregnancy rates are similar to those following the use of gonadotropins, but rates of multiple gestation are lower and there is virtually no risk of ovarian hyperstimulation.

None of these methods is effective in women with premature ovarian failure in whom donor oocyte or adoption are the methods of choice.
Tubal Disease If hysterosalpingography suggests a tubal or uterine cavity abnormality, or if a patient is ≥35 at the time of initial evaluation, laparoscopy with tubal lavage is recommended, often with a hysteroscopy. Although tubal reconstruction may be attempted if tubal disease is identified, IVF is often used instead, as these patients are at increased risk of developing an ectopic pregnancy.

Endometriosis Though 60% of women with minimal or mild endometriosis may conceive within 1 year without treatment, laparoscopic resection or ablation appears to improve conception rates. Medical management of advanced stages of endometriosis is widely used for symptom control but has not been shown to enhance fertility (Chap. 326). In moderate to severe endometriosis, conservative surgery is associated with pregnancy rates of 50 and 39% respectively, compared with rates of 25 and 5% with expectant management alone. In some patients, IVF may be the treatment of choice.

Male Factor Infertility Treatment options for male factor infertility have expanded greatly in recent years. Secondary hypogonadism is highly amenable to treatment with pulsatile GnRH or gonadotropins (Chap. 325). In vitro techniques have provided new opportunities for patients with primary testicular failure and disorders of sperm transport. Choice of initial treatment options depends on sperm concentration and motility. Expectant management should be attempted initially in men with mild male factor infertility (sperm count of 15 to 20×10^6/mL and normal motility). Moderate male factor infertility (10 to 15×10^6/mL and 20 to 40% motility) should begin with IUI alone or in combination with treatment of the female partner with clomiphene or gonadotropins, but it may require IVF with or without intracytoplasmic sperm injection (ICSI). For men with a severe defect (sperm count of <10×10^6/mL, 10% motility), IVF with ICSI or donor sperm should be used.

Assisted Reproductive Technologies The development of assisted reproductive technologies (ART) has dramatically altered the treatment of male and female infertility. IVF is indicated for patients with many causes of infertility that have not been successfully managed with more conservative approaches. IVF or ICSI is often the treatment of choice in couples with a significant male factor or tubal disease, whereas IVF using donor oocytes is used in patients with premature ovarian failure and in women of advanced reproductive age. Success rates depend on the age of the woman and the cause of the infertility and are generally 18 to 24% per cycle when initiated in women <40. In women >40, there is a marked decrease in both the number of oocytes retrieved and their ability to be fertilized. Though often effective, IVF is expensive and requires careful monitoring of ovulation induction and invasive techniques, including the aspiration of multiple follicles. ICSI is associated with a significant risk of multiple gestation (31% twins, 6% triplets, and 0.2% higher order multiples).

CONTRACEPTION

Though various forms of contraception are widely available, approximately 30% of births in the United States are the result of unintended pregnancy. Teenage pregnancies continue to represent a serious public health problem in the United States, with >1 million unintended pregnancies each year—a significantly greater incidence than in other industrialized nations.

Contraceptive methods are widely used (Table 45-1). Only 15% of couples report having unprotected sexual intercourse in the past 3 months. A reversible form of contraception is used by >50% of couples. Sterilization (in either the male or female) has been employed as a permanent form of contraception by over a third of couples. Pregnancy termination is relatively safe when directed by health care professionals but is rarely the option of choice.

No single contraceptive method is ideal, although all are safer than carrying a pregnancy to term. The effectiveness of a given method of contraception is dependent on the efficacy of the method itself, compliance, and appropriate use. Knowledge of the advantages and disadvantages of each contraceptive is essential for counseling an individual about the methods that are safest and most consistent with his or her lifestyle. Discrepancies between theoretical and actual effectiveness emphasize the importance of patient education and compliance when considering various forms of contraception (Table 45-1).

**BARRIER METHODS** Barrier contraceptives (such as condoms, diaphragms, and cervical caps) and spermicides are easily available, reversible, and have fewer side effects than hormonal methods. However, their effectiveness is highly dependent on compliance and proper use (Table 45-1). A major advantage of barrier contraceptives is the protection provided against STDs (Chap. 115). Consistent use is associated with a decreased risk of gonorrhea, nongonococcal urethritis, and genital herpes, probably due in part to the concomitant use of spermicides. Condom use also reduces the transmission of HIV infection. Natural membrane condoms may be less effective than latex condoms, and petroleum-based lubricants can degrade condoms and decrease their efficacy for preventing HIV infection. A highly effective female condom, which also provides protection against STDs, was approved in 1994 but has not achieved widespread use.

