Reestablishing high levels of fetal hemoglobin synthesis should ameliorate the symptoms of β thalassemia. Cytotoxic agents such as hydroxyurea and cytarabine promote high levels of HbF synthesis, probably by stimulating proliferation of the primitive HbF-producing progenitor cell population (i.e., F cell progenitors). Unfortunately, no regimen has yet been identified that ameliorates the clinical manifestations of β thalassemia. Butyrates stimulate HbF production, but only transiently. Pulsed or intermittent administration has recently been found to sustain HbF induction in the majority of patients with sickle cell disease. It is unclear whether butyrates will have similar activity in patients with β thalassemia.

**APLASTIC AND HYPOPLASTIC CRISIS IN PATIENTS WITH HEMOGLOBINOPATHIES**

Patients with hemolytic anemias sometimes exhibit an alarming decline in hematocrit during and immediately after acute illnesses. Bone marrow suppression occurs in almost everyone during acute inflammatory illnesses. In patients with short RBC life spans, suppression can affect RBC counts more dramatically. These hypoplastic crises are usually transient and self-correcting before intervention is required.

Aplastic crisis refers to a profound cessation of erythroid activity in patients with chronic hemolytic anemias. It is associated with a rapidly falling hematocrit. Episodes are usually self-limited. Aplastic crises are caused by infection with a particular strain of parvovirus, B19A. Children infected with this virus usually develop permanent immunity. Aplastic crises do not often recur and are rarely seen in adults. Management requires close monitoring of the hematocrit and reticulocyte count. If anemia becomes symptomatic, transfusion support is indicated. Most crises resolve spontaneously within 1 to 2 weeks.

**FURTHER READING**

The megaloblastic anemias are disorders caused by impaired DNA synthesis. Cells primarily affected are those having relatively rapid turnover, especially hematopoietic precursors and gastrointestinal epithelial cells. Cell division is sluggish, but cytoplasmic development progresses normally, so megaloblastic cells tend to be large, with an increased ratio of RNA to DNA. Megaloblastic erythroid progenitors tend to be destroyed in the marrow. Thus, marrow cellularity is often increased but production of red blood cells (RBC) is decreased, an abnormality termed ineffective erythropoiesis (Chap. 52).

Most megaloblastic anemias are due to a deficiency of cobalamin (vitamin B₁₂) and/or folic acid. The various clinical entities associated with megaloblastic anemia are listed in Table 92-1.

### PHYSIOLOGIC AND BIOCHEMICAL CONSIDERATIONS

#### FOLIC ACID

Folic acid is the common name for pteroylmonoglutamic acid. It is synthesized by many different plants and bacteria. Fruits and vegetables constitute the primary dietary source of the vitamin. Some forms of dietary folic acid are labile and may be destroyed by cooking. The minimum daily requirement is normally about 50 μg, but this may be increased severalfold during periods of enhanced metabolic demand such as pregnancy.

The assimilation of adequate amounts of folic acid depends on the nature of the diet and its means of preparation. Folates in various foodstuffs are largely conjugated to a chain of glutamic acid residues. This highly polar side chain impairs the intestinal absorption of the vitamin. However, conjugases (γ-glutamyl carboxypeptidases) in the lumen of the gut convert polyglutamates to mono- and diglutamates, which are readily absorbed in the proximal jejunum.

Plasma folate is primarily in the form of N⁵-methyltetrahydrofolate, a monoglutamate, which is transported into cells by a carrier that is specific for the tetrahydro forms of the vitamin. Once in the cell, the N⁵-methyl group is removed in a cobalamin-requiring reaction (see below), and the folate is then reconverted to the polyglutamate form. Conjugation to polyglutamate may be useful for retention of folate within the cell.

A folate-binding protein occurs in plasma, milk, and other body fluids. The function of this folate binder and its membrane-bound precursor is unknown. Neither the binder nor its precursor is related to the tetrahydrofolate carrier.

Normal individuals have about 5 to 20 mg folic acid in various body stores, half in the liver. In light of the minimum daily requirement, it is not surprising that a deficiency will occur within months if dietary intake or intestinal absorption is curtailed.

The prime function of folate compounds is to transfer 1-carbon moieties such as methyl and formyl groups to various organic compounds (Fig. 92-1). The sources of these 1-carbon moieties is usually serine, which reacts with tetrahydrofolate to produce glycine and N⁵-10-methylenetetrahydrofolate. An alternative source is formiminoglutamic acid, an intermediate in histidine catabolism, which gives up its formimino group to tetrahydrofolate to yield N⁵-formiminotetrahydrofolate and glutamic acid. These derivatives provide entry into an interconvertible donor pool consisting of tetrahydrofolate derivatives carrying various 1-carbon moieties. The constituents of this pool can donate their 1-carbon moieties to appropriate acceptor compounds to form metabolic intermediates, which are ultimately converted to build-

| III. Other |
| A. Nitrous oxide |
| B. Transcobalamin II deficiency (rare) |
| C. Congenital enzyme defects (rare) |

#### FOLIC ACID DEFICIENCY

| I. Inadequate intake: unbalanced diet (common in alcoholics, teenagers, some infants) |
| II. Increased requirements |
| A. Pregnancy |
| B. Infancy |
| C. Malignancy |
| D. Increased hematopoiesis (chronic hemolytic anemias) |
| E. Chronic exfoliative skin disorders |
| F. Hemodialysis |

| III. Malabsorption |
| A. Tropical sprue |
| B. Nontropical sprue |
| C. Drugs: Phenytoin, barbiturates, (?) ethanol |

| IV. Impaired metabolism |
| A. Inhibitors of dihydrofolate reductase: methotrexate, pyrimethamine, triamterene, pentamidine, trimethoprim |
| B. Alcohol |
| C. Rare enzyme deficiencies: dihydrofolate reductase, others |

#### OTHER CAUSES

| I. Drugs that impair DNA metabolism |
| A. Purine antagonists: 6-mercaptopurine, azathioprine, etc. |
| B. Pyrimidine antagonists: 5-fluorouracil, cytosine arabinoside, etc. |
| C. Others: procarbazine, hydroxyurea, acyclovir, zidovudine |

| II. Metabolic disorders (rare) |
| A. Hereditary orotic aciduria |
| B. Lesch-Nyhan syndrome |
| C. Others |

| III. Megaloblastic anemia of unknown etiology |
| A. Refractory megaloblastic anemia |
| B. Di Guglielmo’s syndrome* |
| C. Congenital dyserythropoietic anemia |

* A form of acute myeloid leukemia with atypical, dysplastic changes in erythroid series.
Folate metabolism. Folate is essential for the de novo synthesis of purines, deoxynucleotide monophosphate (dTMP), and methionine, serving as an intermediate carrier of 1-carbon fragments used in the biosynthesis of these compounds. Its active form is tetrahydrofolate (THF). THF acquires the 1-carbon fragment principally from serine, which is converted to glycine in the course of the reaction. For purine synthesis, the 1-carbon fragment is oxidized to the level of formaldehyde, then transferred to substrate. For methionine synthesis, a cobalamin–requiring reaction, the 1-carbon fragment is first reduced to the level of a methyl group, then transferred to homocysteine. In these reactions the cofactor is released as THF, which can immediately participate in another 1-carbon transfer cycle. During the production of dTMP from dUMP, however, the 1-carbon fragment is reduced from formaldehyde to a methyl group in the course of the transfer reaction. The hydrogen atoms used for this reduction come from the cofactor, which is therefore released, not as THF, but as dihydrofolate (DHF). To participate further in the 1-carbon transfer cycle, the DHF has to be re-reduced to THF, a reaction catalyzed by dihydrofolate reductase.

Coenzyme B12. COBALAMIN is a complex organometallic compound in which a cobalt atom is situated within a corrin ring, a structure similar to the porphyrin from which heme is formed. Unlike heme, however, cobalamin cannot be synthesized in the human body and must be supplied in the diet. The only dietary source of cobalamin is animal products, phagocytes, and plasma. On entering the stomach, dietary cobalamin in food is released and forms a stable complex with gastric R binder, one of a closely related group of glycoproteins of unknown function that are found in secretions (e.g., saliva, milk, gastric juice, bile), phagocytes, and plasma. For purine synthesis, the 1-carbon fragment is first reduced to the level of formaldehyde, then transferred to substrate. For methionine synthesis, a cobalamin–requiring reaction, the 1-carbon fragment is first reduced to the level of a methyl group, then transferred to homocysteine. In these reactions the cofactor is released as THF, which can immediately participate in another 1-carbon transfer cycle. During the production of dTMP from dUMP, however, the 1-carbon fragment is reduced from formaldehyde to a methyl group in the course of the transfer reaction. The hydrogen atoms used for this reduction come from the cofactor, which is therefore released, not as THF, but as dihydrofolate (DHF). To participate further in the 1-carbon transfer cycle, the DHF has to be re-reduced to THF, a reaction catalyzed by dihydrofolate reductase.

Cobalamin is an essential cofactor for two enzymes in human cells: methionine synthase and methylmalonyl-CoA (CoA) synthase. Cobalamin exists in two metabolically active forms, identified by the alkyl group attached to the sixth coordination position of the cobalt atom: methylcobalamin and adenosylcobalamin. The vitamin preparation that is used therapeutically is cyanocobalamin (also called vitamin B12). Cyanocobalamin has no known physiologic role and must be converted to a biologically active form before it can be used by tissues.

Methylcobalamin is the form required for methionine synthase, an enzyme needed for the introduction of a methyl group (N5-methyltetrahydrofolate) to homocysteine to form methionine. During gastric digestion, the cobalamin, which then binds to intrinsic factor (IF), a 50-kDa glycoprotein produced by the parietal cells of the stomach. The secretion of IF generally parallels that of hydrochloric acid. The cobalamin–IF complex is resistant to proteolytic digestion and travels to the distal ileum, where specific receptors on the mucosal brush border bind and absorb the cobalamin–IF complex. Thus, IF, like iron-binding transferrin, is a cell-directed carrier protein. The receptor-bound cobalamin–IF complex is then secreted into the circulation, from which it is rapidly taken up by the liver, bone marrow, and other cells. The pathway of cobalamin absorption is shown in Fig. 92–2. Normally, about 2 mg cobalamin is stored in the liver, and another 2 mg is stored elsewhere in the body. In view of the minimum daily requirement, about 3 to 6 years would be required for a normal individual to become deficient in cobalamin if absorption were to cease abruptly.

Although TC II is the acceptor for newly absorbed cobalamin, most circulating cobalamin is bound to TC I, a glycoprotein closely related to gastric R binder. TC I appears to be derived in part from leukocytes. The paradox that most circulating cobalamin is bound to TC I rather than TC II, even though TC II initially carries all the cobalamin that is absorbed by the intestine, is explained by the fact that cobalamin bound to TC II is rapidly cleared from the blood (t1/2 about 1 h), while clearance of cobalamin bound to TC I requires many days. The function of TC I is unknown.
which catalyzes the conversion of homocysteine to methionine (Fig. 92-1). When this reaction is impaired, folate metabolism is deranged; it is this derangement that underlies the defect in DNA synthesis and the megaloblastic maturation pattern in patients who are deficient in cobalamin. In cobalamin deficiency, the unconjugated N5-methyltetrahydrofolate newly taken from the bloodstream cannot be converted to other forms of tetrahydrofolate by methyl transfer. This is the so-called folate trap hypothesis. Because N5-methyltetrahydrofolate is a poor substrate for the conjugating enzyme, it largely remains in the unconjugated form and slowly leaks from the cell. Tissue folate deficiency therefore develops, and this results in megaloblastic hematopoiesis.

This hypothesis explains why tissue folate stores in cobalamin deficiency are substantially reduced, with a disproportionate reduction in conjugated, as compared with unconjugated, folates, despite normal or supranormal serum folate levels. It also explains why large doses of folate can produce a partial hematologic remission in patients with cobalamin deficiency.

Megaloblastic changes in both cobalamin and folate deficiency as well as in methotrexate treatment are related to a deficiency in production of dTMP. In addition, the excess deoxyuridylate that accumulates can be phosphorylated and mistakenly incorporated into DNA in place of thymidylate; base pairing can be affected by this U-for-T substitution.

Plasma homocysteine levels are elevated in both folate and cobalamin deficiency, and high levels of plasma homocysteine appear to be a risk factor for venous and arterial thrombosis. It is not yet known if hyperhomocysteinemia due to folate or cobalamin deficiency predisposes to thrombosis or alters its response to treatment.

Impairment in the conversion of homocysteine to methionine may also contribute to the neurologic complications of cobalamin deficiency (see below). The methionine formed in this reaction is needed also to contribute to the neurologic complications of cobalamin deficiency (see below).

Adenosylcobalamin is required for the conversion of methylenalonyl CoA to succinyl CoA. Lack of this cofactor leads to a risk factor for venous and arterial thrombosis. It is not yet known if hyperhomocysteinemia due to folate or cobalamin deficiency predisposes to thrombosis or alters its response to treatment.

The biochemical lesion that results in megaloblastic maturation of bone marrow cells also causes structural and functional abnormalities of the rapidly proliferating epithelial cells of the intestinal mucosa. Thus severe deficiency of one vitamin can lead to malabsorption of the other. Furthermore, as discussed above, a deficiency of cobalamin causes a secondary reduction in cellular folic acid.

Finally, megaloblastic anemias may occasionally be induced by factors unrelated to a vitamin deficiency. Most such cases are caused by drugs that interfere with DNA synthesis. Less commonly, megaloblastic maturation is a feature of certain acquired hematopoietic stem cell defects. Rarest of all are specific congenital enzyme deficiencies.

COBALAMIN DEFICIENCY The clinical features of cobalamin deficiency involve the blood, the gastrointestinal tract, and the nervous system. The hematologic manifestations are almost entirely the result of anemia, although very rare pancytopenia may appear, due to thrombocytopenia. Symptoms of anemia may include weakness, light-headedness, vertigo, and tinnitus, as well as palpitations, angina, and the symptoms of congestive failure. On physical examination, the patient with florid cobalamin deficiency is pale, with slightly icteric skin and eyes. Elevated bilirubin levels are related to high erythroid cell turn-over in the marrow. The pulse is rapid, and the heart may be enlarged; auscultation will usually reveal a systolic flow murmur.

The gastrointestinal manifestations reflect the effect of cobalamin deficiency on the rapidly proliferating gastrointestinal epithelium. The patient sometimes complains of a sore tongue, which on inspection will be smooth and beefy red. Anorexia with moderate weight loss may also be evident, possibly accompanied by diarrhea and other gastrointestinal symptoms. These latter manifestations may be caused in part by megaloblastosis of the small intestinal epithelium, which results in malabsorption.

The neurologic manifestations often fail to remit fully on treatment. The initial pathology is demyelination, followed by axonal degeneration and eventual neuronal death; the final stage, of course, is irreversible. Sites of involvement include peripheral nerves; the spinal cord, where the posterior and lateral columns undergo demyelination; and the cerebrum itself. Signs and symptoms include numbness and paresthesia in the extremities (the earliest neurologic manifestations), weakness, and ataxia. There may be sphincter disturbances. Reflexes may be diminished or increased. The Romberg and Babinski’s signs may be positive, and position and vibration senses are usually diminished. Disturbances of mentation will vary from mild irritability and forgetfulness to severe dementia or frank psychosis. It should be emphasized that neurologic disease may occur in a patient with a normal hematocrit and normal RBC indices. Although it has many benefits, folate supplementation of food may increase the likelihood of neurologic presentations of cobalamin deficiency.

In the classic patient, in whom hematologic problems predominate, the blood and bone marrow show characteristic megaloblastic changes (described under “Diagnosis,” below). The anemia may be very severe—hematocrits of 15 to 20 are not infrequent—but is surprisingly well tolerated by the patient because it develops slowly.

Defective Release of Cobalamin from Food Cobalamin in food is tightly bound to enzymes in meat and is split from these enzymes by hydrochloric acid and pepsin in the stomach. People >70 years commonly have achlorhydria. Therefore, they are unable to release cobalamin from food sources but retain the ability to absorb crystalline B12, the form most commonly found in multivitamins. The exact incidence of the defect in cobalamin release from food has not been well defined; estimates vary from 10 to >50% of those over age 70 years. Only a minority of these persons go on to develop frank cobalamin deficiency, but many have biochemical changes, including low levels of cobalamin bound to TC II and elevated homocysteine levels, that augur cobalamin deficiency (see below).

Similarly, patients on drugs that suppress gastric acid production, such as protonzole, may also fail to release cobalamin from food. However, the proton pump inhibitors do not inhibit IF secretion by parietal cells.
Pernicious Anemia  Pernicious anemia, considered the most common cause of cobalamin deficiency, is caused by the absence of IF, due to either atrophy of the mucosa or autoimmune destruction of parietal cells. It is most frequently seen in individuals of northern European descent and African Americans and is much less common in southern Europeans and Asians. Men and women are equally affected. It is a disease of the elderly, the average patient presenting near age 60; it is rare under age 30, although typical pernicious anemia can be seen in children under age 10 (juvenile pernicious anemia). Inherited conditions in which a histologically normal stomach secretes either an abnormal IF or none at all will induce cobalamin deficiency in infancy or early childhood.

The incidence of pernicious anemia is substantially increased in patients with other diseases thought to be of immunologic origin, including Graves’ disease, myxedema, thyroiditis, idiopathic adenocortical insufficiency, vitiligo, and hypoparathyroidism. Patients with pernicious anemia also have abnormal circulating antibodies related to their disease: 90% have antiparietal cell antibody, which is directed against the H-K-ATPase, while 60% have anti-IF antibody. Anti-parietal cell antibody is also found in 50% of patients with gastric atrophy without pernicious anemia, as well as in 10 to 15% of an unselected patient population, but anti-IF antibody is usually absent from these patients. Relatives of patients with pernicious anemia have an increased incidence of the disease, and even clinically unaffected relatives may have anti-IF antibody in their serum. Finally, treatment with glucocorticoids may reverse the disease.

Cytotoxic T cells may also contribute to the destruction of parietal cells in pernicious anemia. Pernicious anemia is unusually common in patients with agammaglobulinemia, supporting a role for the cellular immune system in its pathogenesis. In contrast, Helicobacter pylori does not cause parietal cell destruction in pernicious anemia.

The most characteristic finding in pernicious anemia is gastric atrophy affecting the acid- and pepsin-secreting portion of the stomach; the antrum is spared. Other pathologic changes are secondary to the deficiency of cobalamin; these include megaloblastic alterations in the gastric and intestinal epithelium and the neurologic changes described above. The abnormalities in the gastric epithelium appear as cellular atypia in gastric cytology specimens, a finding that must be carefully distinguished from the cytologic abnormalities seen in gastric malignancy.

The clinical manifestations are primarily those of cobalamin deficiency, as described above. The disease is of insidious onset and progresses slowly. Laboratory examination will reveal hypergastrinemia and pentagastrin-fast achlorhydria as well as the hematologic and other laboratory abnormalities discussed under “Diagnosis.”

Through appropriate replacement therapy, patients with pernicious anemia should experience complete and lifelong correction of all abnormalities in the gastric epithelium, retarding the transfer of the vitamin from R binder to IF and impairing the binding of the cobalamin-IF complex to the ileal receptors. Chronic pancreatitis may also cause cobalamin malabsorption by impairing the transfer of the vitamin from R binder to IF. This abnormality can be detected by tests of cobalamin absorption (see below, Schilling test), but it is invariably mild and never causes clinical cobalamin deficiency. Finally, a rare congenital disorder, Imerslund-Gräbeck disease, involves a selective defect in cobalamin absorption accompanied by proteinuria. Affected individuals have a mutation in cubulin, a receptor that mediates intestinal absorption of the cobalamin-IF complex.

Nitrous Oxide  Inhalation of nitrous oxide as an anesthetic destroys endogenous cobalamin. As ordinarily used, the magnitude of the effects is not sufficient to cause clinical cobalamin deficiency, but repeated or protracted exposure (>6 h), particularly in older patients with borderline cobalamin stores, can lead to severe megaloblastic anemia and/or acute neurologic deficits.

Folic Acid Deficiency  Since January 1998, folic acid has been added to all enriched grain products by order of the U.S. Food and Drug Administration; accordingly, the incidence of folic acid deficiency has fallen markedly. Patients with folic acid deficiency are more often malnourished than those with cobalamin deficiency. The gastrointestinal manifestations are similar to but may be more widespread and more severe than those of pernicious anemia. Diarrhea is often present, and cholelithiasis and glossitis are also encountered. However, in contrast to cobalamin deficiency, neurologic abnormalities do not occur.

The hematologic manifestations of folic acid deficiency are the same as those of cobalamin deficiency. Folic acid deficiency can generally be attributed to one or more of the following factors: inadequate intake, increased demand, or malabsorption.

Inadequate Intake  Alcoholics may become folate deficient because their main source of caloric intake is alcoholic beverages. Distilled spirits are virtually devoid of folic acid, while beer and wine do not contain enough of the vitamin to satisfy the daily requirement. In addition, alcohol may interfere with folate metabolism. Narcotic addicts are also prone to become folate deficient because of malnutrition. Many indigent and elderly individuals who subsist primarily on canned foods or “tea and toast” and occasional teenagers whose diet consists of “junk food” develop folate deficiency.

Increased Demand  Tissues with a relatively high rate of cell division such as the bone marrow or gut mucosa have a large requirement for folate. Therefore, patients with chronic hemolytic anemias or other causes of very active erythropoiesis may become deficient. Pregnant women formerly were at risk to become deficient in folic acid because of the high demand of the developing fetus. Deficiency in the first
weeks of pregnancy can cause neural tube defects in newborns. Often the pregnancy was not detected until the defect had developed; thus, provision of folic acid supplementation to women after they learned they were pregnant was ineffective. However, folate food supplementation has decreased neural tube defects by >50%. Folate deficiency may also occur during the growth spurts of infancy and adolescence. Patients on chronic hemodialysis may require supplementary folate to replace that lost in the dialysate.

Malabsorption Folic acid deficiency is a common accompaniment of tropical sprue. Both the gastrointestinal symptoms and malabsorption are improved by the administration of either folic acid or antibiotics by mouth. Patients with nontropical sprue (gluten-sensitive enteropathy) may also develop significant folic acid deficiency that parallels other parameters of malabsorption. Similarly, folate deficiency in alcoholics may be due in part to malabsorption. In addition, other primary small-bowel disorders are sometimes associated with folate deficiency (Chap. 275).

DRUGS Next to deficiency of folate or cobalamin, the most common cause of megaloblastic anemia is drugs. Agents that cause megaloblastic anemia do so by interfering with DNA synthesis, either directly or by antagonizing the action of folate. They can be classified as follows:

1. Direct inhibitors of DNA synthesis. They include purine analogues (6-mercaptopurine), pyrimidine analogues (6-thioguanine, 6-mercaptopurine), and other drugs that interfere with DNA synthesis by a variety of mechanisms (hydroxyurea, procarbazine). The antiviral agent azidothymidine (AZT), used for treating HIV, often causes severe megaloblastic anemia.

2. Folate antagonists. The most toxic of these is methotrexate, a powerful inhibitor of dihydrofolate reductase, which is used in the treatment of certain malignancies and rheumatologic disorders. Much less toxic but still capable of inducing a megaloblastic anemia are several weak dihydrofolate reductase inhibitors used to treat a variety of nonmalignant conditions. These drugs include pentamidine, trimethoprim, triamterene, and pyrimethamine.

3. Others. A number of drugs antagonize folate by mechanisms that are poorly understood but are thought to involve an effect on absorption of the vitamin by the intestine. In this category are the anticonvulsants phenytoin, primidone, and phenobarbital. Megaloblastic anemia induced by these agents is mild.

OTHER MECHANISMS Hereditary Megaloblastic anemia may be seen in several hereditary disorders. Orotic aciduria is a deficiency of orotidylate decarboxylase and phosphorylase, leading to a defect in pyrimidine metabolism and characterized by retarded growth and development as well as by the excretion of large amounts of orotic acid. Congenital folic acid malabsorption causes megaloblastic anemia, accompanied by ataxia and mental retardation. A thiamine-responsive megaloblastic anemia accompanied by nerve deafness and diabetes mellitus has been reported in several children. Megaloblastic changes as well as multinuclearity of RBC precursors are seen in the marrow of certain patients with congenital dyserythropoietic anemia, a group of inherited disorders characterized by mild to moderate anemia and a benign course.

TC II deficiency, like the congenital abnormalities in cobalamin absorption, causes pronounced deficiency in cobalamin in infancy or early childhood. Megaloblastic anemia is not seen in hereditary TC I deficiency.

Refractory Megaloblastic Anemia Megaloblastic erythropoiesis may sometimes be seen in myelodysplasia. Megaloblastic changes are restricted to the RBC series (see below). Myelodysplasia often produces a distinct morphologic picture most apparent in orthochromatic normoblasts in which a megaloblastic nucleus is associated with severely hypochromic cytoplasm. This variant has been called "megaloblastoid" and refers to the presence of both nuclear and cytoplasmic maturation defects. "Megaloblastoid" does not mean "mildly megaloblastic." As with other forms of myelodysplasia, refractory megaloblastic anemia is associated with an increased incidence of acute leukemia.

Megaloblastic changes are seen in erythremic myelosis and acute erythroleukemia, where RBC precursors are prominently involved. Here, the marrow is characterized by bizarre erythroid maturation, with multinuclearity and multipolar mitotic figures in the RBC precursors (Chap. 96).

MEGALOBLASTIC DISEASE WITHOUT ANEMIA Megaloblastic disease is easily overlooked in nonanemic patients. It can present in one of two ways.

Acute Megaloblastic Disease Occasionally, a full-blown megaloblastic state can develop over the course of just a few days. This is usually seen following nitrous oxide anesthesia but may occur in any patient with a serious illness requiring intensive care, especially a patient receiving multiple transfusions, dialysis, or total parenteral nutrition. An acute megaloblastic state can also be precipitated by the administration of a weak antifolate (e.g., trimethoprim) to a patient with marginal tissue folate stores.

The condition resembles an immune cytopenia, with a rapidly developing thrombocytopenia and/or leukopenia in the absence of anemia. The blood smear may be completely normal, but the marrow is floridly megaloblastic. Acute megaloblastic anemia responds rapidly to treatment with folate plus cobalamin in the usual therapeutic doses.

Cobalamin Deficiency without Anemia Cobalamin deficiency without hematologic abnormalities is surprisingly common, especially in the elderly. The risk of a nonhematologic presentation for cobalamin deficiency is increased by the folate food fortification because folate can mask the hematologic effects of cobalamin deficiency. Between 10 and 30% of persons over age 70 years have metabolic evidence of cobalamin deficiency, either elevated homocysteine levels, low cobalamin, or both. Only 10% of these patients have defective production of IF, and the remainder often have atrophic gastritis and cannot release cobalamin from their food (see above). Serum cobalamin levels may be normal or low, but serum levels of methylmalonic acid are almost invariably increased due to a deficiency of cobalamin at the tissue level. The neuropsychiatric abnormalities tend to improve, and serum methylmalonic acid levels generally return to normal after treatment with cobalamin. Neurologic defects do not always reverse with cobalamin supplementation.

DIAGNOSIS The finding of significant macrocytosis [mean corpuscular volume (MCV) > 100 fL] suggests the presence of a megaloblastic anemia. Other causes of macrocytosis include hemolysis, liver disease, alcoholism, hypothyroidism, and aplastic anemia. If the macrocytosis is marked (MCV > 110 fL), the patient is much more likely to have a megaloblastic anemia. Macrocytosis is less marked with concurrent iron deficiency or thalassemia. The reticulocyte index is low, and the leukocyte and platelet count may also be decreased, particularly in severely anemic patients. The blood smear (Fig. 92-3) demonstrates marked anisocytosis and poikilocytosis, with a variety of megaloblastic changes. This test is useful in ruling out megaloblastic or other processes that might masquerade as megaloblastic anemia. Cobalamin deficiency, either elevated homocysteine levels, low cobalamin-TC II levels, or both. Only 10% of these patients have defective production of IF, and the remainder often have atrophic gastritis and cannot release cobalamin from their food (see above). Serum cobalamin levels may be normal or low, but serum levels of methylmalonic acid are almost invariably increased due to a deficiency of cobalamin at the tissue level. The neuropsychiatric abnormalities tend to improve, and serum methylmalonic acid levels generally return to normal after treatment with cobalamin. Neurologic defects do not always reverse with cobalamin supplementation.

FIGURE 92-3 Megaloblastic anemia. Oval macrocytes, well filled with hemoglobin, are admixed with lesser numbers of large red blood cells, some of which are teardrop-shaped. Note also hypersegmented granulocyte.
be corrected by the administration of antibiotics. The Schilling test can provide equally reliable information after the patient has had adequate therapy with parenteral cobalamin.

A normal Schilling test in a patient with documented cobalamin deficiency may indicate poor absorption of the vitamin when mixed with food. This can be established by repeating the Schilling test with radioactive cobalamin scrambled with an egg.

Serum methylmalonic acid and homocysteine levels are also useful in the diagnosis of megaloblastic anemias. Both are elevated in cobalamin deficiency, while elevated levels of homocysteine but not methylmalonic acid are seen in folate deficiency. These tests measure tissue vitamin stores and may demonstrate a deficiency even when the more traditional but less reliable folate and cobalamin levels are borderline or even normal. Patients (particularly older patients) without anemia and with normal serum cobalamin levels but elevated levels of serum methylmalonic acid may develop neuropsychiatric abnormalities. Treatment of patients with this “subtle” cobalamin deficiency will usually prevent further deterioration and may result in improvement.

TREATMENT

Cobalamin Deficiency Apart from specific therapy related to the underlying disorder (e.g., antibiotics for intestinal overgrowth with bacteria), the mainstay of treatment for cobalamin deficiency is replacement therapy. Because the defect is nearly always malabsorption, patients are generally given parenteral treatment, specifically in the form of intramuscular cyanocobalamin. Parenteral treatment begins with 1000 μg cobalamin per week for 8 weeks, followed by 1000 μg cyanocobalamin intramuscularly every month for the rest of the patient’s life. Cobalamin deficiency can also be managed very effectively by oral replacement therapy with 2 mg crystalline B12 per day; however, compliance is a greater concern with oral than intramuscular treatment.

The response to treatment is gratifying. Shortly after treatment is begun, and several days before a hematologic response is evident in the peripheral blood, the patient will experience an increase in strength and an improved sense of well-being. Marrow morphology begins to revert toward normal within a few hours after treatment is initiated. Reticulocytosis begins 4 to 5 days after therapy is started and peaks at about day 7 (Fig. 92-5), with subsequent remission of the anemia over the next several weeks. If a reticulocytosis does not occur, or if it is less brisk than expected from the level of the hematocrit, a search should be made for other factors contributing to the anemia (e.g., infection, coexisting iron and/or folate deficiency, or hypothyroidism). Hypokalemia and salt retention may occur early in the course of therapy. Thrombocytosis may also be seen.

In most cases, replacement therapy is all that is needed for the treatment of cobalamin deficiency. Occasionally, however, a patient with a severe anemia will have such a precarious cardiovascular status that emergency transfusion is necessary. This must be done with great caution.
The loss of red cells either through hemorrhage or, less commonly, through premature destruction of the red cells (hemolysis) may cause anemia. Hemolysis or blood loss normally leads to an increase in red cell production, detected by an increase in reticulocyte index.

HEMOLYTIC ANEMIAS

Red blood cells (RBC) normally survive 90 to 120 days in the circulation. The life span of RBC may be shortened in a number of disorders, often resulting in anemia if the bone marrow is not able to replenish adequately the prematurely destroyed RBC.

In all patients with hemolytic anemia, a careful history and physical examination provide important clues to the diagnosis. The patient may complain of fatigue and other symptoms of anemia (Chap. 52). Less commonly, jaundice and even red-brown urine (hemoglobinuria) are reported. A complete drug and toxin exposure history and the family history often provide crucial information. The physical examination may show jaundice of skin and mucosae. Splenomegaly is encountered in a majority of hemolytic anemias. Other historic and physical findings are associated with specific hemolytic anemias (see below).

Laboratory tests may be used initially to demonstrate the presence of hemolysis (Table 93.1) and define its cause. An elevated reticulocyte count in the patient with anemia is the most useful indicator of hemolysis, reflecting erythroid hyperplasia of the bone marrow; biopsy of the bone marrow is often unnecessary. Reticulocytes are also elevated in patients with active blood loss, those with myelophthisis, and those who are recovering from suppression of erythropoesis (Chap. 52). The morphology of the RBC may provide evidence both of hemolysis and of its cause; the characteristic abnormalities and their associated causes and syndromes are listed in Table 93-2. While the findings on the peripheral blood smear alone are rarely pathognomonic, they may provide important clues to the presence of hemolysis and to diagnosis.

Hemolysis results in increased heme catabolism and enhanced formation of unconjugated bilirubin. The plasma level of unconjugated bilirubin may be high enough to produce readily apparent jaundice (detectable usually when serum bilirubin is >34 μmol/L or 2 mg/dL).

**Note:** N, normal.
The unconjugated (indirect) bilirubin level can be further elevated by a commonly encountered defect in conjugation of bilirubin (Gilbert’s syndrome) (Chap. 284). In patients with hemolysis, the level of unconjugated bilirubin never exceeds 70 to 80 μmol/L (4 to 5 mg/dL) unless liver function is impaired.

In the absence of tissue damage in other organs, serum enzyme levels can be useful in the diagnosis and monitoring of patients with hemolysis. Lactate dehydrogenase (LDH), particularly LDH-2, is elevated by accelerated RBC destruction. Serum AST (SGOT) may be somewhat elevated, whereas ALT (SGPT) is not.

Haptoglobin is an α globulin that is present in high concentration (~1.0 g/L) in the serum. It binds specifically to the globin in hemoglobin. The hemoglobin-haptoglobin complex is cleared rapidly by the mononuclear phagocyte system. Thus patients with significant hemolysis, either intravascular or extravascular, have low or absent levels of serum haptoglobin. The fact that haptoglobin synthesis is decreased in patients with hepatocellular disease and increased in inflammatory states must be considered in the interpretation of serum haptoglobin.

Intravascular hemolysis (which is uncommon) results in the release of hemoglobin into the plasma. In these cases, plasma hemoglobin is increased in proportion to the degree of hemolysis (plasma hemoglobin may be falsely elevated due to lysis of RBC in vitro). If the haptoglobin-binding capacity of the plasma is exceeded, free hemoglobin tetramer dissociates into dimers that pass through renal glomeruli. This filtered hemoglobin is reabsorbed by the proximal tubule, where it is catabolized in situ, and the heme iron is incorporated into storage proteins (ferritin and hemosiderin). The presence of hemosiderin in the urine, detected by staining the sediment with Prussian blue, indicates that a significant amount of circulating free hemoglobin has been filtered by the kidneys. When the absorptive capacity of the tubular cells is exceeded, hemoglobinuria ensues and indicates severe intravascular hemolysis. Hemoglobinuria must be distinguished from hematuria (in which case RBC are seen on urine examination) and from myoglobinuria due to rhabdomyolysis; in all three cases, the urine is positive with the benzidine reaction, commonly used in analysis of urine. After centrifugation of an anticoagulated blood specimen, the plasma of patients with hemoglobinuria has a reddish-brown color, whereas that of patients with myoglobinuria is normal in color. Because of its higher molecular weight, hemoglobin has lower glomerular permeability than myoglobin and is less rapidly cleared by the kidneys.

**CLASSIFICATION**

The hemolytic anemias can be grouped into three categories (Table 93-3). Accelerated RBC destruction can be caused by (1) a molecular defect (hemoglobinopathy or enzymopathy) inside the red cell, (2) an abnormality in membrane structure and function, or (3) an environmental factor such as mechanical trauma or an autoantibody. In *intracorpuscular* types of hemolysis, the patient’s RBC have an abnormally short life span in a normal recipient (with a compatible blood type), while compatible normal RBC survive normally in the patient. The opposite is true in *extracorpuscular* types of hemolysis. Finally, hemolytic disorders can be either inherited or acquired.

**INHERITED HEMOLYTIC ANEMIAS**

The inherited hemolytic anemias are due to inborn defects in one of three main components of red cells: the membrane, enzymes, or hemoglobin. These defects are often known at the genomic level, but their identification still largely depends on their clinical and laboratory manifestations.

**Red Cell Membrane Disorders**

These are usually readily detected by morphologic abnormalities of the RBC on the blood film. The three inherited RBC membrane abnormalities are hereditary spherocytosis, hereditary elliptocytosis (including hereditary pyropoikilocytosis), and hereditary stomatocytosis.

**HEREDITARY SPHEROCYTOSIS**

Hereditary spherocytosis is characterized by spherical RBC due to a molecular defect in one of the proteins in the cytoskeleton of the RBC membrane; this leads to a loss of membrane and hence decreased ratio of surface area to volume and consequently spherocytosis. Usually an autosomal dominant trait, this disorder has an incidence of 1:1000 to 1:4500. In ~20% of patients, the absence of hematologic abnormalities in family members suggests either autosomal recessive inheritance or a spontaneous mutation. The disorder is sometimes clinically apparent in early infancy but often escapes detection until adult life.

**Clinical Manifestations**

The major clinical features of hereditary spherocytosis are anemia, splenomegaly, and jaundice. Jaundice may be intermittent and tends to be less pronounced in early childhood. Because of the increased bile pigment production, pigmented gallstones are common, even in childhood. Compensatory erythropoietic hyperplasia of the bone marrow occurs, with the extension of red marrow into the midshaft of long bones and occasionally with extramedullary erythropoiesis, at times leading to the formation of paravertebral masses visible on chest x-ray. Because the bone marrow’s capacity to increase erythropoiesis nearly matches the rate of hemolysis, anemia is usually mild or moderate and may even be absent in an otherwise healthy individual. Compensation may be temporarily interrupted by episodes of relative erythropoietic hypoplasia precipitated by infections, particularly parvovirus. Splenomegaly is very common. The hemolytic rate may increase transiently during systemic infections, which induce further splenic enlargement. Chronic leg ulcers, similar to those observed in sickle cell anemia, occur occasionally.

The characteristic erythrocyte abnormality is the spherocyte (Fig. 93-1). The mean corpuscular volume (MCV) is usually normal or slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is increased to 0.35 to 0.40 g/dL. Spherocytosis may be quantitatively assessed by measurement of the osmotic fragility of the RBC on exposure to hypotonic solutions causing a net influx of water (Fig. 93-2). On microscopic examination, spherocytes are usually detected as small cells without central pallor.

**Inherited** | **Acquired**
Pathogenesis  

The molecular abnormality in hereditary spherocytosis primarily involves the proteins responsible for tethering the lipid bilayer to the underlying cytoskeletal network. About 50% of patients have a defect in ankyrin, the protein that forms a bridge between protein 3 and spectrin (Fig. 93-3). Homozygotes who have a recessive inheritance pattern for ankyrin deficiency have more severe anemia than heterozygotes with the more common dominant form. About 25% of patients have a mutation of protein 3, resulting in a deficiency of that protein and mild anemia with dominant inheritance. Most of the remaining 25% have mutations of spectrin, leading to impaired synthesis or self-association. β-spectrin mutants are generally mild, with dominant inheritance, while α-spectrin deficiency is severe, with a recessive inheritance pattern. Less often, deficiency of palladin (protein 4.2) is a cause of hereditary spherocytosis. Because the lipid bilayer is not well anchored when these proteins are defective, part of it is lost by vesiculation, resulting in a more spherical and less deformable cell. Because of their shape and rigidity, spherocytes are trapped in the spleen where their increased metabolic rate cannot be sustained, causing a further loss of surface membrane. This “conditioning” produces a subpopulation of hyperspheroidal RBC in the peripheral blood.

Diagnosis  

Hereditary spherocytosis must be distinguished primarily from the spherocytic hemolytic anemias associated with RBC antibodies. The family history of anemia and/or splenectomy is helpful, from the spherocytic hemolytic anemias associated with RBC antibodies. The great majority of patients manifest only mild hemolysis, with little or no anemia. RBC destruction occurs predominantly in an enlarged spleen. Hemolysis is corrected by splenectomy.

Splenectomy is recommended in patients with moderate or severe hemolysis. Although the RBC defect and its consequent morphology persist, anemia is ameliorated. The operative risk is low, particularly if performed by laparoscopy, RBC survival after splenectomy is normal or nearly so; if it is not, an accessory spleen or another diagnosis should be sought. Because of the potential for gallstones and for episodes of bone marrow hypoplasia or hemolytic crises, splenectomy should be performed in symptomatic individuals; cholecystectomy should not be performed without splenectomy, as intrahepatic gallstones may result. Splenectomy in children should be postponed until age 4, if possible, to minimize the risk of severe infections with gram-positive encapsulated organisms. Pneumococcal, meningococcal, and Haemophilus influenzae vaccines should be administered at least 2 weeks before splenectomy. In patients with severe hemolysis, folic acid (1 mg/d) should be administered prophylactically.

Hereditary elliptocytosis and hereditary pyropoikilocytosis  

Hereditary elliptocytosis is an autosomal dominant trait and affects 1 per 4000 to 5000 people, a frequency similar to that of hereditary spherocytosis (rarely, patients with myelodysplastic disorders of the bone marrow may have acquired elliptocytosis). In most affected individuals, a structural abnormality of erythrocyte spectrin leads to impaired assembly of the cytoskeleton. In some families, affected individuals have a deficiency of erythrocyte membrane protein 4.1, which stabilizes the interaction of spectrin and actin in the cytoskeleton (Fig. 93-3). In Southeast Asia, the incidence of hereditary ovalocytosis is high; a small internal deletion of protein 3 makes the membrane rigid and confers resistance against malaria.

The great majority of patients manifest only mild hemolysis, with little or no anemia. RBC destruction occurs predominantly in an enlarged spleen. Hemolysis is corrected by splenectomy.

The blood smear reveals elongated or oval red cells (elliptocytes). Patients with marked hemolysis have microspherocytes, bizarre-shaped RBC, and RBC fragments, all of which increase in number after splenectomy. The degree of hemolysis does not correlate with the percentage of elliptocytes.

Hereditary pyropoikilocytosis is a rare disorder related to hereditary elliptocytosis and is characterized by bizarre-shaped, microcytic RBC that undergo disruption at temperatures of 44 to 45°C (in contrast,
normal RBC are stable up to 49°C). This condition results from a deficiency of spectrin and an abnormality of spectrin self-assembly. Hemolysis is usually severe, is recognized in childhood, and is partially responsive to splenectomy.

**HEREDITARY STOMATOCYTOSIS** Stomatocytes are cup-shaped RBC that have a slitlike central zone of pallor on blood smears. The disorder is inherited in an autosomal dominant pattern. RBC have an increased permeability to sodium and potassium, which is compensated for by an increased active transport of these cations. In some patients, the RBC are swollen with an excess of ions and water and a decreased mean corpuscular hemoglobin concentration (overhydrated stomatocytes, “hydrocytosis”); many of these patients lack the RBC membrane protein 7.2 (stomatin). RBC lacking Rh proteins (Rhnull cells) are also stomatocytic and have a shortened life span. In other patients, the RBC are shrunken, with a decreased ion and water content, appearing as target cells on blood smears. Most patients have splenomegaly and mild anemia. Splenectomy decreases but does not totally correct the hemolytic process.

**Red Cell Enzyme Defects** During its maturation, the RBC loses its nucleus, ribosomes, and mitochondria and thus its capability for protein synthesis and oxidative phosphorylation. The mature circulating RBC has a relatively simple pattern of intermediary metabolism (Fig. 93-4).