**STERILIZATION** Sterilization is the method of birth control most frequently chosen by fertile men and multiparous women (>30) (Table 45-1). Sterilization prevents fertilization by surgical interruption of the fallopian tubes in women or the vas deferens in men. Although tubal ligation and vasectomy are potentially reversible, these procedures should be considered permanent and should not be undertaken without careful patient counseling.

Several methods of tubal ligation have been developed, all of which are highly effective with a 10-year cumulative pregnancy rate of 1.85 per 100 women. However, when pregnancy does occur, the risk of ectopic pregnancy may be as high as 30%. In addition to prevention of pregnancy, tubal ligation reduces the risk of ovarian cancer, possibly by limiting the upward migration of potential carcinogens.

**Vasectomy** is an outpatient surgical procedure that has little risk...
and is highly effective. The development of azoospermia may be delayed for 2 to 6 months, and other forms of contraception must be used until two sperm-free ejaculations provide proof of sterility.

**INTRAUTERINE DEVICES** IUDs inhibit pregnancy primarily through a spermicidal effect caused by a sterile inflammatory reaction produced by the presence of a foreign body in the uterine cavity (copper IUDs) or by the release of progestins (Progestasert, Mirena). IUDs provide a high level of efficacy in the absence of systemic metabolic effects, and ongoing motivation is not required to ensure efficacy once the device has been placed. However, only 1% of women in the United States use this method compared to a utilization rate of 15 to 30% in much of Europe and Canada. This relatively low utilization rate continues despite evidence that the newer devices are not associated with increased rates of pelvic infection and infertility, as occurred with earlier devices. Screening for STDs should be performed prior to insertion, and an IUD should not be used in women at high risk for development of STDs or in women at high risk for bacterial endocarditis.

**HORMONAL METHODS**

**Oral Contraceptive Pills** Because of their ease of use and efficacy, oral contraceptive pills are the most widely used form of hormonal contraception. They act by suppressing ovulation, changing cervical mucus, and altering the endometrium. The current formulations are made from synthetic estrogens and progestins. The estrogen component of the pill consists of ethinyl estradiol or mestranol, which is metabolized to ethinyl estradiol. Multiple synthetic progestins are available. Norethindrone and its derivatives are used in many formulations. Low-dose norgestimate and the more recently developed progestins (desogestrel, gestodene, drospirenone) have a less androgenic profile; levonorgestrel appears to be the most androgenic of the progestins and should be avoided in patients with hyperandrogenic features. The three major formulations of oral contraceptives are: (1) fixed-dose estrogen-progestin combination, (2) phasic estrogen-progestin combination, and (3) progestin only. Combination formulations are administered daily for 3 weeks followed by a week of no medication during which menstrual bleeding generally occurs. Progestin-only pills are administered continuously. There has been recent interest in the development of extended oral contraceptives, reducing the number of episodes of withdrawal bleeding. An oral, trimonthly regimen is currently under investigation in the United States. Preliminary studies indicate that headache is reduced, although there is an early incidence of breakthrough bleeding.

Current doses of ethinyl estradiol range from 20 to 50 μg. However, indications for the 50-μg dose are rare, and the majority of formulations contain 35 μg of ethinyl estradiol. The reduced estrogen and progesterone content in the second- and third-generation pills has decreased both side effects and risks associated with oral contraceptive use (Table 45-2). At the currently used doses, patients must be cautioned not to miss pills due to the potential for ovulation. Side effects, including break-through bleeding, amenorrhea, breast tenderness, and weight gain, are often responsive to a change in formulation.

The microdose progestin-only minipill is less effective as a contraceptive, having a pregnancy rate of 2 to 7 per 100 women-years. However, it may be appropriate for women with cardiovascular disease or for women who cannot tolerate synthetic estrogens.

**New Methods** A weekly contraceptive patch (Ortho Evra) is now available. It has similar efficacy to oral contraceptives and may be associated with less breakthrough bleeding. Approximately 2% of patches fail to adhere, and a similar percentage of women have skin reactions. Efficacy is lower in women >90 kg. A monthly contraceptive injection (Lunelle) is also available. This estrogen/progestin combination is highly effective, with a first-year failure rate of <0.2%, but it may be less effective in obese women. Its use is associated with bleeding irregularities that diminish over time. Fertility returns rapidly after discontinuation. A monthly vaginal ring (NuvaRing) is now approved for contraceptive use. It is highly effective, with a 12-month failure rate of 0.7%. The device is intended to be left in place during intercourse.