**Embden-Meyerhof pathway**  
- Glucose → ATP, ADP  
- Glucose-6-phosphate → G6PD, 6-phosphogluconate  
- Fructose-6-phosphate → ATP, ADP  
- Fructose-1, 6-diphosphate → aldolase  
- Glyceraldehyde-3-phosphate → NAD+, NADH  
- 1,3-Bisphosphoglycerate → 2,3-bisphosphoglycerate mutase  
- 2-Phosphoglycerate → enolase  
- Phosphoenolpyruvate → pyruvate kinase

**Hexose monophosphate shunt**  
- Glucose 6-phosphate isomerase  
- G6PD, NADPH, NADP+  
- Phosphoglucone dehydrogenase  
- Glutathione reductase  
- Glutathione

**Figure 93-4** RBC metabolism. The Embden-Meyerhof pathway (glycolysis) generates ATP for energy and membrane maintenance. The generation of NADPH maintains hemoglobin in a reduced state. The hexose monophosphate shunt generates NADPH that is used to reduce glutathione, which protects the red cell against oxidant stress. Regulation of 2,3-bisphosphoglycerate levels is a critical determinant of oxygen affinity of hemoglobin. Enzyme deficiency states in order of prevalence: glucose-6-phosphate dehydrogenase (G6PD) > pyruvate kinase > glucose-6-phosphate isomerase > rare deficiencies of other enzymes in the pathway. The more common enzyme deficiencies are encircled.

**TREATMENT**

Most patients do not require therapy. Those with severe hemolysis should be given folic acid (1 mg/d). Blood transfusions may be necessary during a hypoplastic crisis. Women with PK deficiency may become very anemic during pregnancy, sometimes leading to the diagnosis for the first time. Patients with PK or glucose phosphate isomerase deficiency may benefit from splenectomy.

**DEAdditional In the Embden-Meyerhof Pathway** Most of the glycolytic enzyme defects are inherited in an autosomal recessive pattern. Since the gene frequency for this group of defects is low, true heterozygotes are often the offspring of a consanguineous mating. More often, affected individuals are compound heterozygotes. Patients with severe hemolysis usually present during early childhood with anemia, jaundice, and splenomegaly. The RBC are often relatively deficient in ATP, resulting in a leak of potassium ion out of these cells. These RBC are rigid and thus more readily sequestered by the mononuclear phagocyte system.

Some of these glycolytic enzyme deficiencies such as pyruvate kinase (PK) deficiency and hexokinase deficiency are localized to the RBC, with no apparent metabolic abnormality in other cells. In other disorders, the enzyme deficiency is more widespread.

About 95% of the clinically significant defects in the glycolytic pathway are due to PK deficiency, and about 4% are due to glucose phosphate isomerase deficiency. The remainder, shown in Fig. 93-4, are extremely rare. Most have been encountered in isolated families; clinical manifestations are variable.

**Laboratory Findings** Patients have a normocytic (or slightly macrocytic), normochromic anemia with reticulocytosis. In those with PK deficiency, bizarre erythrocytes, including spiculated cells, are noted on the peripheral smear, especially after splenectomy. Spherocytes are usually absent; the term *congenital nonspherocytic hemolytic anemia* has been applied to these disorders. The diagnosis of this group of anemias depends on specific enzymatic assays. Abnormalities in enzymatic properties may be useful in distinguishing among enzyme mutants. DNA sequencing is the only definitive way to identify a mutant.

**DEFINITIONS**

**G6PD Deficiency** This is by far the most common congenital shunt defect, affecting more than 200 million people throughout the world; like hemoglobin S, it partially protects the patient from malaria by providing a defective home for the merozoite. Over 400 variants of G6PD have been described, resulting in considerable clinical heterogeneity among affected individuals. Most are missense mutations resulting in altered enzymatic properties.

The normal G6PD is designated as type B. About 20% of individuals of African descent have a G6PD (designated A+) that differs by a single amino acid and is electrophoretically distinguishable but functionally normal. Among the clinically significant G6PD variants, the
most common, the so-called A− type, is due to two base substitutions and is encountered primarily in individuals of central African descent. The A− G6PD has the same electrophoretic mobility as the A+ type, but it is unstable and has abnormal kinetic properties. This variant is found in about 11% of African-American males. A second relatively common G6PD variant is encountered among groups of Mediterranean origin, particularly Sardinians and Sephardic Jews; this variant is more severe than the A− variant and may result in nonpheroperoxidase hemolytic anemia in the absence of known oxidative stress. A third relatively common and slightly less severe variant occurs in southern Chinese populations.

The G6PD gene is located on the X chromosome; thus the deficiency state is a sex-linked trait. Affected males (hemizygotes) inherit the abnormal gene from their mothers who are usually carriers (heterozygotes). Because of inactivation of one of the two X chromosomes (Lyon hypothesis: Chap. 56), the heterozygote has two populations of RBC: normal and deficient in G6PD. Most female carriers have no problems. Those who happen to have a high proportion of deficient cells resemble the male hemizygotes. G6PD activity normally declines ~50% during the 120-day life span of the RBC. This decay is moderately accelerated in A− RBC and markedly so in RBC containing the Mediterranean variant. Individuals with the A− variant normally have a slightly shortened RBC survival time, but they are not anemic.

Clinical problems arise only when the affected individual is subjected to some type of environmental stress. Most often, hemolytic episodes are triggered by viral and bacterial infections. The mechanism is unknown. In addition, drugs or poisons that pose an oxidant threat to the RBC (most commonly sulfia drugs, antimalarials, and nitrofurantoin) cause hemolysis in individuals deficient in G6PD (Table 93-4). Although aspirin is frequently mentioned as a likely offender, it has no deleterious effect in A− individuals. Accidental ingestion of toxic compounds such as naphthalene (moth balls) may cause severe hemolysis. Metabolic acidosis can precipitate an episode of hemolysis in individuals deficient in G6PD.

Clinical and Laboratory Features The patient may experience an acute hemolytic crisis within hours of exposure to the oxidant stress, leading to hemoglobinuria and peripheral vascular collapse in severe cases. Since only the older population of RBC is rapidly destroyed, the hemolytic crisis is usually self-limited, even if the exposure to the oxidant continues. Among black males with the A− variant, the RBC mass decreases by a maximum of 25 to 30%. The oxidation of hemoglobin leads to the formation of Heinz bodies, visualized by means of a supravital stain such as crystal violet. However, Heinz bodies are usually not seen after the first day or so, since these inclusions are readily removed by the spleen. Their removal leads to the formation of “bite cells” (RBC that have lost a peripheral portion of the cell). Multiple bites cause the formation of fragments. A few phagocytes also may be present. Individuals with the Mediterranean type G6PD have much lower overall enzyme activity than those with the A− variant and, therefore, have more severe clinical manifestations.

A minority of patients are exquisitely sensitive to fava beans and develop a fulminating hemolytic crisis after exposure. The oxidants in Vicia fava are two β-glycosides whose aglycones, when autooxidized, produce oxygen free radicals. The incidence of favism is highly variable due to variations in concentration, in absorption, or in metabolism of the aglycones. Favism is seldom encountered in individuals with the A− variant.

The diagnosis of G6PD deficiency should be considered in any individual, particularly a male of African or Mediterranean descent, who experiences an acute hemolytic episode. The patient should be questioned about possible exposure to oxidant agents. The diagnosis can be established by a number of tests that assess either the enzyme activity or the effects of its deficiency. However, the test may yield a false-negative result during a hemolytic episode when the old RBC deficient in the enzyme have already lysed.

**TREATMENT**

Since hemolysis in patients deficient in A− G6PD is usually self-limited, no specific treatment is necessary. Splenectomy does not benefit Mediterranean patients with chronic hemolysis. Blood transfusions are rarely indicated. Adequate urine flow should be maintained if hemoglobinuria develops during an acute hemolytic episode.

Hemolytic episodes can be prevented by warning patients about risks posed by oxidant drugs and fava beans and by prompt treatment of infections.

**OTHER ENZYME DEFECTS**

Hemolytic anemia may sometimes be caused by abnormalities in enzymes of nucleotide metabolism. Individuals with pyrimidine 5′-nucleotidase deficiency have marked coarse basophilic stippling in their RBC because the mRNA of the cell is not properly metabolized. Hemolytic anemia also has been noted in individuals whose RBC have supranormal levels of adenosine deaminase and relatively low levels of ATP.

**Hemoglobinopathies**

Hemolysis is a component of anemias related to some hemoglobinopathies (Chap. 91).

**ACQUIRED HEMOLYTIC ANEMIAS**

In most patients with acquired hemolytic anemia, RBC are made normally but are prematurely destroyed because of damage acquired in the circulation. (The exceptions are rare disorders characterized by acquired dysplasia of the cells of the bone marrow and the production of structurally and functionally abnormal RBC.) The damage that occurs may be mediated by antibodies or toxins or may be due to abnormalities in the circulation, including an overactive mononuclear phagocyte system or traumatic lysis by natural or artificial impediments to circulation. The acquired hemolytic anemias are classified into five categories (Table 93-5).

</table>
Hypersplenism  The spleen is particularly efficient in trapping and destroying RBC that have minimal defects. This unique ability of the spleen to filter mildly damaged RBC results from its unusual vascular anatomy (Chap. 54). Almost all the blood circulating through the spleen flows rapidly from arterioles in the white pulp to sinuses in the spleen’s red pulp and then into the venous system. In contrast, a small portion of splenic blood flow (normally 1 to 2%) passes into the “marginal zone” of the lymphatic white pulp. Although the cells that occupy this zone are not phagocytic, they serve as a mechanical filter that hinders the progress of severely damaged blood cells. As RBC leave this zone and enter the red pulp, they flow into narrow cords, rich in macrophages, that end blindly but communicate with sinuses through small openings between the lining cells of the sinuses. These openings, averaging 3 μm in diameter, test the ability of RBC (4.5 μm in diameter) to undergo deformation. RBC that cannot re-enter the vascular sinuses are engulfed by phagocytic cells and destroyed (see Fig. 54-1).

The normal spleen retains reticulocytes for 1 to 2 days but otherwise poses no threat to normal RBC until they become senescent. However, in the face of splenomegaly, increased destruction of the cells of the blood, including the RBC, may take place due to pooling of the blood in a relatively nutrient-poor environment full of phagocytic cells. Splenic sequestration that causes cytopenia is called hypersplenism. In infiltrative diseases of the spleen, substantial splenomegaly may exist with no apparent hemolysis; inflammatory and congestive splenomegaly is commonly associated with modest shortening of RBC survival time, along with more marked glucocytopenia and thrombocytopenia. Patients with cytopenia(s) sufficient to produce symptoms generally benefit from splenectomy.

Immunologic Causes of Hemolysis Immune hemolysis in the adult is usually induced by IgG or IgM antibodies reacting specifically with antigens associated with the patient’s RBC (often called “autoantibodies”) or with alloantigens on transfused RBC (alloantibodies) (Chap. 99).

The Coombs antiglobulin test is the major tool for diagnosing autoimmune hemolysis. This test relies on the ability of antibodies specific for immunoglobulins (especially IgG) or complement components (especially C3) to agglutinate RBC coated with these proteins. With specific anti-IgG and anti-C3, the direct Coombs test detects IgG or C3 on the patient’s RBC, which indicates the presence of immune hemolysis and may help define its cause (Table 93-6). Rarely, neither IgG nor complement may be found on the RBC of the patient (Coombs-negative immune hemolytic anemia).

Antibodies in the serum of the patient that recognize RBC antigens can be detected by reacting the serum with normal RBC bearing the antigen. With the exception of cold-reacting antibodies and some drug-related antibodies (see below), this is of value primarily in compatibility testing for transfusion.

“WARM” ANTIBODIES Antibodies that react at body temperature (warm antibodies) are nearly always IgG, rarely IgM or IgA. Autologous warm antibodies cause autoimmune hemolytic (or immunohemolytic) anemia, warm antibody type.

Clinical Manifestations Immune hemolytic anemia of the warm antibody type occurs at all ages, but it is more common in adults, particularly women. In approximately one-fourth of patients this disorder occurs as a complication of an underlying disease affecting the immune system, especially lymphoid neoplasms (Chap. 97); collagen vascular diseases, especially systemic lupus erythematosus (SLE); and congenital immunodeficiency diseases (Table 93-7). A wide variety of drugs may stimulate antibody formation, resulting in a similar syndrome (see below).

The presentation and course of IgG immunohemolytic anemia are quite variable. In its mildest form, the only manifestation is a positive direct Coombs test. In this instance, insufficient antibody is present on the RBC surface to permit the reticuloendothelial system to recognize the cell as abnormal. Most symptomatic patients have a moderate to severe anemia [hemoglobin levels 60 to 100 g/L and reticulocyte counts 10 to 30% (200 to 600 × 10^9/L)], spherocytosis (Fig. 93-3), and splenomegaly. Occasionally, venous thrombosis occurs.

Severe immunohemolytic anemia presents with fulminant hemolysis associated with hemoglobinemia, hemoglobinuria, and shock; this syndrome may be rapidly fatal unless aggressively treated.

The direct Coombs test is positive in 98% of patients; usually IgG is detected with or without C3. The pattern of IgG and C3 fixation on the patient’s RBC may indicate the origin of the disorder. Immune thrombocytopenia also may be present (Evans syndrome), a disorder in which separate antibodies are directed against platelets and RBC.

Pathogenesis IgG antibodies lyse RBC by two mechanisms: (1) immune adherence, particularly that due to the IgG antibody, is also enhanced by the transit of RBC into splenic cords and sinuses, which brings cells into direct contact with phagocytic cells.

TREATMENT

Patients having a mild degree of hemolysis usually do not require therapy. In those with clinically significant hemolysis, initial therapy consists of glucocorticoids (e.g., prednisone, 1.0 mg/kg per day). A rise in hemoglobin is frequently noted within 3 or 4 days and occurs

COLD-ANTIBODY IMMUNOHEMOLYTIC ANEMIA

1. Cold agglutinin disease
   a. Acute: Mycoplasma infection, infectious mononucleosis
   b. Chronic: Idiopathic, lymphoma
2. Paroxysmal cold hemoglobinuria
im in most patients within 1 to 2 weeks. Prednisone is continued until the hemoglobin level has risen to normal values, and thereafter it is tapered rapidly to about 20 mg/d, then slowly over the course of several months. An algorithm for this tapering process is given in Fig. 93-6.

For chronic therapy with prednisone, alternate-day administration is preferred. More than 75% of patients achieve an initial significant and sustained reduction in hemolysis; however, in half these patients the disease recurs, either during glucocorticoid tapering or after its cessation. Glucocorticoids have two modes of action: an immediate effect due to inhibiting clearance of IgG-coated RBC by the mononuclear phagocyte system and a later effect due to inhibiting antibody synthesis. Splenectomy is recommended for patients who cannot tolerate or fail to respond to glucocorticoid therapy.

Patients who have been refractory to glucocorticoid therapy and to recent attempts at tapering are treated with immunosuppressive drugs. A success rate of ∼50% has been reported. Intravenous gamma globulin may cause rapid cessation of hemolysis; however, it is not nearly as effective in this disorder as in immune thrombocytopenia.

Patients with severe anemia may require blood transfusions. Because the antibody in this disease is usually a “panagglutinin,” reacting with nearly all normal donor cells, compatible cross-matching is impossible. The goal in selecting blood for transfusion is to avoid administering RBC with antigens to which the patient may have alloantibodies. A common procedure is to adsorb the panagglutinin present in the patient’s serum with the patient’s own RBC from which antibody has been previously eluted. Serum cleared of autoantibody can then be tested for the presence of alloantibody to donor blood groups. ABO-compatible RBC matched in this fashion are administered slowly, with watchfulness for signs of an immediate-type hemolytic transfusion reaction.

**Prognosis**

Immune hemolytic anemia is often transient in children, particularly when it follows a viral infection, but is usually chronic in adults, lasting many years with exacerbations and remissions. In most patients, hemolysis is controlled by glucocorticoid therapy alone, by splenectomy, or by a combination. Fatalities occur among three rare subsets of patients: (1) those with overwhelming hemolysis who die from anemia; (2) those whose host defenses are impaired by glucocorticoids, splenectomy, and/or immunosuppressive agents; and (3) those with major thrombotic events coincident with active hemolysis.

When immunohemolysis develops as a complication of an underlying disorder, the prognosis is often determined by the primary disease.

**IMMUNOHEMOLYTIC ANEMIA SECONDARY TO DRUGS**

Drugs cause immunohemolytic anemia by two mechanisms of action: (1) they induce a disorder identical in almost every respect to warm-antibody immunohemolytic anemia [e.g., α-methyldopa (an antihypertensive; Chap. 230)], or (2) they become associated as haptons with the RBC surface and induce the formation of an antibody directed against the RBC-drug complex (e.g., penicillin, quinidine).

A positive direct Coombs test is observed in up to 10% of patients receiving α-methyldopa therapy in doses of 2 g/d or higher. A small minority of these patients develop spherocytosis and hemolysis, which may be severe. The autoantibodies cross-react with the normal Rh protein.

In most other cases of drug-induced hemolysis, the antibody is directed against the combination of the drug and the membrane glycoprotein to which it is attached. The hemolytic reaction in vivo is dependent on the presence of the drug and usually ceases shortly after the drug has been discontinued. Penicillin and its congeners may cause this type of reaction if the drug is given in very high doses (10 million units per day or more). The direct Coombs test is positive only with anti-IgG; the indirect Coombs test is positive only when the normal cells have been coated with penicillin. Complement is not usually fixed, and the hemolysis in vivo is usually not severe. Since the antibody is usually IgG, spherocytosis and splenic destruction may occur.

Most other drugs (such as quinine, quinidine, sulfonamides, sulfonylureas, phenacetin, stibophen, and dipyrone) do not adhere as tightly to their glycoproteins, and the drug-antibody complexes are removed during the washing steps of the direct and indirect Coombs reactions. These antibodies (particularly IgM) are usually able to fix complement, and C3d and C4d remain on the RBC surface; thus the direct Coombs test is positive with anti-C3 but not anti-IgG. The antibody is detected in the indirect Coombs test only when the drug is added to the incubation mixture. Hemolysis may be quite severe, sometimes resulting in signs of intravascular hemolysis; resolution is usually prompt after the drug is discontinued.

**IMMUNE HEMOLYSIS DUE TO COLD-REACTIVE ANTIBODIES**

Antibodies that react with polysaccharide antigens are usually IgM and bind antigen better at temperatures lower than 37°C, hence the name cold-reactive antibodies. Uncommonly, the antibody is IgG (the Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria).

IgM cold-reacting antibodies readily agglutinate RBC and are called cold agglutinins. They arise in two clinical settings: (1) monoclonal antibodies, the product of lymphocytic neoplasia or paraneoplasia; and (2) polyclonal antibodies in response to infection. In many elderly patients, the “neoplasm” is benign monoclonal gammopathy that does not progress, and the paraprotein remains its only manifes-
Chronic cold agglutinin disease tends to be unremitting. The overall prognosis is dominated by the underlying lymphoma, if present. In those patients in whom cold agglutinin disease appears to arise spontaneously, malignant lymphoma may develop after several years.

**Paroxysmal Cold Hemoglobinuria (PCH)** Now a rare disorder, PCH was more prevalent when tertiary syphilis was prevalent; now, most cases are either secondary to a viral infection or are autoimmune. PCH results from the formation of the Donath-Landsteiner antibody, an IgG antibody that is directed against the P antigen (Chap. 99) and that can induce complement-mediated lysis. Attacks are precipitated by exposure to cold and are associated with hemoglobinuria and hemoglobinemia; chills and fever; back, leg, and abdominal pain; headache; and malaise. Recovery from the acute episode is prompt, and between episodes patients are usually asymptomatic. When this syndrome accompanies acute viral infections (e.g., measles and mumps in children), it is self-limited but may be severe. Although the direct Coombs test may show complement to be present (seldom IgG), this test may be negative. The diagnosis is made by demonstrating cold-reacting IgG antibodies either by lytic tests (when the titer is very high) or by special antiglobulin tests. When PCH is secondary to syphilis, it responds to therapy for syphilis. Chronic autoimmune PCH may respond to prednisone or cytotoxic therapy (azathioprine or cyclophosphamide) but does not respond to splenectomy. The natural history of this disease often extends over many years.

**Hemolysis Due to Trauma in the Circulation** RBC may be fragmented by mechanical trauma as they circulate; this circumstance leads to intravascular hemolysis and in most cases to RBC fragments called schistocytes. Schistocytes are identified by the sharp points that result from the faulty sealing of the fractured membrane (Fig. 93-7). Mechanical trauma leading to hemolysis occurs in three clinical settings: (1) when RBC flow through small vessels over the surface of bony prominences and are subject to external impact during various physical activities, (2) when RBC flow across a pressure gradient created by an abnormal heart valve or valve prosthesis (macrovascular), and (3) when the deposition of fibrin or small platelet thrombi in the microvasculature exposes RBC to a physical impediment that fragments them (microvascular) (Table 93-8).

**External Impact** Hemoglobinemia and hemoglobinuria have been observed in a small proportion of individuals who have undergone a prolonged march or a prolonged run, most typically on a hard surface and while wearing thin-soled shoes. Hemolysis can be prevented by the insertion of a soft inner sole in the runner’s shoes. No abnormality of RBC has been demonstrated, even during the acute episode.

**Macrovascular Traumatic Hemolysis** Hemolysis associated with fragmented RBC (Fig. 93-7) occurs in approximately 10% of patients with artificial aortic valve prostheses. In contrast, traumatic hemolysis is rare in recipients of porcine valves. Severe hemolysis may occur after repair of osmium primum or endocardial cushion defects with a prosthetic patch. Mitral valve prostheses may produce hemolysis, but since the pressure gradient across these valves is lower than across aortic prostheses, the incidence is lower. A moderately shortened RBC survival time with little or no anemia occurs in some patients with severe calcific aortic stenosis. Indeed, almost any intracardiac lesion that alters hemodynamics may lead to some shortening of RBC survival. Traumatic hemolysis has been observed in patients who have undergone aortofemoral bypass.