**Long-Term Contraceptives** Long-term progestin administration in the form of Depo-Provera and Norplant (Table 45-1) act primarily by inhibiting ovulation and causing changes in the endometrium and cervical mucus that result in decreased implantation and sperm transport. Depo-Provera requires an intramuscular injection and is effective for 3 months, but return of fertility after discontinuation may be delayed for up to 12 to 18 months. Norplant requires surgical insertion but is effective for up to 5 years after insertion; fertility is possible shortly after its removal. Amenorrhea, irregular bleeding, and weight gain are the most common adverse effects associated with both injectable forms of contraception. A major advantage of the injectable progestin-based contraceptives is the apparent lack of increased arterial and venous thromboembolic events, but increased gallbladder disease and decreased bone density may result.

**Postcoital Contraception** Postcoital contraceptive methods prevent implantation or cause regression of the corpus luteum and are highly efficacious if used appropriately. Unprotected intercourse without regard to the time of the month carries an 8% incidence of pregnancy, an incidence that can be reduced to 2% by the use of emergency contraception within 72 h of unprotected intercourse. Certain oral contraceptives can be used within 72 h of unprotected intercourse [Ovral (2 tablets, 12 h apart) and Lo/Ovral (4 tablets, 12 h apart)]. Preven (50 mg ethinyl estradiol and 0.25 mg levonorgestrel) and Plan B (0.75 mg levonorgestrel) are now approved for postcoital contraception. Side effects are common with these high doses of hormones and include nausea, vomiting, and breast soreness. Recent studies suggest that 600 mg mifepristone (RU486), a progesterone receptor antagonist, may be equally as effective or more effective than hormonal regimens, with fewer side effects.

**MALE HORMONAL CONTRACEPTION** An effective and reversible male contraceptive has long been sought, and surveys indicate that a “male pill” would be acceptable to both men and women. Complete suppression of spermatogenesis is required for acceptable contraception but is not achieved reliably with testosterone alone. However, the combination of a long-acting testosterone preparation with a GnRH antagonist or a
Superficial spreading melanoma is the most common type of malignant melanoma and demonstrates color variegation (black, blue, brown, pink, and white) and irregular borders.

Section 9 Alterations in the Skin

Approach to the Patient with a Skin Disorder

The challenge of examining the skin lies in distinguishing normal from abnormal, significant findings from trivial ones, and in integrating pertinent signs and symptoms into an appropriate differential diagnosis. The fact that the largest organ in the body is visible is both an advantage and a disadvantage to those who examine it. It is advantageous because no special instrumentation is necessary and because the skin can be biopsied with little morbidity. However, the casual observer can be misled by a variety of stimuli and overlook important, subtle signs of skin or systemic disease. For instance, the sometimes minor differences in color and shape that distinguish a malignant melanoma (Fig. 46-1) from a benign pigmented nevus (Fig. 46-2) can be difficult to recognize. To aid in the interpretation of skin lesions, a variety of descriptive terms have been developed to characterize cutaneous lesions (Tables 46-1 and 46-2 and Fig. 46-3) and to formulate a differential diagnosis (Table 46-3). For instance, the finding of large numbers of scaling papules, usually indicative of a primary skin disease, places the patient in a different diagnostic category than would hemorrhagic papules, which may indicate vasculitis or sepsis (Figs. 46-4 and 46-5, respectively). It is important to differentiate primary skin lesions from secondary skin changes. If the examiner focuses on linear erosions overlying an area of erythema and scaling, he or she may incorrectly assume that the erosion is the primary lesion and the redness and scale are secondary, while the correct interpretation would be that the patient has a pruritic eczematous dermatitis with erosions caused by scratching.
TABLE 46-2 Common Dermatologic Terms

Lichenification: A distinctive thickening of the skin that is characterized by accentuated skin-fold markings and that feels thick on palpation.

Crust: Dried exudate of body fluids that may be either yellow (serous exudate) or red (hemorrhagic exudate).

Milia: Small, firm, white papules that are filled with keratin (and may in part resemble pustules).