**FIGURE 93-7** The helmet-shaped red blood cell and the small triangular-shaped red blood cells seen on this smear represent morphologic evidence of mechanical damage to red blood cells within the blood vessels.

* Malignant hypertension, eclampsia, renal graft rejection, hemangiomas, immune disease (scleroderma).

Clinical Manifestations In severe cases, hemoglobin levels fall to 50 to 70 g/L with reticulocytosis, fragmented RBC in the peripheral blood, depressed haptoglobin, elevated serum LDH, and hemoglobinemia and hemoglobinuria. Iron loss (as hemoglobin or hemosiderin) in the urine may lead to iron deficiency. The direct Coombs test may rarely become positive.

Iron deficiency should be corrected by the administration of oral iron. The elevated hemoglobin that results may permit a decrease in the cardiac output and a slowing of the hemolytic rate. Limitation in physical activity also lessens the hemolytic rate. When these measures fail, any paravalvular leak must be repaired or the prosthetic valve replaced.

MICROVASCULAR TRAUMATIC HEMOLYSIS If fibrin or platelet microthrombi are deposited in arteriolar sites, RBC may be trapped on the meshwork and fragmented by high shear forces.

Abnormalities of the Vessel Wall Disorders such as malignant hypertension, eclampsia [hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome], renal allograft rejection, disseminated cancer, hemangiomas, or disseminated intravascular coagulation (DIC) may cause traumatic hemolysis (Chaps. 101, 102). The degree of hemolysis induced by this family of disorders is usually quite mild, but a large number of fragments may be seen in the peripheral blood. In some patients, thrombocytopenia may be severe. Therapy is best directed at the primary disease. Thus, reversal of renal graft rejection, treatment of malignant hypertension and eclampsia, control of cancer, and the like lead to a cessation of hemolysis. The relative importance of the primary vascular abnormality versus fibrin deposition is unclear.

THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) This disorder is characterized by arteriolar lesions in various organs that contain platelet thrombi and produce thrombocytopenia and hemolytic anemia due to fragmentation of RBC (see Chap. 101).

HEMOLYTIC-UREMIC SYNDROME This disorder is similar to TTP and is characterized by the same arteriolar lesions, which may be confined to the kidney, and by similar laboratory findings (see Chap. 101).

DISSEMINATED INTRAVASCULAR COAGULATION Inappropriate activation of the clotting system with deposition of fibrin in small vessels may lead to RBC fragmentation in the microvasculature. RBC fragmentation occurs in about one-fourth of patients with DIC (Chap. 102). The degree of hemolysis is much less in DIC than in either TTP or the hemolytic-uremic syndrome, and anemia with reticulocytosis is rare.

Environmental Alteration of the Red Cell Membrane by “Toxic” Effects A variety of infections may be associated with severe hemolysis. The microbes that cause bartonellosis (Chap. 144), as well as malaria and babesiosis (Chap. 195), directly paralyze RBC. Clostridium welchii (Chap. 126) produces a phospholipase that can cleave the phosphoryl bond of lecithin, thereby lysing human RBC. A mild, transient hemolysis frequently accompanies bacteremia with diverse organisms such as pneumococci, staphylococci, and Escherichia coli.

Hemolysis may result from the direct action of snake and spider venoms on the RBC. Although cobra venom is directly lytic in vitro, the clinical disease induced by the bite of the cobra is one of moderate hemolysis associated with spherocytosis. Spider bites, particularly the bite of the brown recluse spider, induce acute intravascular hemolysis associated with spherocytosis and fragments of complement components on the RBC. The hemolysis continues for several days up to 1 week.

Copper has a direct hemolytic effect on RBC. Hemolysis has been observed after exposure of individuals to copper salts (such as during hemodialysis). Transient episodes of hemolysis occur in patients with Wilson’s disease (Chap. 339).

The RBC membrane is unstable at temperatures above 49°C due to denaturation of the cytoskeletal protein spectrin. The RBC undergoes a process of budding, cleavage, and resealing above this temperature. Patients with extensive burns have prominent spherocytosis, hemoglobinemia, and sometimes hemoglobinuria.

SPUR CELL ANEMIA Hemolytic anemia with bizarre-shaped RBC occurs in about 5% of patients with severe hepatocellular disease, particularly advanced Laennec’s cirrhosis.

Clinical Manifestations Anemia is more severe than that observed in otherwise uncomplicated cirrhosis. Splenomegaly is always present and is greater than in patients who have cirrhosis without spur cell anemia. The RBC are irregularly shaped with multiple spicules, and a small number of bizarre-shaped fragments are commonly seen on peripheral blood smears (see Fig. 98-3).

Pathogenesis The surface membrane of a spur cell contains 50 to 70% excess cholesterol, but its total phospholipid content is normal. Cholesterol out of proportion to phospholipid decreases the membrane fluidity and cell deformability. These rigid, cholesterol-laden RBC cannot pass through the filtering system of the spleen, further impeded by congestive splenomegaly in cirrhosis. In contrast, the target-shaped RBC is more common in liver disease and has an excess of both cholesterol and phospholipid.

Diagnosis Patients with spur cell anemia have severe hemolysis and characteristic RBC morphology. Spur cells or acanthocytes have irregular spikes (irregular in length of projections and their spacing) and must be distinguished from regularly spaced, crenated RBC (echinocytes). Echinocytes are a frequent artifact on portions of some blood smears, and they are uniformly present in some patients with uremia (“burr cells”) (Fig. 93-8). Small, dense, crenated spheres (spheroechinocytes) are sometimes seen in congenital nonspherocytic hemolytic anemia due to enzyme deficiencies in the Embden-Meyerhof pathway (see above). RBC of similar morphology are seen in patients with abetalipoproteinemia. However, hemolysis is minimal.

Transfusion therapy is of limited benefit. Lipid-lowering agents have been unsuccessful. Splenectomy has been reported to prevent both the
conditioning of RBC in the spleen and their premature destruction. However, splenectomy carries a high risk in patients with severe liver disease complicated by portal hypertension and coagulation defects. It must be reserved for patients in whom hemolysis is a major problem and who are relatively good surgical risks.

**Prognosis**  Spur cell anemia occurs during the late stages of cirrhosis, and >90% of patients succumb to their underlying liver disease within 1 year of the diagnosis of spur cell anemia.

**Paroxysmal Nocturnal Hemoglobinuria (PNH)**  This hemolytic disorder is distinctive because it is an intracorpuscular defect acquired at the stem cell level.

**Clinical Manifestations**  The three common manifestations of PNH are hemolytic anemia, venous thrombosis, and deficient hematopoiesis. Anemia is highly variable, with hematocrit values ranging from ≤20% to normal. RBC are normochromic and normocytic unless iron deficiency has occurred from chronic iron loss in the urine.

Clinical hemoglobinuria is intermittent in most patients and never occurs in some, but hemosiderinuria is usually present. Since hemolysis is due to abnormalities of the RBC leading to sensitivity to the hemolytic action of complement, it is manifest when complement is activated, for example, by infection.

Granulocytopenia and thrombocytopenia are common and reflect impaired hematopoiesis. The life span of the platelet is normal. However, the activation of complement indirectly stimulates platelet aggregation and hypercoagulability; this probably accounts for the tendency toward thrombosis seen in PNH.

Venous thrombosis is a common complication of patients of European origin, affecting ~40% at one time or another; it is less common in Asian patients. It occurs primarily in intra-abdominal veins (hepatic, portal, mesenteric) and results in Budd-Chiari syndrome, congestive splenomegaly, and abdominal pain. It may occur in cerebral venous sinuses and is a common cause of death in patients with PNH.

The bone marrow may appear normocellular, but in vitro marrow progenitor assays are abnormal. In about 15 to 30% of long-term survivors of aplastic anemia, PNH cells appear in the circulation; in some patients, the manifestations of PNH become dominant. Patients with PNH may have aplastic periods lasting from weeks to years. PNH may be seen in association with other stem cell disorders, including myelofibrosis and (rarely) other myelodysplastic or myeloproliferative disorders.

**Pathogenesis**  PNH is an acquired clonal disease, arising from an inactivating somatic mutation in a single hematopoietic stem cell of a gene on the X-chromosome (pig-A) necessary for the biosynthesis of the glycosylphosphatidylinositol (GPI) anchor. This anchor attaches a number of proteins to the external membrane surface, and its partial or complete absence results in the absence of those proteins; to date, about 20 proteins have been found to be missing on the blood cells of patients with PNH. Two of these are the complement defense proteins CD55 [PNH decay accelerating factor (DAF)] and CD59, which block complement activation on the cell surface. Their absence accounts for the sensitivity of RBC to complement lysis and for the tendency of platelets to abnormally initiate clotting. The normal clones of stem cells do not completely disappear, and the proportion of cells that are abnormal varies among patients and over time in a single patient.

**Diagnosis**  PNH should be suspected in anyone with otherwise unexplained hemolytic anemia, especially with leukopenia and/or thrombocytopenia and with evidence of intravascular hemolysis (hemoglobinemia, hemoglobinuria, hemosiderinuria, elevated LDH). Anyone recovering from aplastic anemia should be examined at intervals for the appearance of the diagnostic cells. The diagnosis is often delayed because (1) it is not considered, (2) hemoglobinuria is confused with hematuria, (3) elevation of the LDH is attributed to liver disease, and (4) the diagnostic tests [the acidified serum lysis test (Ham test) and the sucrose lysis test] are not reliable.

For many years, the diagnosis of PNH depended on the demonstration of the lysis of RBC after complement activation either by acid (Ham test) or by reduction in ionic strength (sucrose lysis test). These tests are inferior to the analysis of GPI-linked proteins (e.g., CD59, DAF) on RBC and granulocytes by flow cytometry.

**TREATMENT**

Transfusion therapy is useful in PNH not only for raising the hemoglobin level but also for suppressing the marrow production of RBC during episodes of sustained hemoglobinuria. Washed RBC are the preferred source to prevent exacerbation of hemolysis. Therapy with androgens sometimes results in a rise in hemoglobin level. Glucocorticoids reduce the rate of hemolysis in moderate doses (15 to 30 mg prednisone) on alternate days.

Iron deficiency is common. Iron replacement may exacerbate hemolysis because of the formation of many new RBC, which may be sensitive to complement. This occurrence may be minimized by giving prednisone (60 mg/d) or by suppressing the bone marrow with transfusions.

Acute thrombosis in PNH, particularly Budd-Chiari syndrome and cerebral thrombosis, should be treated with thrombolytic agents. Heparin therapy should be instituted rapidly and maintained using low-molecular-weight heparin, at least for several weeks to months and perhaps indefinitely in severe cases. Anyone who has had a major thrombosis should chronically receive at least warfarin therapy. Antithrombin globulin (total dose, 150 mg/kg over 4 to 10 days) is often of use in treating marrow hypoplasia; prednisone counteracts the immune-complex disease that results from the administration of this foreign protein.

In patients with either hypoplasia or thrombosis who have an appropriate sibling donor, marrow transplantation should be considered early in the course of the disease. The usual conditioning programs are sufficient to eradicate the aberrant clone.

**ANEMIA OF ACUTE BLOOD LOSS**

The normal capacity to compensate for acute blood loss involves cardiovascular mechanisms, an adjustment in the oxygen affinity of hemoglobin, and an increase in erythropoiesis in the marrow. The signs and symptoms of blood loss relate to the volume of the blood lost and the time frame over which the hemorrhage occurs (Table 93-9). Losses of up to 20% of the blood volume are normally tolerated by redistribution of blood flow mediated by reflex venospasm, but the presence of fever or pain may interfere with this compensation. With larger losses, blood volume redistribution is not adequate to maintain normal blood pressure: initially, hypotension is only seen on standing, but with greater losses the patient has hypotension in sitting or supine positions. If the blood loss is more gradual, plasma volume increases, but albumin production usually lags behind the fluid shifts. It may take 2 to 3 days for the liver to generate the albumin lost in a 1500-mL bleed.

early in life, can also present as marrow failure in normal-appearing adults. Acquired aplastic anemia is often stereotypical in its manifestations, with the abrupt onset of low blood counts in a previously well young adult; seronegative hepatitis or a course of an incrimental medical drug may precede the onset. The diagnosis in these instances is

### FURTHER READING

uncomplicated. Sometimes blood count depression is moderate or incomplete, resulting in anemia, leukopenia, and thrombocytopenia in some combination. Aplastic anemia is related to both paroxysmal nocturnal hemoglobinuria (PNH; Chap. 93) and to MDS, and in some cases a clear distinction among these disorders may not be possible.

**Epidemiology** The incidence of acquired aplastic anemia in Europe and Israel is 2 cases per million persons annually. In Thailand and China, rates of 5 to 7 per million have been established. In general, men and women are affected with equal frequency, but there is a biphasic age distribution, with the major peak in the teens and twenties and a second rise in the elderly.

**Etiology** The origins of aplastic anemia have been inferred from several recurring clinical associations (Table 94-2); unfortunately, these relationships are neither a reliable guide in an individual patient nor necessarily etiologic. In addition, while most cases of aplastic anemia are idiopathic, little other than history separates these cases from those with a presumed etiology such as a drug exposure.

**Radiation** Marrow aplasia is a major acute sequela of radiation. Radiation damages DNA; tissues dependent on active mitosis are particularly susceptible. Nuclear accidents can involve not only power plant workers but also employees of hospitals, laboratories, and industry (food sterilization, metal radiography, etc.), as well as innocents exposed to stolen, misplaced, or misused sources. While the radiation dose can be approximated from the rate and degree of decline in blood counts, dosimetry by reconstruction of the exposure can help to estimate the patient’s prognosis and also to protect medical personnel from contact with radioactive tissue and excreta. MDS and leukemia, but probably not aplastic anemia, are late effects of irradiation.

**Chemicals** Benzene is a notorious cause of bone marrow failure. Vast quantities of epidemiologic, clinical, and laboratory data link benzene to aplastic anemia, acute leukemia, and blood and marrow abnormalities. The occurrence of leukemia is roughly correlated with cumulative exposure, but susceptibility must also be important, as only a minority of even heavily exposed workers develop benzene myelotoxicity. The employment history is important, especially in industries where benzene is used for a secondary purpose, usually as a solvent. Benzene-related blood diseases have declined with regulation of industrial exposure. Although benzene is no longer generally available as a household solvent, exposure to its metabolites occurs in the normal diet and in the use of lead-free gasoline. The association between marrow failure and other chemicals is much less well substantiated.

**Drugs** (See Table 94-3) Many chemotherapeutic drugs have marrow suppression as a major toxicity; effects are dose-dependent and will occur in all recipients. In contrast, idiosyncratic reactions to a large and diverse group of drugs may lead to aplastic anemia without a clear dose-response relationship. These associations rested largely on accumulated case reports until a large international study in Europe in the 1980s quantitated drug relationships, especially for nonsteroidal analgesics, sulfonamides, thyrostatic drugs, some psychotropics, penicillamine, allopurinol, and gold. Not all associations necessarily reflect causation: a drug may have been used to treat the first symptoms of bone marrow failure (antibiotics for fever or the preceding viral illness) or provoked the first symptom of a preexisting disease (petechiae by nonsteroidal anti-inflammatory agents administered to the thrombocytopenic patient). In the context of total drug use, idiosyncratic reactions, while individually devastating, are rare events. Chlor-

### TABLE 94-3 Some Drugs and Chemicals Associated with Aplastic Anemia

| Agents that regularly produce marrow depression as major toxicity in commonly employed doses or normal exposures: |
| Cytotoxic drugs used in cancer chemotherapy: alkylating agents, antimetabolites, antimitotics, some antibiotics |

| Agents that frequently but not inevitably produce marrow aplasia: |
| Benzene |

| Agents associated with aplastic anemia but with a relatively low probability: |
| Chloramphenicol |
| Insecticides |
| Antiprotozoals: quinacrine and chloroquine, mepracine |
| Nonsteroidal anti-inflammatory drugs (including phenylbutazone, indomethacin, ibuprofen, sulindac, aspirin) |
| Anticonvulsants (hydantoins, carbamazepine, phenacemide, felbamate) |
| Heavy metals (gold, arsenic, bismuth, mercury) |
| Sulfonamides: some antibiotics, antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), antidiabetes drugs (tolbutamid, chlorpropamide), carbonic anhydrate inhibitors (acetazolamide and methazolamide) |
| Antihistamines (cimetidine, chlorpheniramine) |
| D-Penicillamine |
| Estrogens (in pregnancy and in high doses in animals) |

| Agents whose association with aplastic anemia is more tenuous: |
| Other antibiotics (streptomycin, tetracycline, mecthinil, mebendazole, trimethoprim/sulfamethoxazole, flucytosine) |
| Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chloridiazepoxide, meprobamate, methyprylon) |
| Allopurinol |
| Methyldopa |
| Quinidine |
| Lithium |
| Guanidine |
| Potassium perchlorate |
| Thiocyanate |
| Carbimazole |

**Note:** Terms set in italic show the most consistent association with aplastic anemia.
amphemical, the most infamous culprit, reportedly produced aplasia in only about 1/60,000 therapy courses, and even this number is almost certainly an overestimate (risks are almost invariably exaggerated when based on collections of cases; although the introduction of chlor-amphemical was perceived to have created an epidemic of aplastic anemia, its diminished use was not followed by a changed frequency of marrow failure). Risk estimates are usually lower when determined in population-based studies; furthermore, the low absolute risk is also made more obvious: even a 10- or 20-fold increase in risk translates, in a rare disease, to but a handful of drug-induced aplastic anemia cases among hundreds of thousands of exposed patients.

Infections  Hepatitis is the most common preceding infection, and posthepatitis marrow failure accounts for about 5% of etiologies in most series. Patients are usually young men who have recovered from a bout of liver inflammation 1 to 2 months earlier; the subsequent pancytopenia is very severe. The hepatitis is seronegative (non-A, non-B, non-C, non-G) and presumably due to a novel, as yet undiscovered, virus. Fulminant liver failure in childhood also follows seronegative hepatitis, and marrow failure occurs at a high rate in these patients. Marrow failure can rarely follow infectious mononucleosis, and Epstein-Barr virus has been found in the marrow of a few aplastic anemia patients, some without a suggestive preceding history. Parvovirus B19, the cause of transient aplastic crisis in hemolytic anemias and of some pure red cell aplasias (see below), does not usually cause generalized bone marrow failure. Blood count depression is frequent in the course of many viral and bacterial infections but is moderate and resolves with the infection.

Immunologic Diseases  Aplasia is a major consequence and the cause of death in transfusion-associated graft-versus-host disease, which can occur after infusion of unirradiated blood products to an immunodeficient recipient. Aplastic anemia is strongly associated with the rare collagen vascular syndrome called eosinophilic fasciitis, which is characterized by painful induration of subcutaneous tissues (Chap. 303). Pancytopenia with marrow hypoplasia can also occur in systemic lupus erythematosus.

Pregnancy  Aplastic anemia very rarely may occur and recur during pregnancy and resolve with delivery or with spontaneous or induced abortion.

Paroxysmal Nocturnal Hemoglobinuria  An acquired mutation in the PIG-A gene in a hematopoietic stem cell is required for the development of PNH, but PIG-A mutations probably occur commonly in normal individuals. If the PIG-A mutant stem cell proliferates, the result is a clone of progeny deficient in glycosylphosphatidylinositol-linked cell surface membrane proteins (Chap. 93). Such PNH clones are now most accurately enumerated using fluorescence-activated flow cytometry of CD55 or CD59 expression on granulocytes rather than Ham or sucrose lysis tests on red cells. Small clones of deficient cells can be detected in about half of patients with aplastic anemia at the time of presentation [and PNH cells are also seen in MDS (see below)]; frank hemolysis and thrombotic episodes occur in patients with PNH clones. Functional studies of bone marrow from PNH patients, even those with mainly hemolytic manifestations, show evidence of defective hematopoiesis. Patients with an initial clinical diagnosis of PNH, especially younger individuals, may later develop frank marrow aplasia and pancytopenia; patients with an initial diagnosis of aplastic anemia may suffer from hemolytic PNH years after recovery of blood counts. One explanation for the aplastic anemia/PNH syndrome is selection of the deficient clones, because they are favored for proliferation in the peculiar environment of immune-mediated marrow destruction.

Congenital Disorders  Fanconi’s anemia, an autosomal recessive disorder, manifests as congenital developmental anomalies, progressive pancytopenia, and an increased risk of malignancy. Chromosomes in Fanconi’s anemia are peculiarly susceptible to DNA cross-linking agents, the basis for a diagnostic assay. Patients with Fanconi’s anemia typically have short stature, café au lait spots, and anomalies involving the thumb, radius, and genitourinary tract. At least eight different genetic defects have been defined by complementation analysis. The most common, type A Fanconi’s anemia, is due to a mutation in FANCA. The Fanconi’s anemia genes play a role in the cellular response to DNA damage, a response that includes BRCA1, ATM, and NBS1.

Dyskeratosis congenita is characterized by mucous membrane leukoplakia, dystrophic nails, reticular hyperpigmentation, and the development of aplastic anemia during childhood. The common X-linked variety is due to mutations in the DKC1 (dyskerin) gene; the more unusual autosomal dominant type has been linked to hTERC, the RNA component of the telomerase complex. These two genes products cooperate in maintaining telomere length. In Shwachman-Diamond syndrome, marrow failure is seen with pancreatic insufficiency and malabsorption.