Erosion: Loss of epidermis without an associated loss of dermis.

Ulcer: Loss of epidermis and at least a portion of the underlying dermis.

Excoriations: Linear, angular erosions that may be covered by crust and are caused by scratching.

Atrophy: An acquired loss of substance. In the skin, this may appear as a depression with intact epidermis (i.e., loss of dermal or subcutaneous tissue) or as sites of shiny, delicate, wrinkled lesions (i.e., epidermal atrophy).

Scar: A change in the skin secondary to trauma or inflammation. Sites may be erythematous, hypopigmented, or hypertrophic depending on their age or character. Sites on hair-bearing areas may be characterized by destruction of hair follicles.

Pruritus: A sensation that elicits the desire to scratch. Pruritus is often the predominant symptom of inflammatory skin diseases (e.g., atopic dermatitis, allergic contact dermatitis); it is also commonly associated with xerosis and aged skin. Systemic conditions that can be associated with pruritus include chronic renal disease, cholestasis, pregnancy, malignancy, polycythemia vera, and delusions of parasitosis.

The shape of lesions is also an important feature. Flat, round, erythematous papules and plaques are common in many cutaneous diseases. However, target-shaped lesions that consist in part of erythematous plaques are specific for erythema multiforme (Fig. 46-9). In the same way, the arrangement of individual lesions is important. Erythematous papules and vesicles can occur in many conditions, but their arrangement in a specific linear array suggests an external etiology such as allergic contact (Fig. 46-10) or primary lesion must be determined. Thus, when lesions are distributed on elbows, knees, and scalp, the most likely possibility based solely on distribution is psoriasis or dermatitis herpetiformis (Figs. 46-7 and 46-8, respectively). The primary lesion in psoriasis is a scaly papule that soon forms erythematous plaques covered with a white scale, whereas that of dermatitis herpetiformis is an urticarial papule that quickly becomes a small vesicle. In this manner, identification of the primary lesion directs the examiner toward the proper diagnosis. Secondary changes in skin can also be quite helpful. For example, scale represents excessive epidermis, while crust is the result of a discontinuous epithelial cell layer. Palpation of skin lesions can also yield insight into the character of an eruption. Thus red papules on the lower extremities that blanch with pressure can be a manifestation of many different diseases, but hemorrhagic red papules that do not blanch with pressure indicate palpable purpura characteristic of necrotizing vasculitis (Fig. 46-4).

Skin Biopsy  A skin biopsy is a straightforward minor surgical procedure; however, it is important to biopsy a lesion that is most likely to yield diagnostic findings. This decision may require expertise in skin diseases and knowledge of superficial anatomic structures in selected areas of the body. In this procedure, a small area of skin is anesthetized with 1% lidocaine with or without epinephrine. The skin lesion in question can be excised with a scalpel or removed by punch biopsy. In the latter technique, a punch is pressed against the surface of the skin and rotated with downward pressure until it penetrates to the subcutaneous tissue. The circular biopsy is then lifted with forceps, and the bottom is cut with iris scissors. Biopsy sites may or may not need suture closure, depending on size and location.

KOH Preparation  A potassium hydroxide (KOH) preparation is performed on scaling skin lesions where a fungal etiology is a possibility. The edge of such a lesion is scraped gently with a scalpel blade, and the removed scale is collected on a glass microscope slide and treated with 1 to 2 drops of a solution of 10 to 20% KOH. KOH dissolves keratin and allows easier visualization of fungal elements. Brief heating of the slide accelerates dissolution of keratin. When the preparation

**FIGURE 46-7**  Psoriasis is characterized by small and large erythematous plaques with adherent silvery scale.
FIGURE 46-8 Dermatitis herpetiformis manifested by pruritic, grouped vesicles in a typical location. The vesicles are often excoriated and may occur on knees, buttocks, and posterior scalp.

is viewed under the microscope, the refractile hyphae will be seen more easily when the light intensity is reduced and the condenser is lowered. This technique can be utilized to identify hyphae in dermatophyte infections (see Fig. 190-1), pseudohyphae and budding yeast in Candida infections (see Fig. 187-1), and fragmented hyphae and spores in tinea versicolor. The same sampling technique can be used to obtain scale for culture of selected pathogenic organisms.