IMMUNOCOMPETENT INJURIES  Bone marrow failure results from severe damage to the hematopoietic cell compartment. In aplastic anemia, replacement of the bone marrow by fat is apparent in the morphology of the biopsy specimen (Fig. 94-1) and magnetic resonance imaging (MRI) of the spine; cells bearing the CD34 antigen, a marker of early hematopoietic cells, are greatly diminished; and in functional studies, committed and primitive progenitor cells are virtually absent—in vitro assays have suggested that the stem cell pool is reduced to ≤1% of normal in severe disease at the time of presentation. Qualitative abnormalities, such as limited number of operating stem cell clones or shortened telomere length, may follow from the quantitative deficiency, reflecting the shrunk and stressed state of hematopoiesis. An intrinsic stem cell defect exists for constitutional aplastic anemia, as cells from patients with Fanconi’s anemia exhibit chromosome damage and death on exposure to certain chemical agents. Aplastic anemia does not appear to result from defective stroma or growth factor production.

Drug Injuries  Extrinsic damage to the marrow follows massive physical or chemical insults such as high doses of radiation and toxic chemicals. For the more common idiosyncratic reaction to modest doses of medical drugs, altered drug metabolism has been invoked as a likely mechanism. The metabolic pathways of many drugs and chemicals, especially if they are polar and have limited water solubility, involve enzymatic degradation to highly reactive electrophilic compounds; these intermediates are toxic because of their propensity to bind to cellular macromolecules. For example, derivative hydroquinones and quinolones are responsible for benzene-induced tissue injury. Excessive generation of toxic intermediates or failure to detoxify the intermediates may be genetically determined and apparent only on specific drug challenge; the complexity and specificity of the pathways imply multiple susceptibility loci and would provide an explanation for the rarity of idiosyncratic drug reactions.

IMMUNE-RELATED INJURY  The recovery of marrow function in some patients prepared for bone marrow transplantation with antilymphocyte globulin (ALG) first suggested that aplastic anemia might be immune-mediated. Consistent with this hypothesis was the frequent failure of simple bone marrow transplantation from a syngeneic twin, without conditioning cytotoxic chemotherapy, which also argued both against simple stem cell absence as the cause and for the presence of a host factor producing marrow failure. Laboratory data support an important role for the immune system in aplastic anemia. Blood and bone marrow cells of patients can suppress normal hematopoietic progenitor cell growth, and removal of T cells from aplastic anemia bone marrow improves colony formation in vitro. Increased numbers of activated cytotoxic T cells are observed in aplastic anemia patients and usually decline with successful immunosuppressive therapy; cytokine measurements show a Th1 immune response (interferon γ, interleukin 2, and tumor necrosis factor). Interferon and tumor necrosis factor induce Fas expression on CD34 cells, leading to apoptotic cell death; localization of activated T cells to bone marrow and local production of their soluble factors are probably important in stem cell destruction.

Early immune system events in aplastic anemia are not well un-
understood. Analysis of T cell receptor expression suggests an oligo-
clonal, antigen-driven cytotoxic T cell response. Many different exogenous antigens appear capable of initiating a pathologic immune response, but at least some of the T cells may recognize true self-
antigens. The rarity of aplastic anemia despite common exposures (medicines, hepatitis virus) suggests that genetically determined fea-
tures of the immune response can convert a normal physiologic re-
sponse into a sustained abnormal autoimmune process.

**CLINICAL FEATURES**

**History**  Aplastic anemia can appear with seeming abruptness or have a more insidious onset. Bleeding is the most com-
mon early symptom; a complaint of days to weeks of easy bruising, oozing from the gums, nose bleeds, heavy menstrual flow, and some-
times petechiae will have been noticed. With thrombocytopenia, mas-

tive hemorrhage is unusual, but small amounts of bleeding in the cen-
tral nervous system can result in catastrophic intracranial or retinal hemorrhage. Symptoms of anemia are also frequent, including lassi-
tude, weakness, shortness of breath, and a pounding sensation in the ears. Infection is an unusual first symptom in aplastic anemia (unlike in agranulocytosis, where pharyngitis, anorectal infection, or frank sepsis occur early). A striking feature of aplastic anemia is the restric-
tion of symptoms to the hematologic system, and patients often feel and look remarkably well despite drastically reduced blood counts. Systemic complaints and weight loss should point to other etiologies of pancytopenia. Prior drug use, chemical exposure, and preceding viral illnesses must often be elicited with repeated questioning. A fam-
ily history of hematologic diseases or blood abnormalities may indi-
cate a constitutional etiology of marrow failure.

**LABORATORY STUDIES**

**Blood**  The smear shows large erythrocytes and a paucity of platelets and granulocytes. Mean corpuscular volume (MCV) is commonly increased. Reticulocytes are absent or few, and lymphocyte numbers may be normal or reduced. The presence of im-
mature myeloid forms suggests leukemia or MDS; nucleated red blood cells suggest marrow fibrosis or tumor invasion; abnormal platelets suggest either peripheral destruction or MDS.

**Bone Marrow**  The bone marrow is usually readily aspirated but appears dilute on smear, and the fatty biopsy specimen may be grossly pale on withdrawal; a “dry tap” suggests fibrosis or myelophthisis. In severe aplasia the smear of the aspirated specimen shows only red cells, res-
idual lymphocytes, and stromal cells; the biopsy, which should be >1 cm in length, is superior for determination of cellularity and shows mainly fat under the microscope, with hematopoietic cells occupying <25% of the marrow space. In the most serious cases the biopsy is virtually 100% fat. The correlation between marrow cellularity and disease severity is imperfect. Some patients with moderate disease by blood counts will have empty iliac crest biopsies, while “hot spots” of hematopoiesis may be seen in severe cases. If an iliac crest specimen is inadequate, cells may also be obtained by aspiration from the sternum. Residual hematopoietic cells should have normal morphology, except for mildly megaloblastic erythropoiesis; megakaryocytes are invariably greatly reduced and usually absent. Areas adjacent to the spicule should be searched for myeloblasts. Gran-
ulomas (in cellular specimens) may indicate an infec-
tious etiology of the marrow failure.

**Ancillary Studies**  Chromosome breakage studies of pe-
ripheral blood using diepoxybutane (DEB) or mito-

---

**FIGURE 94-1**  A. Normal bone marrow biopsy. B. Normal bone marrow aspirate smear. The marrow is normally 30 to 70% cellular, and there is a heterogeneous mix of myeloid, erythroid, and lymphoid cells. C. Aplastic anemia biopsy. D. Marrow smear in aplastic anemia. The marrow shows replacement of hematopoietic tissue by fat and only residual stromal and lymphoid cells.
myelitis C should be performed on children and younger adults to exclude Fanconi’s anemia. Chromosome studies of bone marrow cells are often revealing in MDS and should be negative in typical aplastic anemia. Flow cytometric assays have replaced the Ham test for the diagnosis of PNH. Serologic studies may show evidence of viral infection, especially Epstein-Barr virus and HIV. Posthepatitis aplastic anemia is typically seronegative. The spleen size should be determined by scanning if the physical examination of the abdomen is unsatisfactory. MRI may be helpful to assess the fat content on a few vertebral in order to distinguish aplasia from MDS.

**DIAgnosis** The diagnosis of aplastic anemia is usually straightforward, based on the combination of pancytopenia with a fatty, empty bone marrow. Aplastic anemia is a disease of the young and should be a leading diagnosis in the pancytopenic adolescent or young adult. When pancytopenia is secondary, the primary diagnosis is usually obvious from either history or physical examination: the massive spleen of alcoholic cirrhosis, the history of metastatic cancer or systemic lupus erythematosus, or obvious miliary tuberculosis on chest radiograph (Table 94-1).

Diagnostic problems can occur with atypical presentations and among related hematologic diseases. While pancytopenia is most common, some patients with bone marrow hypocellularity have depression of only one or two of three blood lines, sometimes showing later progression to more recognizable aplastic anemia. The bone marrow in constitutional aplastic anemia is indistinguishable morphologically from the aspirate in acquired disease. The diagnosis can be suggested by family history, abnormal blood counts since childhood, or the presence of associated physical anomalies. Aplastic anemia may be difficult to distinguish from the hypocellular variety of MDS: MDS is favored by finding morphologic abnormalities, particularly of megakaryocytes and myeloid precursor cells, and typical cytogenetic abnormalities (see below).

**Prognosis** The natural history of severe aplastic anemia is rapid deterioration and death. Provision first of red blood cell and later platelet transfusions and effective antibiotics were of some benefit, but few patients showed spontaneous recovery. The major prognostic determinant is the blood count; severe disease is defined by the presence of two of three parameters: absolute neutrophil count <500/μL, platelet count <20,000/μL, and corrected reticulocyte count <1% (or absolute reticulocyte count <60,000/μL). Survival of patients who fulfill these criteria is about 20% at 1 year after diagnosis with only supportive care; patients with very severe disease, defined by an absolute neutrophil count <200/μL, fare even more poorly. Treatment has markedly improved survival in this disease.

**Treatment**

Severe acquired aplastic anemia can be cured by replacement of the absent hematopoietic cells (and the immune system) by stem cell transplant, or it can be ameliorated by suppression of the immune system to allow recovery of the patient’s residual bone marrow function. Hematopoietic growth factors have limited usefulness and glucocorticoids are of no value. Suspect exposures to drugs or chemicals should be discontinued; however, spontaneous recovery of severe blood count depression is rare, and a waiting period before beginning treatment may not be advisable unless the blood counts are only modestly depressed.

**Bone Marrow Transplantation** This is the best therapy for the young patient with a fully histocompatible sibling donor (Chap. 100). Human leukocyte antigen (HLA) typing should be ordered as soon as the diagnosis of aplastic anemia is established in a child or younger adult. In transplant candidates, transfusion of blood from family members should be avoided so as to prevent sensitization to histocompatibility antigens; while transfusions in general should be minimized, limited numbers of blood products probably do not seriously affect outcome. For allogeneic transplant from fully matched siblings, long-term survival rates for children are 80% or better. Transplant morbidity and mortality are increased among adults, due mainly to the higher risk of chronic graft-versus-host disease and serious infections. Graft rejection was historically a major determinant of outcome in bone marrow transplant for aplastic anemia; high rates of primary or secondary graft failure may be related to the pathophysiology of marrow failure as well as to alloimmunization from transfusions.

Most patients do not have a suitable sibling donor. Occasionally, a full phenotypic match can be found within the family and serve as well. Far more available are other alternative donors, either unrelated but histocompatible volunteers, or closely but not perfectly matched family members. Survival using alternative donors is about half that of conventional sibling transplants. These patients will be at risk for late complications, especially a higher rate of cancer, if radiation is used as a component of conditioning. Most older adults who undergo alternative donor transplants succumb to transplant-related complications.

**Immunosuppression** Used alone, ALG or antithymocyte globulin (ATG) induces hematologic recovery (independence from transfusion and a leukocyte count adequate to prevent infection) in about 50% of patients. The addition of cyclosporine to either ALG or ATG has further increased response rates to about 70% and especially improved outcomes for children and for severely neutropenic patients. Combined treatment is now standard for patients with severe disease. Hematologic response strongly correlates with survival. Improvement in granulocyte number is generally apparent within 2 months of treatment. Most recovered patients continue to have some degree of blood count depression, the MCV remains elevated, and the bone marrow cellularity returns toward normal only very slowly, if at all. Relapse (recurrent pancytopenia) is frequent, often occurring as cyclosporine is discontinued; most, but not all, patients respond to reinstitution of immunosuppression, but some responders become dependent on continued cyclosporine administration. Development of MDS, with typical marrow morphologic or cytogenetic abnormalities, occurs in about 15% of treated patients, usually but not invariably associated with a return of pancytopenia, and some patients develop leukemia. Although the laboratory diagnosis of PNH can generally be made at the time of presentation of aplastic anemia by flow cytometry, recovered patients showing frank hemolysis should be retested for PNH. Bone marrow examinations should be performed if there is an unfavorable change in blood counts.

Horse ATG is given at 40 mg/kg per day for 4 days; rabbit ALG is administered at 3.5 mg/kg per day for 5 days. For ATG, anaphylaxis is a rare but occasionally fatal complication; allergy should be tested by a skin-prick test with an undiluted solution and immediate observation; desensitization is feasible. ATG binds to peripheral blood cells; therefore, platelet and granulocyte numbers may fall further during active treatment. Serum sickness, a flulike illness with a characteristic cutaneous eruption and arthralgia, often develops about 10 days after initiating treatment. Most patients are given methylprednisolone, 1 mg/kg per day for 2 weeks, to ameliorate the immune consequences of heterologous protein infusion. Excessive or extended glucocorticoid therapy is associated with avascular joint necrosis. Cyclosporine is administered orally at an initial dose of 12 mg/kg per day in adults (15 mg/kg per day in children), with subsequent adjustment according to blood levels obtained every 2 weeks. Trough levels should be between 150 and 200 ng/mL. The most important side effects of chronic cyclosporine treatment are nephrotoxicity, hypertension, seizures, and opportunistic infections, especially Pneumocystis carinii (prophylactic treatment with monthly inhaled pentamidine is recommended).

Most patients with aplastic anemia lack a suitable marrow donor and immunosuppression is the treatment of choice. Long-term survival is equivalent with transplantation and immunosuppression. However, successful transplantation will resolve marrow failure, while patients who recover adequate blood counts after immunosuppression remain at risk of relapse and malignant evolution. Because of the excellent results in chil-
In order to maintain the platelet count, regimen of prophylaxis requires transfusions once or twice weekly in used prophylactically or only as needed remains unclear. Any rational cellular stability is unproven. Whether platelet transfusions are better fibrinolysis such as aminocaproic acid have not been shown to relieve and diminish leukocytes in the product; HLA-matched platelets are often single donors to reduce exposure and physical or chemical methods and can be avoided or minimized by several strategies, including use and presumably also from other vascular beds, increases precipitously

Outcomes following both transplant and immunosuppression have improved with time. High doses of cyclophosphamide, without stem cell rescue, have been reported to produce durable hematologic recovery, without relapse or evolution to MDS, but this treatment can produce sustained severe fatal neutropenia and response is often delayed. Several new immunosuppressive drugs in clinical trial may further improve outcome.

Other Therapies The effectiveness of androgens has not been verified in controlled trials, but occasional patients will respond or even demonstrate blood count dependence on continued therapy. For patients with moderate disease or those with severe pancytopenia in whom immunosuppression has failed, a 3- to 4-month trial is appropriate. Hematopoietic growth factors, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage CSF (GM-CSF), and interleukin 3 are not recommended as initial therapy for severe aplastic anemia, and even their role as adjuncts to immunosuppression is not well defined. Some patients may respond to combinations of growth factors after immunosuppression has failed. Some manifestations of anemia are common, especially after several courses of antibacterial antibiotics, usually ceftazidime or a combination of an aminoglycoside, cephalosporin, and semisynthetic penicillin. Therapy is empirical and must not await results of culture, although specific foci of infection such as oropharyngeal or anorectal abscesses, pneumonia, sinusitis, and typhilitis (necrotizing colitis) should be sought on physical examination and with radiographic studies. When indwelling plastic catheters become contaminated, vancomycin should be added. Persistent or recrudescent fever implies fungal disease: Candida or Aspergillus are common, especially after several courses of antibacterial antibiotics, and a progressive course may be averted by timely initiation of antifungal therapy. Granulocyte transplants using G-CSF-mobilized peripheral blood have been effective in the treatment of overwhelming or refractory infections in a few patients. Hand washing, the single best method of preventing the spread of infection, remains a neglected practice. Nonabsorbed antibiotics for gut decontamination are poorly tolerated and not of proven value. Total reverse isolation does not reduce mortality from infections.

Both platelet and erythrocyte numbers can be maintained by transfusion. Alloimmunization limits the usefulness of platelet transfusions and can be avoided or minimized by several strategies, including use of single donors to reduce exposure and physical or chemical methods to diminish leukocytes in the product; HLA-matched platelets are often effective in patients refractory to random donor products. Inhibitors of fibrinolysis such as aminocaproic acid have not been shown to relieve mucosal oozing; the use of low-dose glucocorticoids to induce “vascular stability” is unproven. Whether platelet transfusions are better used prophylactically or only as needed remains unclear. Any rational regimen of prophylaxis requires transfusions once or twice weekly in order to maintain the platelet count >10,000/μL (oozing from the gut, and presumably also from other vascular beds, increases precipitously at counts <5000/μL). Menstruation should be suppressed either by oral estrogens or nasal follicle-stimulating hormone/luteinizing hormone (FSH/LH) antagonists. Aspirin and other nonsteroidal anti-inflammatory agents inhibit platelet function and must be avoided.

Red blood cells should be transfused to maintain a normal level of activity, usually at a hemoglobin value of 70 g/L (90 g/L if there is underlying cardiac or pulmonary disease); a regimen of 2 units every 2 weeks will replace normal losses in a patient without a functioning bone marrow. In chronic anemia, the iron chelator deferoxamine should be added at around the fiftieth transfusion in order to avoid secondary hemochromatosis.

**PURE RED CELL APLASIA** Other, more restricted forms of marrow failure occur, in which only a single circulating cell type is affected and the regenerative marrow shows corresponding or decreased numbers of specific precursor cells: regenerative anemia as in PRCA (see below), thrombocytopenia with amegakaryocytosis (Chap. 101), and neutropenia without marrow myeloid cells in agranulocytosis (Chap. 55). In general, and in contrast to aplastic anemia and MDS, the unaffected lineages appear quantitatively and qualitatively normal. Agranulocytosis, the most frequent of these syndromes, is usually a complication of medical drug use (with agents similar to those related to aplastic anemia), either by a mechanism of direct chemical toxicity or by immune destruction. Agranulocytosis has an incidence similar to aplastic anemia but is especially frequent among the elderly and in women. The syndrome should resolve with discontinuation of exposure, but significant mortality is attached to neutropenia in the older and often previously unwell patient. Both pure white cell aplasia (agranulocytosis without incriminating drug exposure) and amegakaryocytic thrombocytopenia are exceedingly rare and, like PRCA, appear to be due to destructive antibodies or lymphocytes and can respond to immunosuppressive therapies. In all the single lineage failure syndromes, progression to pancytopenia or leukemia is unusual.

**DEFINITION AND DIFFERENTIAL DIAGNOSIS** PRCA is characterized by anemia, reticulocytopenia, and absent or rare erythroid precursor cells in the bone marrow. The classification of PRCA is shown in Table 94-4. In adults, PRCA is acquired. An identical syndrome can occur constitutionally: Diamond-Blackfan anemia, or congenital PRCA, is diagnosed at birth or in early childhood and often responds to glucocorticoid treatment. Temporary red cell failure occurs in transient aplastic crisis of hemolytic anemias, due to acute parvovirus infection.

(Chap. 168), and in transient erythroblastopenia of childhood, which affects normal children.

**CLINICAL ASSOCIATIONS AND ETIOLOGY** PRCA has important associations with immune system diseases. A small minority of cases occur with a thymoma. More frequently, red cell aplasia can be the major manifestation of large granular lymphocytosis or may occur in chronic lymphocytic leukemia. Some patients may be hypogammaglobulinemic. As with agranulocytosis, PRCA can be due to an idiosyncratic reaction to a drug.

Like aplastic anemia, PRCA results from diverse mechanisms. Antibodies to red blood cell precursors are frequently present in the blood, but T cell inhibition is probably the more common immune mechanism. Cytotoxic lymphocyte activity restricted by histocompatibility locus or specific for human T cell leukemia/lymphoma virus 1–infected cells, as well as natural killer cell activity inhibitory of erythropoiesis, have been demonstrated in particularly well-studied individual cases.

**Persistent Parvovirus B19 Infection** Chronic parvovirus infection is an important, treatable cause of PRCA. This common virus causes a benign exanthem of childhood (fifth disease) and a polyarthralgia syndrome in adults. In patients with underlying hemolysis (or any condition that increases demand for red blood cell production), parvovirus infection can cause a transient aplastic crisis and an abrupt but temporary worsening of the anemia due to failed erythropoiesis. In normal individuals, acute infection is resolved by production of neutralizing antibodies to the virus, but in the setting of congenital, acquired, or iatrogenic immunodeficiency, persistent viral infection may occur. The bone marrow shows red cell aplasia and the presence of giant pronormoblasts (Fig. 94-2), which is the cytopathic sign of B19 parvovirus infection. Viral tropism for human erythroid progenitor cells is due to its use of erythrocyte P antigen as a cellular receptor for entry. Direct cytoxicity of virus causes anemia if demands on

erythrocyte production are high; in normal individuals, the temporary cessation of red cell production is not clinically apparent, and skin and joint symptoms are mediated by immune complex deposition.

**TREATMENT**

History, physical examination, and routine laboratory studies may disclose an underlying disease or a suspect drug exposure. Thymoma should be sought by radiographic procedures. Tumor excision is indicated, but anemia does not necessarily improve with surgery. The diagnosis of parvovirus infection requires detection of viral DNA sequences in the blood (IgG and IgM antibodies are commonly absent). The presence of erythroid colonies has been considered predictive of response to immunosuppressive therapy in idiopathic PRCA.

Red cell aplasia is compatible with long survival with supportive care alone: a combination of erythrocyte transfusions and iron chelation. For persistent B19 parvovirus infection, almost all patients respond to intravenous immunoglobulin therapy (for example, 0.4 g/kg daily for 5 days), although relapse and retreatment may be expected, especially in patients with AIDS. The majority of patients with idiopathic PRCA respond favorably to immunosuppression. Most first receive a course of glucocorticoids, followed in the absence of a response by cyclosporine, ATG, azathioprine, or cyclophosphamide.

**MYELODYSPLASIA**

**DEFINITION** The myelodysplasias (MDS) are a heterogeneous group of hematologic disorders broadly characterized by cytopenias associated with a dysmorphic (or abnormal appearing) and usually cellular bone marrow, and consequent ineffective blood cell production. A clinically useful nosology of these entities was first developed by the French-American-British Cooperative Group in 1983. Five entities were defined: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). The World Health Organization classification (2002) recognizes that the distinction between RAEB-t and acute myeloid leukemia is arbitrary and groups them together as acute leukemia, notes that CMML behaves as a myeloproliferative disease, and separates refractory anemias with dysmorphic change restricted to erythroid lineage from those with multilineage changes (Table 94-5).

**EPIDEMIOLOGY** Idiopathic MDS is a disease of the elderly; the mean age at onset is 68 years. There is a slight male preponderance. MDS is a relatively common form of bone marrow failure, with reported incidence rates of 35 to >100 per million persons in the general population and 120 to >500 per million in the elderly. MDS is rare in children, but monocyctic leukemia can be seen. Therapy-related MDS is not age-related and may occur in as many as 15% of patients within a decade following intensive combined modality treatment for cancer. Rates of MDS have increased over time, due to the recognition of the syndrome by physicians and the aging of the population.

**ETIOLOGY AND PATHOPHYSIOLOGY** MDS is caused by environmental exposures such as radiation and benzene; other risk factors have been reported inconsistently. Secondary MDS occurs as a late toxicity of cancer treatment, usually with a combination of radiation and the radiomimetic alkylating agents such as busulfan, nitrosourea, or procarbazine (with a latent period of 5 to 7 years) or the DNA topoisomerase inhibitors (2 years). Both acquired aplastic anemia following immunosuppressive treatment and Fanconi’s anemia can evolve into MDS.

MDS is a clonal hematopoietic stem cell disorder leading to impaired cell proliferation and differentiation. Cytogenetic abnormalities are found in about half of patients, and some of the same specific lesions are also seen in frank leukemia; aneuploidy is more frequent

Laboratory studies

Anemia is present in the majority of cases, either alone or as part of bi- or pan cytopenia; isolated neutropenia or thrombocytopenia is more unusual. Macrocytosis is common, and the smear may be dimorphic with a distinctive population of large red blood cells. Platelets are also large and lack granules. In functional studies, they may show marked abnormalities, and patients may have bleeding symptoms despite seemingly adequate numbers. Neutrophils are hypogranulated; have hyposegmented, ringed, or abnormally segmented nuclei; contain Dohle bodies; and may be functionally deficient. Circulating myeloblasts usually correlate with marrow blast numbers, and their quantitation is important for classification and prognosis. The total white blood cell count is usually normal or low, except in chronic myelomonocytic leukemia. As in aplastic anemia, MDS also can be associated with a clonal population of PHN cells.

Bone marrow

The bone marrow is usually normal or hypercellular but in 20% of cases is sufficiently hypocellular to be confused with aplasia. No single characteristic feature of marrow morphology distinguishes MDS, but the following are commonly observed: dyserythropoietic changes (especially nuclear abnormalities) and ringed sideroblasts in the erythroid lineage; hypogranulation and hyposegmentation in granulocytic precursors, with an increase in myeloblasts; and megakaryocytes showing reduced numbers of disorganized nuclei. Megaloblastic nuclei associated with defective hemoglobinization in the erythroid lineage are common. Prognosis strongly correlates with the proportion of marrow blasts. Cytogenetic analysis and fluorescent in situ hybridization can identify genetic lesions.

Differential diagnosis

Deficiencies of vitamin B₁₂ or folate should be excluded by appropriate blood tests; vitamin B₁₂ deficiency can be assessed by a therapeutic trial of pyridoxine if the bone marrow shows ringed sideroblasts. Marrow dysplasia can be observed in acute viral infections, drug reactions, or chemical toxicity but should be transient. More difficult are the distinctions between hypocellular MDS and aplasia or between refractory anemia with excess blasts and early acute leukemia. The World Health Organization considers the presence of 20% blasts in the marrow as the criterion that separates acute myeloid leukemia from MDS.

Prognosis

The median survival varies greatly from years for patients with 5q– or sideroblastic anemia to a few months in refractory anemia with excess blasts or severe pancytopenia associated with monosomy 7; an International Prognostic Scoring System (Table 94-6) assists in making predictions. Most patients die as a result of complications of pancytopenia and not due to leukemic transformation; perhaps one-third will succumb to other diseases unrelated to their MDS. Precipitous worsening of pancytopenia, acquisition of new chromosomal abnormalities on serial cytogenetic determination, and increase in the number of blasts are all poor prognostic indicators. The outlook in therapy-related MDS, regardless of type, is poor, and most patients will progress within a few months to refractory acute myeloid leukemia.

Treatment

The therapy of MDS is generally unsatisfactory. Only stem cell transplantation offers cure; survival rates of 50% at 3 years have been reported, but older patients are particularly prone to develop treatment-related mortality and morbidity. Results of transplant using matched unrelated donors are comparable, although most series contain younger and more highly selected cases. MDS associated with trisomy 8 may respond to cyclosporine.

MDS has been regarded as particularly refractory to cytotoxic chemotherapy regimens but is probably no more resistant to effective treatment than acute myeloid leukemia in the elderly, in whom drug toxicity is often fatal and remissions, if achieved, are brief. Low doses of cytotoxic drugs have been administered for their “differentiating” potential. 5-azacytidine inhibits DNA methylation and may induce the expression of genes; its use in MDS can improve blood counts and modestly improves survival compared to best supportive care. Amifostine, an organic thio phosphate that blocks apoptosis, can improve blood counts but has significant toxicities. Both azacytidine and amifostine are approved by the U.S. Food and Drug Administration for use in MDS. ATG may improve blood counts in one-third of MDS patients; those who are young, HLA-D2 positive, and have a PNH clone are more likely to respond.

Hematopoietic growth factors can improve blood counts but, as in most other marrow failure states, have been most beneficial to patients with the least severe pancytopenia. G-CSF treatment alone failed to improve survival in a controlled trial. Erythropoietin alone or in combination with G-CSF can improve hemoglobin levels, especially in those with low serum erythropoietin levels who have no or only a modest need for transfusions.

The same principles of supportive care described for aplastic anemia apply to MDS. Because many patients will be anemic for years,

**Cytopathies defined as Hb <100 g/L, platelet count <100,000/μL, absolute neutrophil count <1500/μL.**
Polycythemia vera, chronic idiopathic myelofibrosis, essential thrombocytosis, and chronic myeloid leukemia (CML) are commonly classified together under the rubric the chronic myeloproliferative disorders, because their pathophysiology involves the clonal expansion of a multipotent hematopoietic progenitor cell with the overproduction of one or more of the formed elements of the blood. These entities may transform into acute leukemia naturally or as a consequence of mutagenic treatment. However, while polycythemia vera, idiopathic myelofibrosis, essential thrombocytosis, and CML share similar phenotypic characteristics, CML is genotypically distinct from the other three disorders because it alone is associated with translocation of genetic material between the long arms of chromosomes 9 and 22, resulting in the production of the unique fusion protein, bcr-abl. The new World Health Organization classification of myeloid neoplasms has expanded the list of chronic myeloproliferative disorders to include the exceedingly rare entities chronic neutrophilic leukemia, chronic eosinophilic leukemia, and the hypereosinophilic syndrome. In addition, a category of myelodysplastic/myeloproliferative diseases was created to encompass juvenile myelomonocytic leukemia, atypical chronic myeloid leukemia [lacking t(9;22)], and chronic myelomonocytic leukemia. The word “chronic” was also added to idiopathic myelofibrosis to distinguish this disorder from the rarer syndrome of acute panmyelosis with myelofibrosis, a rare form of acute leukemia. These classification changes were made in recognition of the considerable overlap in clinical presentation and hematopathology that characterizes the chronic myeloproliferative disorders. Systemic mastocytosis, while having phenotypic overlap with the chronic myeloproliferative diseases, was given its own category in recognition of the many distinct clinical syndromes that characterize mast cell proliferation. In this chapter, only polycythemia vera, chronic idiopathic myelofibrosis, and essential thrombocytosis will be discussed as their clinical overlap is substantial and their clinical course distinct from the other myeloproliferative disorders. CML is discussed in Chap. 96.
and secondary erythrocytosis. Polycythemia vera erythroid progenitor cells are more resistant to apoptosis induced by erythropoietin deprivation, due to upregulation of bcl-XL, an antiapoptotic protein. Polycythemia vera erythroid progenitors do not divide more rapidly than their normal counterparts, but they accumulate because they do not die normally. Additionally, the transformed hematopoietic progenitor cells in polycythemia vera, as in other neoplastic disorders, exhibit clonal dominance and suppress the proliferation of normal hematopoietic progenitor cells by an unknown mechanism. Consequently, the circulating formed elements of the blood represent only progeny of the transformed clone.

**CLINICAL FEATURES** Although massive splenomegaly may be the initial presenting sign in polycythemia vera, most often the disorder is first recognized by the discovery of a high hemoglobin or hematocrit, but with the exception of aquagenic pruritus, no symptoms distinguish polycythemia vera from other causes of erythrocytosis.

Uncontrolled erythrocytosis can lead to neurologic symptoms such as vertigo, tinnitus, headache, and visual disturbances. Systolic hypertension also accompanies the elevated red cell mass. In some patients, venous or arterial thrombosis may be the presenting manifestation of polycythemia vera. Intraabdominal venous thrombosis is particularly common and may be catastrophic when there is sudden compromise of the hepatic vein. Polycythemia vera should be suspected in any patient who develops the Budd-Chiari syndrome. Digital ischemia may also occur. Easy bruising, epistaxis, or gastrointestinal hemorrhage may be observed, and polycythemia vera patients are frequently hypermetabolic. Hyperuricemia with secondary gout, uric acid stones, and acip-epidemic disease also complicate the disorder. Because isolated erythrocytosis is a common initial presentation for polycythemia vera but no clonal marker is available for the disease, the first task of the physician is to distinguish this autonomous clonal form of erythrocytosis from the many other types of erythrocytosis, most of which are correctable (Table 95-1).

Erythropoiesis is normally regulated by the glycoprotein hormone erythropoietin. Erythropoietin, which in adults is produced primarily in the kidneys and to a small extent in the liver, promotes the proliferation of erythroid progenitor cells, maintains their survival, and facilitates their differentiation. Because erythropoietin acts as a survival factor, it is constitutively produced and, like the red cell mass, its level is constant as long as tissue oxygenation is adequate. The plasma erythropoietin level, like the red cell mass, differs among individuals but in adults is not affected by either age or gender. Erythropoietin production is regulated at the level of gene transcription. Hypoxia is the only physiologic stimulus that increases the number of cells producing erythropoietin, and thus the production of erythropoietin is independent of its plasma level. In the absence of renal or hepatic disease, plasma erythropoietin levels reflect erythropoietin production, and therefore the assay for plasma erythropoietin is a surrogate assay for tissue hypoxia. Erythropoietin is active at the picomolar level, and its production is tightly regulated. Thus, the plasma erythropoietin level does not rise outside the normal range until the hemoglobin level falls below 105 g/L. This is not meant to imply that an increase in erythropoietin production does not occur as the hemoglobin level falls below normal, but because the normal range for plasma erythropoietin is wide (4 to 26 mU/mL), unless the patient’s baseline level is known, any increase will not be recognized until the hemoglobin falls below 105 g/L. Thereafter, there is a log-linear inverse correlation between the plasma erythropoietin and hemoglobin levels. With erythrocytosis, erythropoietin production is suppressed; this suppression reflects not only the increase in tissue oxygen transport associated with the increase in red cell number but also additional negative-feedback mechanisms unrelated to oxygen transport but related to the increase in blood viscosity and an increase in red cell precursors capable of metabolizing erythropoietin. The summation of these mechanisms accounts for the paradoxical observation that many patients with hypoxic erythrocytosis due to cyanotic congenital heart disease or obstructive lung disease have a “normal” plasma erythropoietin level. The plasma erythropoietin level is a useful diagnostic test in patients with isolated erythrocytosis, because an elevated level excludes polycythemia vera as the cause for the erythrocytosis.

**DIAGNOSIS** When confronted with an elevated hemoglobin or hematocrit level, it is important to obtain previous values to determine the duration of this abnormality. Because the hemoglobin or hematocrit level is affected by the plasma volume, and hematocrit and red cell mass are not linearly related, a red cell mass determination must also be performed to distinguish absolute erythrocytosis from relative erythrocytosis due to a reduction in plasma volume alone (also known as stress or spurious erythrocytosis or Geisbo¨ck’s syndrome). Red cell mass determination is important because in polycythemia vera, in contrast to erythropoietin-driven erythrocytosis, the plasma volume is frequently elevated, masking not only the true extent of red cell mass expansion but often its presence. Indeed, a significant proportion of patients with polycythemia vera have a hematocrit within the normal range, particularly patients with a substantial splenomegaly. Failure to recognize this phenomenon is undoubtedly the basis for many of the reported instances of hepatic or portal vein thrombosis in patients with an “undefined” myeloproliferative disorder.

Red cell mass is reliably determined by isotope dilution using the patient’s 51Cr-tagged red cells; extrapolations made after determining only the plasma volume are unacceptable. Furthermore, to allow ample time for equilibration of the labeled red cells, measurements should be made over a period of $\geq 90$ min.

Once the presence of absolute erythrocytosis has been established, its cause must be determined. An elevated plasma erythropoietin level suggests either an hypoxic cause for erythrocytosis or autonomous erythropoietin production, in which case assessment of pulmonary function and an abdominal computed tomography scan to evaluate renal and hepatic anatomy are appropriate. A normal erythropoietin level does not exclude an hypoxic cause for erythrocytosis. In polycythemia vera, in contrast to hypoxic erythrocytosis, the arterial oxygen saturation is normal. However, a normal oxygen saturation does not exclude a high-affinity hemoglobin as a cause for erythrocytosis, and it is here that documentation of previous hemoglobin levels and a family study become important. Because there is no clonal marker for polycythemia vera, clinical guidelines have been proposed to define the disease. A modified version is provided in Table 95-2. However, these guidelines do not establish clonality, and in some patients the underlying disorder only becomes apparent over time. Diagnostic ambiguity does not preclude the initiation of therapy.

Other laboratory studies that may aid in diagnosis include the red cell count, mean corpuscular volume, and red cell distribution width (RDW). Only three situations cause microcytic erythrocytosis: $\beta$-thalassemia trait, hypoxic erythrocytosis, and polycythemia vera. However, with $\beta$-thalassemia trait the RDW is normal, whereas with hy-

*It must be emphasized that these criteria do not establish clonality.

The etiology of chronic idiopathic myelofibrosis (other designations include agnogenic myeloid metaplasia or myelofibrosis with myeloid metaplasia) is a clonal disorder of a multipotent hematopoietic progenitor cell of unknown etiology characterized by marrow fibrosis, myeloid metaplasia with extramedullary hematopoiesis, and splenomegaly. Chronic idiopathic myelofibrosis is uncommon; in the absence of a specific clonal marker, establishing this diagnosis is difficult because myelofibrosis and myeloid metaplasia with splenomegaly are also features of both polycythemia vera and CML. Furthermore, myelofibrosis and myeloid metaplasia with splenomegaly are also features of both chronic idiopathic myelofibrosis and myeloid metaplasia.

Erythromelalgia is a curious syndrome of unknown etiology primarily involving the lower extremities and manifested usually by erythema, warmth, and pain of the affected appendage and occasionally digital infarction. It occurs with a variable frequency in patients with a myeloproliferative disorder and is usually responsive to salicylates. Some of the central nervous system symptoms observed in patients with polycythemia vera may represent a variant of erythromelalgia.

If left uncontrolled, erythrocytosis can lead to intravascular thrombosis involving vital organs such as the liver, heart, brain, or lungs. Patients with massive splenomegaly are particularly prone to thrombotic events because the associated increase in plasma volume masks the true extent of the red cell mass elevation as measured by the hematocrit or hemoglobin level. A “normal” hematocrit or hemoglobin level in a polycythemia vera patient with massive splenomegaly should be considered as indicative of an elevated red cell mass until proven otherwise.

**CHRONIC IDIOPATHIC MYELOFIBROSIS**

Chronic idiopathic myelofibrosis (other designations include agnogenic myeloid metaplasia or myelofibrosis with myeloid metaplasia) is a clonal disorder of a multipotent hematopoietic progenitor cell of unknown etiology characterized by marrow fibrosis, myeloid metaplasia with extramedullary hematopoiesis, and splenomegaly. Chronic idiopathic myelofibrosis is uncommon; in the absence of a specific clonal marker, establishing this diagnosis is difficult because myelofibrosis and myeloid metaplasia with splenomegaly are also features of both polycythemia vera and CML. Furthermore, myelofibrosis and splenomegaly occur in a variety of benign and malignant disorders (Table 95-3), many of which are amenable to specific therapies not effective in chronic idiopathic myelofibrosis. In contrast to the other chronic myeloproliferative disorders and so-called acute or malignant myelofibrosis, which can occur at any age, chronic idiopathic myelofibrosis primarily affects individuals in their sixth decade or later.

**ETIOLOGY**

The etiology of chronic idiopathic myelofibrosis is unknown. Although nonrandom chromosome abnormalities such as 20q−, 13q−, and trisomy 1q are not uncommon, no specific cytoge-
nomic abnormality has been identified. The degree of myelofibrosis and the extent of extramedullary hematopoiesis are not related. Fibrosis in this disorder is associated with overproduction of transforming growth factor β and thrombopoietin. Importantly, fibroblasts in chronic idiopathic myelofibrosis are not part of the neoplastic clone.

**CLINICAL FEATURES** No specific signs or symptoms are associated with chronic idiopathic myelofibrosis. Most patients are asymptomatic at presentation and usually detected by the discovery of splenic enlargement and/or abnormal blood counts during a routine examination. A blood smear reveals the characteristic features of extramedullary hematopoiesis: teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes; myeloblasts may also be present but have no prognostic significance (Fig. 95-1). Anemia, usually mild initially, is the rule, while the leukocyte and platelet counts are either normal or increased but either can be depressed. Mild hepatomegaly may accompany the splenomegaly, and both the lactate dehydrogenase and serum alkaline phosphatase levels can be elevated. The level of leukocyte alkaline phosphatase can be low, normal, or elevated. Marrow may be un accessible due to the myelofibrosis (Fig. 95-2), and bone x-rays may reveal osteosclerosis. Exuberant extramedullary hematopoiesis can cause ascites, pulmonary hypertension, intestinal or ureteral obstruction, intracranial hypertension, pericardial tamponade, spinal cord compression, or skin nodules. Splenic enlargement can be sufficiently rapid to cause splenic infarctions with fever and pleuritic chest pain. Hyperuricemia and secondary gout may ensue.

**DIAGNOSIS** While the clinical picture described above is characteristic of chronic idiopathic myelofibrosis, all of the clinical features described can be observed in polycythemia vera or CML. Massive splenomegaly commonly masks erythrocytosis in polycythemia vera, and reports of intraabdominal thromboses in chronic idiopathic myelofibrosis likely represent instances of unrecognized polycythemia vera. Furthermore, many other disorders have features that overlap with chronic idiopathic myelofibrosis but respond to distinctly different therapies. Therefore, the diagnosis of chronic idiopathic myelofibrosis is one of exclusion, which requires that the disorders listed in Table 95-3 be ruled out.

The presence of teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes establishes the presence of extramedullary hematopoiesis; the presence of leukocytosis, thrombocytosis with large and bizarre platelets, as well as circulating myeloblasts suggests the presence of a myeloproliferative disorder as opposed to a secondary form of myelofibrosis (Table 95-3). Marrow is usually not aspirable due to increased marrow reticulin, but marrow biopsy will reveal a hypercellular marrow with trilineage hyperplasia and, in particular, increased megakaryocytes, but there are no characteristic morphologic abnormalities that distinguish idiopathic myelofibrosis from the other chronic myeloproliferative disorders. Splenomegaly due to extramedullary hematopoiesis may be sufficiently massive to cause portal hypertension and variceal formation. In some patients, exuberant extramedullary hematopoiesis can dominate the clinical picture. An intriguing feature of chronic idiopathic myelofibrosis is the occurrence of autoimmune abnormalities such as immune complexes, antinuclear antibodies, rheumatoid factor, or a positive Coombs’ test. Whether these represent a host reaction to the disorder or are involved in its pathogenesis is unknown. Cytogenetic analysis of blood or marrow is useful both to exclude CML and for prognostic purposes, because complex karyotype abnormalities portend a poor prognosis in chronic idiopathic myelofibrosis. For unknown reasons, the number of circulating CD34+ cells is markedly increased in chronic idiopathic myelofibrosis.

**COMPLICATIONS** Chronic idiopathic myelofibrosis has a median survival of only 5 years (range 1 to 15 years), a duration much shorter than for polycythemia vera or essential thrombocyto sis. The natural history of chronic idiopathic myelofibrosis is one of inexorable marrow failure with transfusion-dependent anemia and increasing organomegaly. Patients are prone to deep-seated tissue infections, particularly of the lungs. As with CML, chronic idiopathic myelofibrosis can evolve from a chronic phase to an accelerated phase with constitutional symptoms and increasing marrow failure. About 10% of patients develop an aggressive form of acute leukemia for which therapy is usually ineffective. Important prognostic factors for disease acceleration include anemia; thrombocytopenia; age; the presence of complex cytogenetic abnormalities; and constitutional symptoms such as unexplained fever, night sweats, or weight loss. Any nonrandom cytogenetic abnormality is associated with a shortened life span, and the presence or development of multiple cytogenetic abnormalities is highly indicative of disease acceleration.

**TREATMENT**

No specific therapy exists for chronic idiopathic myelofibrosis. Anemia may be exacerbated by deficiency of folic acid or iron, and in rare instances, pyridoxine therapy has been effective. However, anemia is more often due to ineffective erythropoiesis not compensated for by the extramedullary hematopoiesis in the spleen and liver; neither androgens nor erythropoietin has been consistently effective therapy. Erythropoietin may worsen splenomegaly. A red cell splenic sequestration study can establish the presence of hypersplenism, for which splenectomy is indicated. Splenectomy may also be necessary if splenomegaly impairs alimentation and should be performed before cachexia sets in. In this situation, splenectomy should not be avoided because of concern over rebound thrombocytosis, loss of hematopoietic capacity, or compensatory hepatomegaly. However, for unexplained reasons, splenectomy increases the risk of blastic transformation. Allopurinol can control significant hyperuricemia, and

hydroxyurea has proved useful for controlling organomegaly. The role of IFN-α is undefined, and its side effects are more pronounced in the older individuals who are affected with this disorder, but reversal of myelofibrosis has been observed. Glucocorticoids are used to control autoimmune complications and may ameliorate anemia alone or in combination with thalidomide. Allogeneic bone marrow transplantation should be considered in younger patients.