Tzanck Smear A Tzanck smear is a cytologic technique most often used in the diagnosis of herpesvirus infections [simplex or varicella-zoster (see Figs. 164-1 and 164-3). An early vesicle, not a pustule or crusted lesion, is unroofed, and the base of the lesion is scraped gently with a scalpel blade. The material is placed on a glass slide, air-dried, and stained with Giemsa or Wright’s stain. Multinucleated epithelial giant cells suggest the presence of herpes, but culture or immunofluorescence testing must be performed to identify the specific virus.

Diascopy Diascopy is designed to assess whether a skin lesion will blanch with pressure as, for example, in determining whether a red lesion is hemorrhagic or simply blood-filled. For instance, urticaria (Fig. 46-11) will blanch with pressure, whereas a purpuric lesion caused by necrotizing vasculitis (Fig. 46-4) will not. Diascopy is performed by pressing a microscope slide or magnifying lens against a lesion and noting the amount of blanching that occurs. Granulomas often have an “apple jelly” appearance on diascopy.

Wood’s Light A Wood’s lamp generates 360-nm ultraviolet (or “black”) light that can be used to aid the evaluation of certain skin disorders. For example, a Wood’s lamp will cause erythrasma (a superficial, intertriginous infection caused by Corynebacterium minutissimum) to show a characteristic coral red color, and wounds colonized by Pseudomonas to appear pale blue. Tinea capitis caused by certain dermatophytes such as Microsporum canis or M. audouini exhibits a yellow fluorescence. Pigmented lesions of the epidermis such as freckles are accentuated, while dermal pigment such as postinflammatory hyperpigmentation fades under a Wood’s light. Vitiligo (Fig. 46-12)
Atopic dermatitis (AD) is the cutaneous expression of the atopic state, characterized by a family history of asthma, hay fever, or dermatitis in up to 70% of patients. Some of the features of AD are shown in Table 47-1. The prevalence of AD is increasing worldwide, with a point prevalence in Norwegian school children as high as 23%.

The etiology of AD is only partially defined, but there is a clear genetic predisposition. When both parents are affected by AD, over 80% of their children manifest the disease. When only one parent is affected, the prevalence drops to slightly over 50%. Patients with AD may display a variety of immunoregulatory abnormalities including increased IgE synthesis; increased serum IgE; increased specific IgE to foods, aeroallergens, bacteria, and bacterial products; increased expression of CD23 (low-affinity IgE receptor) on monocytes and B cells; and impaired delayed type hypersensitivity reactions.

The clinical presentation often varies with age. Half of patients with AD present within the first year of life, and 80% present by 5 years of age. About 80% ultimately coexpress allergic rhinitis or asthma. The infantile pattern is characterized by weeping inflammatory patches and crusted plaques that occur on the face, neck, and extensor surfaces. The childhood and adolescent pattern is marked by dermatitis of flexural skin, particularly in the antecubital and popliteal fossae (Fig. 47-1). AD may resolve spontaneously, but over half of all individuals affected as children will have dermatitis in adult life. The distribution of lesions may be similar to those seen in childhood. However, adults frequently have localized disease, manifesting as hand eczema or lichen simplex chronicus (see below). In patients with localized disease, AD may be suspected because of a typical personal history, family history, or the presence of cutaneous stigmata of AD such as perioral pallor, an extra fold of skin beneath the lower eyelid (Demie’s line), increased palmar skin markings, and an increased incidence of cutaneous infections, particularly with Staphylococcus aureus. Regardless of other manifestations, pruritus is a prominent characteristic of AD and is exacerbated by dry skin. Many of the cutaneous findings in affected patients, such as lichenification, are secondary to rubbing and scratching.
Histologic examination of the skin affected by AD may demonstrate features of acute or chronic dermatitis. Immunopathology shows activated, memory T helper cells. AD skin lesions may also demonstrate IgE-bearing CD1a+ Langerhans cells, and these cells have been implicated in AD disease pathophysiology through mediation of hypersensitivity responses to environmental antigens.

**Rx TREATMENT**

Therapy of AD should include avoidance of cutaneous irritants, adequate moisturizing, judicious use of topical anti-inflammatory agents, and prompt treatment of secondary infection. Patients should be instructed to bathe using warm, but not hot, water and to limit their use of soap. Immediately after bathing while the skin is still moist, a topical anti-inflammatory agent in a cream or ointment base should be applied to areas of dermatitis, and all other skin areas should be lubricated with a moisturizer. Approximately 30 g of a topical agent is required to cover the entire body surface of an average adult.