**ESSENTIAL THROMBOCYTOSIS**

Essential thrombocytosis (other designations include essential thrombocythemia, idiopathic thrombocythosis, primary thrombocythosis, hemorrhagic thrombocythemia) is a clonal disorder of unknown etiology involving a multipotent hematopoietic progenitor cell and is manifested clinically by the overproduction of platelets without a definable cause. Essential thrombocytosis is an uncommon disorder, but its exact frequency is unknown. No clonal marker distinguishes it from the more common nonclonal, reactive forms of thrombocytosis (Table 95-4). Clinical recognition of thrombocytosis is unlikely in the largely asymptomatic persons affected by this disorder. As a consequence, essential thrombocytosis was formerly considered to be a disease of the elderly and to be responsible for significant morbidity due to hemorrhage or thrombosis. However, with the widespread application of platelet counting, it is now clear that essential thrombocytosis can occur at any age in adults and often occurs without symptoms or disturbances of hemostasis. There is an unexplained female predominance, in contrast to the reactive forms of thrombocytosis where no sex bias exists. Because no clonal marker is available for the disorder, clinical criteria have been proposed to distinguish it from the other chronic myeloproliferative disorders, which may also present with thrombocytosis but have differing prognoses and treatment (Table 95-5). These criteria do not establish clonality; therefore, they are truly useful only in identifying disorders such as CML, polycythemia vera, or myelodysplasia, which can masquerade as essential thrombocytosis, as opposed to establishing the presence of essential thrombocytosis. Furthermore, as with “primary” erythrocytosis, nonclonal, benign forms of thrombocytosis exist (such as hereditary overproduction of thrombopoietin) that are not widely recognized because we currently lack the diagnostic tools to do so.

**ETIOLOGY**

Megakaryocytopenia and platelet production depend upon thrombopoietin and its receptor, Mpl. As in the case of early erythroid and myeloid progenitor cells, early megakaryocytic progenitors require the presence of interleukin (IL) 3 and stem cell factor for optimal proliferation, and their subsequent development is enhanced by IL-6 and -11. However, megakaryocyte maturation and differentiation require thrombopoietin.

Megakaryocytes are unique among hematopoietic progenitor cells because they undergo endomitotic as opposed to mitotic reduplication of their genome. In the absence of thrombopoietin, endomitotic megakaryocytic reduplication and, by extension, the cytoplasmic development necessary for platelet production are impaired. Like erythropoietin, thrombopoietin is produced in both the liver and the kidneys, and an inverse correlation exists between the platelet count and plasma thrombopoietic activity. Like erythropoietin, plasma levels of thrombopoietin are controlled in part by the size of its progenitor cell pool. In contrast to erythropoietin, but like its myeloid counterparts granulocyte and granulocyte-macrophage colony-stimulating factors, thrombopoietin not only enhances the proliferation of its target cells but also enhances the reactivity of their end-stage product, the platelet. In addition to its role in thrombopoiesis, thrombopoietin enhances the survival of multipotent hematopoietic stem cells.

The clonality of essential thrombocytosis was established by the use of the isoenzymes of glucose-6-phosphate dehydrogenase in patients who are hemizygous for this gene, by the use of X-linked DNA polymorphisms, and by the identification of nonrandom, although variable, cytogenetic abnormalities. The multipotent hematopoietic progenitor cell involved in this disorder can vary; in some patients lymphocytes contained the same clonal marker as the megakaryocytes, erythrocytes, and myeloid cells, whereas in others the lymphocytes were not involved. Similar observations have been made in polycythemia vera. Furthermore, a number of families have been described in which essential thrombocytosis was inherited, in one instance as an autosomal dominant trait. In one kindred, in addition to essential thrombocytosis, idiopathic myelofibrosis and polycythemia vera were also individually documented.

**CLINICAL FEATURES**

Clinically, essential thrombocytosis is most often identified incidentally when a platelet count is obtained during the course of a routine evaluation. Occasionally, review of previous platelet counts will reveal that an elevation was present but overlooked. No symptoms or signs are specific for essential thrombocytosis, but patients do have hemorrhagic and thrombotic tendencies expressed as easy bruising for the former or microvascular occlusions for the latter, which may be manifested by erythromelalgia, migraine, or transient ischemic attacks. Physical examination is generally unremarkable except occasionally for mild splenomegaly. Massive splenomegaly is more characteristic of the other myeloproliferative disorders, particularly polycythemia vera or idiopathic myelofibrosis.

Anemia is unusual, but a mild neutrophilic leukocytosis is not. The blood smear, however, is most remarkable for the number of platelets present, some of which may be very large. The leukocyte alkaline phosphatase score is either normal or elevated. The large mass of circling platelets may prevent the accurate measurement of serum potassium due to the release of platelet potassium upon blood clotting. This hyperkalemia is a laboratory artifact and is not associated with any electrocardiographic abnormalities. Similarly, arterial oxygen measurements can be inaccurate unless the blood is collected on ice. The prothrombin and partial thromboplastin times are normal, while abnormalities of platelet function such as a prolonged bleeding time and impaired platelet aggregation can be present. However, in spite of much study, characteristic platelet function abnormalities are not yet defined, and no platelet function test predicts clinically significant bleeding or thrombosis.

The elevated platelet count may hinder the collection of a marrow aspirate, but marrow biopsy usually reveals both megakaryocyte hyperplasia and hypertrophy, as well as an overall increase in marrow cellularity. A slight increase in marrow reticulin may be present, but

* The concept that a platelet count greater than 1 × 10⁹/µL distinguishes essential thrombocytosis from other causes of thrombocytosis has no clinical validity.
if extensive, another diagnosis should be considered. The absence of
stainable iron demands an explanation, because iron deficiency alone
can cause thrombocytosis and absent marrow iron is a feature of poly-
cythemia vera.

While nonrandom cytogenetic abnormalities have been identified
in essential thrombocytosis, no consistently identifiable abnormality is
notable, even involving chromosomes 3 and 1 where the genes for
thrombopoietin and its receptor Mpl, respectively, are located.

**DIAGNOSIS** Thrombocytosis is encountered in a variety of clinical dis-
orders (Table 95–4) in which production of cytokines is increased.
Thus, the first obligation when confronted with a high platelet count is
to determine if it is a consequence of another disorder. Cytogenetic
evaluation is mandatory to determine if the thrombocytosis is due to
CML or a myelodysplastic disorder such as the 5q− syndrome.
Because the bcr-abl translocation can be present in the absence of
the Ph chromosome, fluorescence in situ hybridization (FISH) analysis for
bcr-abl expression should be performed in all patients with thrombo-
cytosis rather than a cytogenetic study. Anemia and ringed sideroblasts
are not features of essential thrombocytosis, but they are features of
idiopathic refractory sideroblastic anemia, in which thrombocytosis
can also occur. The presence of massive splenomegaly should suggest
the possibility of another myeloproliferative disorder, and in this set-
ting a red cell mass determination is mandatory because substantial
splenomegaly can mask the presence of erythrocytosis. What appears
to be essential thrombocytosis can evolve into polycythemia vera, re-
vealing the true nature of the underlying myeloproliferative disorder.

**COMPLICATIONS** Perhaps no other condition in clinical medicine has
caused otherwise astute physicians to intervene inappropriately more
often than thrombocytosis, particularly if the platelet count is
caused otherwise astute physicians to intervene inappropriately more
than thrombocytosis, particularly if the platelet count is >1 ×
10^6/μL. It is commonly believed that a high platelet count must cause
intravascular stasis and thrombosis; however, no controlled clinical
study has ever established this association.

To the contrary, very high platelet counts are associated primarily
with hemorage due to acquired von Willebrand disease, while plate-
let counts of <1 × 10^6/μL are more often associated with thrombosis.
This is not meant to imply that an elevated platelet count cannot cause
symptoms in a patient with essential thrombocytosis, but rather that
the focus should be on the patient, not the platelet count. For example,
some of the most dramatic neurologic problems in essential thrombo-
cytosis are migraine-related and may respond only to lowering of
the platelet count; other symptoms may be a manifestation of eryth-
romelalgia and respond simply to platelet cyclooxygenase inhibitors
such as aspirin, without a reduction in platelet number. Still others
may represent an interaction between an atherosclerotic vascular sys-
tem and a high platelet count, and others may have no relationship to
the platelet count whatsoever. Progress in distinguishing essential
thrombocytosis from polycythemia vera and in defining new causes of
hypercoagulability (such as factor V Leiden) make the older literature
on thrombocytosis less reliable.

**TREATMENT** An elevated platelet count in an asymptomatic patient requires no ther-
apy, and before any therapy is initiated in a patient with thrombocy-
tosis, the cause of symptoms must be clearly identified to be a con-
sequence of the elevated platelet count. Platelet pheresis has not been
proven efficacious and cannot be recommended. Furthermore, patients
with essential thrombocytosis treated with ³²P, hydroxyurea, or alkyl-
ating agents are placed at risk of developing acute leukemia without
any proof of benefit from such therapy. If platelet reduction is deemed
necessary on the basis of neurologic symptoms refractory to salicy-
lates, IFN-α or anagrelide, a quinazolin derivative, can reduce the
platelet count, but neither is uniformly effective nor without significant
side effects. Hydroxyurea should be considered only if these agents
are not effective or tolerable. Bleeding associated with thrombocytosis
usually responds to ε-aminocaproic acid, which can be given prophyl-
actically before and after elective surgery. As more clinical experience
is acquired, it appears that essential thrombocytosis is more benign
than previously thought, and that evolution to acute leukemia is more
likely to be a consequence of prior therapy than of the disease itself.
In managing patients with thrombocytosis, the physician’s first obli-
gation is to do no harm.

**ACUTE AND CHRONIC MYELOID LEUKEMIA**

**Meir Wetzler, John C. Byrd, Clara D. Bloomfield**

The myeloid leukemias are a heterogeneous group of diseases char-
acterized by infiltration of the blood, bone marrow, and other tissues
by neoplastic cells of the hematopoietic system. In 2004, the estimated
number of new myeloid leukemia cases in the United States was
16,520. These leukemias comprise a spectrum of malignancies that,
untreated, range from rapidly fatal to slowly growing. Based on their
untreated course, the myeloid leukemias have traditionally been des-
ignated acute or chronic.

**ACUTE MYELOID LEUKEMIA**

**INCIDENCE** The incidence of acute myeloid leukemia (AML) is ~3.6
per 100,000 people per year, and the age-adjusted incidence is higher
in men than in women (4.4 versus 3.0). AML incidence increases with
age; it is 1.7 in individuals <65 years and 16.2 in those >65. A signif-
icant increase in AML incidence has occurred over the past 10 years.

**ETIOLOGY** Heredity, radiation, chemical and other occupational expo-
sures, and drugs have been implicated in the development of AML.
No direct evidence suggests a viral etiology.

**Heredity** Certain syndromes with somatic cell chromosome aneu-
plody, e.g., Down (chromosome 21 trisomy), Klinefelter (XYY and
variants), and Patau (chromosome 13 trisomy), are associated with an
increased incidence of AML. Inherited diseases with excessive chro-
matin fragility, e.g., Fanconi anemia, Bloom syndrome, ataxia telan-
giectasia, and Kostmann syndrome, are also associated with AML.

**Radiation** Survivors of the atomic bomb explosions in Japan had an
increased incidence of myeloid leukemias that peaked 5 to 7 years
after exposure. Therapeutic radiation alone seems to add little risk
of AML but can increase the risk in people exposed to alkylating
agents.
Chemical and Other Exposures Exposure to benzene, which is used as a solvent in the chemical, plastic, rubber, and pharmaceutical industries, is associated with an increased incidence of AML. Smoking and exposure to petroleum products, paint, embalming fluids, ethylene oxide, herbicides, and pesticides, have also been associated with an increased risk of AML.

Drugs Anticancer drugs are the leading cause of treatment-associated AML. Alkylating agent–associated leukemias occur on average 4 to 6 years after exposure, and affected individuals have aberrations in chromosomes 7 and 5. Topoisomerase II inhibitor–associated leukemias occur 1 to 3 years after exposure, and affected individuals often have aberrations involving chromosome 11q23. Chloramphenicol, phenylbutazone, and, less commonly, chloroquine and methoxyxsoralen can result in bone marrow failure that may evolve into AML.

Classification The categorization of acute leukemia into biologically distinct groups is based on morphology, cytochemistry, and immunophenotype as well as cytogenetic and molecular techniques.

Morphologic and Cytochemical Classification The diagnosis of AML is established by the presence of ≥20% myeloblasts in blood and/or bone marrow according to the World Health Organization (WHO) classification. Myeloblasts have nuclear chromatin that is uniformly fine or lacelike in appearance and large nucleoli (2 to 5 per cell). If specific cytoplasmic granules, Auer rods, or the nuclear folding and clef ting characteristic of monocytoid cells are not present, the morphologic features observed under light microscopy may not be sufficient to clarify the diagnosis. A positive myeloperoxidase reaction in >3% of the blasts may be the only feature distinguishing AML from acute lymphoblastic leukemia (ALL).

Until 2000, the diagnosis of AML was established by the presence of ≥30% myeloblasts in the marrow and further classified based on morphology and cytochemistry according to the French, American, and British (FAB) schema, which includes eight major subtypes, M0 to M7 (Table 96-1). The WHO classification modified the FAB schema by reducing the number of blasts required for a diagnosis and incorporating molecular (including cytogenetic), morphologic (multilineage dysplasia), and clinical features (such as prior hematologic disorder) in defining disease entities (Table 96-1).

Immunophenotypic Classification The phenotype of human myeloid leukemia cells can be studied by multiparameter flow cytometry after the cells are labeled with monoclonal antibodies to cell-surface antigens. For example, M0, which is characterized by immature morphology and no lineage-specific cytochemical reactions, is diagnosed by flow cytometric demonstration of the myeloid-specific antigens cluster designation (CD) 13 or 33. Similarly, M7 can often be diagnosed only by expression of the platelet-specific antigens CD41 and/or CD61 or by electron microscopic demonstration of myeloperoxidase.

Chromosomal Classification Chromosomal analysis of the leukemic cell provides the most important pretreatment prognostic information in AML. Two cytogenetic abnormalities have been invariably associated with a specific FAB group: t(15;17)(q22;q12) with M3 and inv(16)(p13q22) with M4Eo, and many chromosomal abnormalities have been associated primarily with one FAB group, including t(8;21)(q22;q22) with M2, and t(9;11)(p22;q23), and other translocations involving 11q23, with M5. As a result of their prognostic significance and association with specific morphologic features, the WHO classification incorporates cytogenetics (Table 96-1). Many of the recurring chromosomal abnormalities in AML have been associated with specific clinical characteristics. More commonly associated with younger age are t(8;21) and t(15;17), and with older age, del(5q) and del(7q). Myeloid sarcomas (see below) are associated with t(8;21) and disseminated intravascular coagulation (DIC) with t(15;17).

Molecular Classification Molecular study of many recurring cytogenetic abnormalities has revealed genes that may be involved in leukemogenesis. The 15;17 translocation encodes a chimeric protein, Pml/RARα, which is formed by the fusion of the retinoic acid receptor-α (RARα) gene from chromosome 17 and the promyelocytic leukemia (PML) gene from chromosome 15. The RARα gene encodes a member of the nuclear hormone receptor family of transcription factors. After binding retinoic acid, RARα can promote expression of a variety of genes. The 15;17 translocation juxtaposes PML with RARα in a head-to-tail configuration that is under the transcriptional control of PML. Three different breakpoints in the PML gene lead to various fusion proteins. The Pml-Rarα fusion protein tends to suppress gene transcription and blocks differentiation of the cells. Pharmacologic doses of the Rarα ligand, all-trans-retinoic acid (tretinoin), relieve the block and promote differentiation (see below).

The inv(16), characteristic of M4Eo or AML with abnormal bone marrow eosinophils, and the t(8;21) both involve subunits of the transcription factor complex core-binding factor (Cbfa), also known as polymavirus enhancer binding protein 2 (Pebp2). This transcription factor contains two subunits, an α subunit, the Am11 protein, and a β subunit, the Pebp2 protein, and is involved in the expression of a number of differentiation-dependent genes in myeloid cells. The inv(16) results in a fusion of the core-binding factor β (CBFB) gene on the q arm (encodes Pebp2 protein) and the myosin heavy chain (MYH11) gene on the p arm. The 8;21 translocation involves the core binding factor α (CBFA) gene on chromosome 21, called the AML1 (also RUNX1) gene, joining the ETO gene on chromosome 8. Similar to the t(15;17) gene product, the Aml1/ETO protein acts to block transcription of CBFA1-CBFB-controlled genes.

Most translocations that involve 11q23 rearrange the myeloid-lymphoid [mixed-lineage leukemia (MLL)] gene. The MLL gene has

two regions that encompass multiple zinc fingers and has at least two additional potential DNA-binding motifs. Abnormalities in the MLL gene are relatively common in patients with AML who do not have 11q23 rearrangements cytogenetically.

The above molecular aberrations are increasingly being used for diagnosis and detection of residual disease after treatment. Molecular aberrations are also being identified that are useful for classifying risk of relapse in patients without cytogenetic abnormalities. A partial tandem duplication (PTD) of the MLL gene is found in 5 to 10% of patients with normal cytogenetics and results in short remission duration. Flt3 (FMS-like tyrosine kinase 3) is a tyrosine kinase receptor important in the development of myeloid and lymphoid lineages. Activating mutations of FLT3 are present in ~30% of adult AML patients due to deletion or internal tandem duplications (ITD) in the juxtamembrane domain or mutations of the activating loop of the kinase. Continuous activation of Flt3 and downstream target kinases, including signal transducer and activator of transcription protein 5, Ras/mitogen-activated protein kinase, and phosphatidylinositol 3-kinase/Akt, provides increased proliferation and antiapoptotic signals to the myeloid progenitor cell. Several clinical studies have demonstrated that presence of FLT3 ITD in patients with normal cytogenetics predicts for short remission duration and inferior survival.

CLINICAL PRESENTATION: Symptoms

Patients with AML most often present with nonspecific symptoms that begin gradually or abruptly and are the consequence of anemia, leukocytosis, leukopenia or leukocyte dysfunction, or thrombocytopenia. Nearly half have had symptoms for ≥3 months before the leukemia was diagnosed.

Half mention fatigue as the first symptom, but most complain of fatigue or weakness at the time of diagnosis. Anorexia and weight loss are common. Fever with or without an identifiable infection is the initial symptom in ~10% of patients. Signs of abnormal hemostasis (bleeding, easy bruising) are noted first in 5% of patients. On occasion, bone pain, lymphadenopathy, nonspecific cough, headache, or diaphoresis is the presenting symptom.

Rarely patients may present with symptoms from a mass lesion located in the soft tissues, breast, uterus, ovary, cranial or spinal dura, gastrointestinal tract, lung, mediastinum, prostate, bone, or other organs. The mass lesion represents a tumor of leukemic cells and is called a granulocytic sarcoma, or chloroma. Typical AML may occur simultaneously, later, or not at all in these patients. This rare presentation is more common in patients with 8:21 translocations.

Physical Findings

Fever, splenomegaly, hepatomegaly, lymphadenopathy, sternal tenderness, and evidence of infection and hemorrage are often found at diagnosis. Significant gastrointestinal bleeding, intrapulmonary hemorrhage, or intracranial hemorrhage occur most often in acute promyelocytic leukemia (APL). Bleeding associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other morphologic subtypes. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingivae, skin, soft tissues, or the meninges with leukemic blasts at diagnosis is characteristic of the monocytic subtypes (FAB M4 and M5).

Hematologic Findings

Anemia is usually present at diagnosis and can be severe. The degree varies considerably irrespective of other hematologic findings, splenomegaly, or the duration of symptoms. The anemia is usually normochromic normocytic. Decreased erythropoiesis often results in a reduced reticulocyte count, and erythrocyte survival is decreased by accelerated destruction. Active blood loss also contributes to the anemia.

The median presenting leukocyte count is about 15,000/µl. Between 25 and 40% of patients have counts <5000/µl, and 20% have counts >100,000/µl. Fewer than 5% have no detectable leukemic cells in the blood. Poor neutrophil function may be noted functionally by impaired phagocytosis and migration and morphologically by abnormal lobulation and deficient granulation.

Platelet counts <100,000/µl are found at diagnosis in ~75% of patients, and about 25% have counts <25,000/µl. Both morphologic and functional platelet abnormalities can be observed, including large and bizarre shapes with abnormal granulation and inability of platelets to aggregate or adhere normally to one another.

Pretreatment Evaluation

Once the diagnosis of AML is suspected, a rapid evaluation and initiation of appropriate therapy should follow (Table 96-2). In addition to clarifying the subtype of leukemia, initial studies should evaluate the overall functional integrity of the major organ systems, including the cardiovascular, pulmonary, hepatic, and renal systems. Factors that have prognostic significance, either for achieving complete remission (CR) or for predicting the duration of CR, should also be assessed before initiating treatment. should be obtained from all patients and cryopreserved for future use as new tests and therapeutics become available. All patients should be evaluated for infection.

Most patients are anemic and thrombocytopenic at presentation. Replacement of the appropriate blood components, if necessary, should begin promptly. Because qualitative platelet dysfunction or the presence of an infection may increase the likelihood of bleeding, evidence of hemorrhage justifies the immediate use of platelet transfusion, even if the platelet count is only moderately decreased. About 50% of patients have a mild to moderate elevation of serum uric acid at presentation. Only 10% have marked elevations, but renal precipitation of uric acid and the nephropathy that may result is a serious but uncommon complication. The initiation of chemotherapy may aggravate hyperuricemia, and patients are usually started immediately on allopurinol or rasburicase (recombinant uric oxidase) and hydration at diagnosis. Finally, the presence in high concentrations of lysozyme, a marker for monocytic differentiation, may be etiologic in renal tubular dysfunction, which could worsen other renal problems.

The blood neutrophil count must be evaluated for infection. The blood neutrophil count be ≥1500/μl and the platelet count ≥100,000/μl. Hemoglobin concentration or hematocrit are not considered in determining CR. Circulating blasts should be absent. While rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. Bone marrow cellularity should be >20% with trilineage maturation. The bone marrow should contain <5% blasts, and Auer rods should be absent. Extramedullary leukemia should not be present. For patients in CR, reverse transcriptase polymerase chain reaction (RT-PCR) to detect AML-associated molecular abnormalities and fluorescence in situ hybridization (FISH) to detect AML-associated cytogenetic aberrations are currently used to detect residual disease. Such detection of minimal residual disease may become a reliable discriminator between patients in CR who do or do not require additional and/or alternative therapies. Prognostic factors are influenced by the treatment used.

Age at diagnosis remains among the most important pretreatment risk factors, with advancing age being associated with a poorer prognosis primarily because of its influence on the patient’s ability to survive induction therapy and thus achieve CR. Age may also influence outcome because AML in older patients differs biologically. The leukemic cells in elderly patients more commonly express CD34 and the multidrug resistance 1 (Mdr1) efflux pump that conveys resistance to natural product–derived agents such as the anthracyclines (see below). With each successive decade of age, a greater proportion of patients have more resistant disease. Chronic and intercurrent diseases impair tolerance to rigorous therapy; acute medical problems at diagnosis reduce the likelihood of survival. Performance status, independent of age, also influences ability to survive induction therapy and thus respond to treatment.

Chromosome findings at diagnosis are an independent prognostic factor. Patients with t(8;21) or inv(16)/t(16;16), t(15;17), or −7 have a very poor prognosis. Molecular markers such as the presence of a PTD of MLL or the ITD of FLT3 may also predict poor outcome of AML patients who otherwise have an intermediate prognosis.

A prolonged symptomatic interval with cytopenias preceding diagnosis or a history of an antecedent hematologic disorder are other pretreatment clinical features that are associated with a lower CR rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >1 month before the diagnosis of AML when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder(s) increases. Secondary AML developing after treatment with cytotoxic agents for other malignancies is extremely difficult to treat successfully.

A high presenting leukocyte count is an independent prognostic factor; duration of CR is inversely related to the presenting leukocyte count or absolute circulating myeloblast count. Among patients with hyperleukocytosis (≥100,000/μl), early central nervous system bleeding and pulmonary leukostasis and relapse contribute to poor outcome.

The FAB classification diagnosis has been found to be an independent prognostic factor in some series. Other characteristics of leukemic cells have been reported to have prognostic significance, including Auer rods, ultrastructural features, in vitro and in vivo growth characteristics and chemotherapeutic sensitivity, and immunophenotype. Expression of the MDR1 gene adversely influences outcome.

In addition to pretreatment variables, several treatment factors correlate with prognosis in AML, including, most importantly, achievement of CR. Another is the rapidity with which the blast cells disappear from the blood after the institution of therapy. In addition, patients who achieve CR after one induction cycle have longer CR durations than those requiring multiple cycles.

PROGNOSTIC FACTORS

Many factors influence the likelihood of entering CR, the length of CR, and the durability of AML. CR is defined after examination of both bone and marrow. The blood neutrophil count must be ≥1500/μl and the platelet count ≥100,000/μl. Hemoglobin concentration or hematocrit are not considered in determining CR. Circulating blasts should be absent. While rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. Bone marrow cellularity should be >20% with trilineage maturation. The bone marrow should contain <5% blasts, and Auer rods should be absent. Extramedullary leukemia should not be present. For patients in CR, reverse transcriptase polymerase chain reaction (RT-PCR) to detect AML-associated molecular abnormalities and fluorescence in situ hybridization (FISH) to detect AML-associated cytogenetic aberrations are currently used to detect residual disease. Such detection of minimal residual disease may become a reliable discriminator between patients in CR who do or do not require additional and/or alternative therapies. Prognostic factors are influenced by the treatment used.

Age at diagnosis remains among the most important pretreatment risk factors, with advancing age being associated with a poorer prognosis primarily because of its influence on the patient’s ability to survive induction therapy and thus achieve CR. Age may also influence outcome because AML in older patients differs biologically. The leukemic cells in elderly patients more commonly express CD34 and the multidrug resistance 1 (Mdr1) efflux pump that conveys resistance to natural product–derived agents such as the anthracyclines (see below). With each successive decade of age, a greater proportion of patients have more resistant disease. Chronic and intercurrent diseases impair tolerance to rigorous therapy; acute medical problems at diagnosis reduce the likelihood of survival. Performance status, independent of age, also influences ability to survive induction therapy and thus respond to treatment.

Chromosome findings at diagnosis are an independent prognostic factor. Patients with t(8;21) or inv(16)/t(16;16), t(15;17), or −7 have a very poor prognosis. Molecular markers such as the presence of a PTD of MLL or the ITD of FLT3 may also predict poor outcome of AML patients who otherwise have an intermediate prognosis.

A prolonged symptomatic interval with cytopenias preceding diagnosis or a history of an antecedent hematologic disorder are other pretreatment clinical features that are associated with a lower CR rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >1 month before the diagnosis of AML when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder(s) increases. Secondary AML developing after treatment with cytotoxic agents for other malignancies is extremely difficult to treat successfully.

A high presenting leukocyte count is an independent prognostic factor; duration of CR is inversely related to the presenting leukocyte count or absolute circulating myeloblast count. Among patients with hyperleukocytosis (≥100,000/μl), early central nervous system bleeding and pulmonary leukostasis and relapse contribute to poor outcome.

The FAB classification diagnosis has been found to be an independent prognostic factor in some series. Other characteristics of leukemic cells have been reported to have prognostic significance, including Auer rods, ultrastructural features, in vitro and in vivo growth characteristics and chemotherapeutic sensitivity, and immunophenotype. Expression of the MDR1 gene adversely influences outcome.

In addition to pretreatment variables, several treatment factors correlate with prognosis in AML, including, most importantly, achievement of CR. Another is the rapidity with which the blast cells disappear from the blood after the institution of therapy. In addition, patients who achieve CR after one induction cycle have longer CR durations than those requiring multiple cycles.

TREATMENT

Treatment of the newly diagnosed patient with AML is usually divided into two phases, induction and postremission management (Fig. 96-1). The initial goal is to quickly induce CR. Once CR is obtained, further therapy must be used to prolong survival and achieve cure. The initial induction treatment and subsequent consolidation therapy are often chosen based upon the patient’s age. The influence of intensifying therapy with traditional chemotherapy agents such as cytarabine and

![Figure 96-1](image-url)
anthracyclines in younger patients (<60 years) appears to increase the cure rate of AML. In older patients, the benefit of intensive therapy has been more difficult to document and therefore pursuit of novel therapies as consolidation for these patients has recently been actively pursued.

**Induction Chemotherapy** The most commonly used CR induction regimens (for patients other than those with APL) consist of combination chemotherapy with cytarabine (cytosine arabinoside) and an anthracycline. Cytarabine is a cell cycle S-phase-specific antimetabolite that becomes phosphorylated intracellularly to an active triphosphate form that interferes with DNA synthesis. Anthracyclines are DNA intercalators. Their primary mode of action is thought to be inhibition of topoisomerase II, leading to DNA breaks. Cytarabine is usually administered as a continuous intravenous infusion at 100 to 200 mg/m² per day for 7 days. Anthracycline therapy generally consists of daunorubicin, 45 to 60 mg/m², intravenously on days 1, 2, and 3 (the 7 and 3 regimen). Treatment with idarubicin at 12 or 13 mg/m² per day for 3 days in conjunction with cytarabine by 7-day continuous infusion is at least as effective and may be superior to daunorubicin in younger patients. The addition of etoposide does not increase the CR rate but may improve the CR duration.

After induction chemotherapy, the bone marrow is examined to determine if the leukemia has been eliminated. If >5% blasts exist with ≥20% cellularity, the patient has traditionally been retreated with cytarabine and an anthracycline in doses similar to those given initially, but for 5 and 2 days, respectively. Our recommendation, however, is to change therapy in this setting. Patients who fail to attain CR after two induction courses should immediately proceed to an allogeneic stem cell transplant (SCT) if an appropriate donor exists. This approach is only applied to patients under the age of 65 to 70 with acceptable end-organ function.

With the 7 and 3 cytarabine/daunorubicin regimen outlined above, 65 to 75% of adults with de novo AML achieve CR. Two-thirds achieve CR after a single course of therapy, and one-third require two courses. About 50% of patients who do not achieve CR have a drug-resistant leukemia, and 50% do not achieve CR because of fatal complications of bone marrow aplasia or impaired recovery of normal stem cells. A higher induction treatment-related mortality and frequency of resistant disease has been observed as age increases in virtually all studies.

High-dose cytarabine-based regimens have very high CR rates after a single cycle of therapy. When given in high doses, more cytarabine may enter the cells, saturate the cytarabine-inactivating enzymes, and increase the intracellular levels of 1-β-D-arabinofuranosylcytosine-triphosphate, the active metabolite incorporated into DNA. Thus, higher doses of cytarabine may increase the inhibition of DNA synthesis and thereby overcome resistance to standard-dose cytarabine. In two randomized studies, high-dose cytarabine with an anthracycline produced CR rates similar to those achieved with standard 7 and 3 regimens. However, the CR duration was longer after high-dose cytarabine than after standard-dose cytarabine.

The hematologic toxicity of high-dose cytarabine-based induction regimens has typically been greater than that associated with 7 and 3 regimens. Toxicity with high-dose cytarabine includes myelosuppression, pulmonary toxicity, and significant and occasionally irreversible cerebellar toxicity. All patients treated with high-dose cytarabine must be closely monitored for cerebellar toxicity. Full cerebellar testing should be performed before each dose, and further high-dose cytarabine should be withheld if evidence of cerebellar toxicity develops. This toxicity occurs more commonly in patients with renal impairment and in those over the age of 60. Indeed, it is the increased toxicity observed with high-dose cytarabine, as opposed to the lack of benefit of this therapy, that has limited the use of this more intensive therapy in elderly AML patients. Clinical trials in the elderly patients have therefore focused upon new agents and attenuated doses of high-dose cytarabine therapy.

**Supportive Care** Measures geared to supporting patients through several weeks of granulocytopenia and thrombocytopenia are critical to the success of AML therapy. Patients with AML should be treated in centers expert in providing supportive measures for their management.

Recombinant hematopoietic growth factors have been incorporated into clinical trials in AML. These trials have been designed to lower the infection rate after chemotherapy. Both granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have reduced the median time to neutrophil recovery by an average of 5 to 7 days. This accelerated rate of neutrophil recovery, however, has not always translated into significant reductions in infection rates. In most randomized studies, both G-CSF and GM-CSF have failed to improve the CR rate, disease-free survival, or overall survival. Although receptors for both G-CSF and GM-CSF are present on AML blasts, therapeutic efficacy is neither enhanced nor inhibited by these agents. The use of growth factors as supportive care for AML patients is controversial. We favor their use in elderly patients, those receiving intensive regimens, patients with uncontrolled infections, or those participating in clinical trials.

Multilumen right atrial catheters should be inserted through a subcutaneous tunnel as soon as patients with newly diagnosed AML have been stabilized. They should be used thereafter for administration of intravenous medications and transfusions, as well as for blood drawing. Antibiotic-impregnated catheters should be considered if the risk or subsequent consequence of line-related infection is high. The separation between the vascular access site and the exit site and the presence of a Dacron cuff in the subcutaneous channel reduce the risk of infection. With meticulous attention to sterile technique in catheter placement and maintenance, catheters may often be left in place for months.

Adequate and prompt blood bank support is critical to therapy of AML. Platelet transfusions should be given as needed to maintain a platelet count >10,000 to 20,000/µL. We believe that the platelet count should be kept at higher levels in febrile patients and during episodes of active bleeding or DIC. Patients with poor posttransfusion platelet count increments may benefit from administration of platelets from human leukocyte antigen (HLA)-matched donors. Red blood cell transfusions should be administered to keep the hemoglobin level >80 g/L (8 g/dL) in the absence of active bleeding, DIC, or congestive heart failure. Blood products leukodepleted by filtration should be used to avert or delay alloimmunization as well as febrile reactions. Blood products should also be irradiated to prevent graft-versus-host disease (GVHD). Cytomegalovirus (CMV)-negative blood products should be used for CMV-seropositive patients who are potential candidates for allogeneic SCT. Leukodepleted products are also effective for these patients if CMV-negative products are not available.

Infectious complications remain the major cause of morbidity and death during induction and postremission chemotherapy for AML. Prophylactic administration of antibiotics in the absence of fever is controversial. Oral nystatin or clotrimazole is recommended to prevent localized candidiasis. For patients who are herpes simplex virus antibody titer–positive, acyclovir prophylaxis is effective in preventing reactivation of latent oral herpes infections.

Fever develops in most patients with AML, but infections are documented in only half of febrile patients. Early initiation of empirical broad-spectrum antibacterial and antifungal antibiotics has significantly reduced the number of patients dying of infectious complications (Chap. 72). An antibiotic regimen adequate to treat gram-negative and gram-positive organisms should be instituted at the onset of fever in a granulocytopenic patient after clinical evaluation, including a detailed physical examination with inspection of the dwelling catheter exit site and a perirectal examination, as well as procurement of cultures and radiographs aimed at documenting the source of fever. Specific antibiotic regimens should be based on antibiotic sensitivity data obtained from the institution at which the patient is being treated. Acceptable regimens include imipenem-cilastatin; an aminoglycoside; a third-generation cephalosporin with
antipseudomonal activity (i.e., ceftazidime or cefepime); or double β-lactam combinations (ceftazidime and piperacillin). Aminoglycosides should be avoided if possible in patients with renal insufficiency. For patients with known immediate-type hypersensitivity reactions to penicillin, aztreonam may be substituted for β-lactams. Aztreonam should be combined with an aminoglycoside or a quinolone antibiotic rather than used alone.

Empirical vancomycin is not given initially in the absence of suspected gram-positive infection or mucositis but should be initiated in neutropenic patients who remain febrile for 3 days; empirical systemic antifungal therapy is added at 7 days if fever persists. While amphotericin B has been used in the past for this, itraconazole and voriconazole have been shown to be equivalent in efficacy and less toxic. Our approach is therefore to use either itraconazole or voriconazole. Liposomal amphotericin, which has also been demonstrated to be equivalent to regular amphotericin and to have less renal toxicity, is utilized when this treatment approach fails. Antibacterial and antifungal antibiotics should be continued until patients are no longer neutropenic, regardless of whether a specific source has been found for the fever.

**Treatment of Promyelocytic Leukemia**

Tretinoin is an oral drug that induces the differentiation of leukemic cells bearing the t(15;17); it is not effective in other forms of AML. APL is responsive to cytarabine and daunorubicin, but about 10% of patients treated with these drugs die from DIC induced by the release of granule components by dying tumor cells. Tretinoin does not produce DIC but produces another complication called the retinoic acid syndrome. Occurring within the first 3 weeks of treatment, it is characterized by fever, dyspnea, chest pain, pulmonary infiltrates, pleural and pericardial effusions, and hypoxia. The syndrome is related to adhesion of differentiated neoplastic cells to the pulmonary vasculature endothelium. Glucocorticoids, chemotherapy, and/or supportive measures can be effective. The mortality of this syndrome is about 10%.

Tretinoin (45 mg/m² per day orally until remission is documented) plus concurrent anthracycline chemotherapy appears to be the safest and most effective treatment for APL. Unlike patients with other types of AML, patients with this subtype benefit from maintenance therapy with either tretinoin or chemotherapy. The optimal regimen is being sought in clinical studies.

Arsenic trioxide produces meaningful responses in up to 85% of patients refractory to tretinoin. The use of arsenic trioxide is being explored as part of initial treatment in clinical trials of APL.

The detection of minimal residual disease by RT-PCR amplification of the t(15;17) chimeric gene product appears to predict relapse. Disappearance of the signal is associated with long-term disease-free survival; its persistence predicts relapse. With increases in the sensitivity of the assay, some patients with persistent abnormal gene product have been found who do not suffer a relapse. Studies are underway to determine whether there is a critical threshold level of transcripts that predicts for leukemia relapse.

**Postremission Therapy**

Induction of a durable first CR is critical to long-term disease-free survival in AML. However, without further therapy virtually all patients experience relapse. Once relapse has occurred, AML is generally curable only by SCT.

Postremission therapy is designed to eradicate any residual leukemic cells; therefore, it should prevent relapse and prolong survival. Approaches to postremission therapy in AML are often based upon age (<55 to 65 and >55 to 65). For younger patients, most studies include intensive chemotherapy and allogeneic or autologous SCT. High-dose cytarabine is more effective than standard-dose cytarabine.

The Cancer and Leukemia Group B (CALGB), for example, compared the duration of CR in patients randomly assigned postremission to four cycles of high (3 g/m², every 12 h on days 1, 3, and 5), intermediate (400 mg/m² for 5 days by continuous infusion), or standard (100 mg/m² per day for 5 days by continuous infusion) doses of cytarabine. A dose-response effect for cytarabine in patients with AML who were ≤60 years was demonstrated. High-dose cytarabine significantly prolonged CR and increased the fraction cured in patients with favorable [t(8;21) and inv(16)] and normal cytogenetics, but it had no significant effect on patients with other abnormal karyotypes. For older patients, exploration of attenuated intensive therapy that includes either chemotherapy or nonmyeloablative allogeneic SCT has been pursued. In addition, early introduction of new agents (Table 96-3) is often pursued.

Allogeneic and autologous SCT in first CR have been studied extensively in younger patients with no major organ dysfunction. Allogeneic SCT is used in patients <65 to 70 years with an HLA-compatible donor. Relapse with this therapy occurs in only a small fraction of patients, but toxicity is relatively high from treatment complications including venoocclusive disease, GVHD, and infections. Autologous transplantation can be administered in young and older patients and uses the same preparative regimens. Patients subsequently receive their own stem cells collected while in remission. The toxicity is lower with autologous SCT (5% mortality rate), but the relapse rate is higher than with allogeneic SCT. The increased relapse rate is due to the absence of the graft-vs-leukemia (GVL) effect seen with allogeneic SCT and possible contamination of the autologous stem cells with tumor cells. Purging the autologous stem cells does not lower the relapse rate with autologous SCT.

Randomized trials comparing intensive therapy and allogeneic and autologous SCT have shown improved duration of remission with allogeneic SCT compared to autologous SCT or chemotherapy alone. However, overall survival is generally not different; the improved disease control with allogeneic SCT is eraced by the increase in fatal toxicity. While stem cells were previously harvested from the bone marrow, virtually all efforts currently collect these from the peripheral blood following mobilization regimens including growth factors with or without chemotherapy. Prognostic factors may help select patients in first CR for whom transplant is most effective.

Our approach includes strong consideration for allogeneic SCT in first CR for patients with high-risk karyotypes. Patients with normal karyotypes who have other poor risk factors (antecedent hematologic disorder, failure to attain remission with a single induction course, hyperleukocytosis, PTD of the MLL gene, and FLT3 abnormalities) are also potential candidates. If a suitable HLA donor does not exist, autologous SCT or novel therapeutic approaches are considered. Other novel transplant strategies including nonmyeloablative SCT are being actively explored for consolidation of high-risk AML patients. Patients with t(8;21) and inv(16) are treated with repetitive doses of high-dose cytarabine, regardless of whether a specific source has been found for the fever.

cytarabine, which offers a high frequency of cure without the morbidity of transplant.

**Relapse** Once relapse occurs after the standard induction and postremission chemotherapy approach described above and outlined in Fig. 96-1, patients are rarely cured with further standard-dose chemotherapy. Patients eligible for allogeneic SCT should receive transplants expeditiously at the first sign of relapse. Long-term disease-free survival is approximately the same (30 to 50%) with allogeneic SCT in first relapse or in second remission. Chemotherapy is administered prior to allogeneic transplant if the AML is rapidly progressing. Autologous SCT rescues about 20% of relapsed patients with AML who have chemosensitive disease. The most important factors predicting response at relapse are the length of the previous CR, whether initial CR was achieved with one or two courses of chemotherapy, and the type of postremission therapy. Because of the poor outcome of patients in early (<12 months) first relapse, it is justified (for patients without HLA-compatible donors) to explore innovative approaches, such as new drugs or immunotherapies (Table 96-3). Patients with longer (>12 months) first CR generally relapse with drug-sensitive disease and have a higher chance of attaining a CR. However, cure for these patients is uncommon, and treatment with novel approaches should be considered if SCT is not possible. New agents (Table 96-3) that may have clinical activity in AML are needed.

For elderly patients (age >60) for whom clinical trials are not available, gemtuzumab ozogamicin (Mylotarg) is another alternative. This therapy is an antibody-targeted chemotherapy consisting of the humanized anti-CD33 antibody linked to calicheamicin, a potent antimicrobial. The CR rate in response to this therapy is ~30%. The effectiveness of this agent in early relapsing (<6 months) or refractory AML patients is limited, possibly due to calicheamicin being a potent Mdr1 substrate. Toxicity, including myelosuppression, infusion toxicity, and venoocclusive disease, can be observed with gemtuzumab ozogamicin. Currently, studies are examining the efficacy of this treatment in combination with chemotherapy for both young and older patients with previously untreated AML.

**CHRONIC MYELOGENOUS LEUKEMIA**

**INCIDENCE** The incidence of chronic myelogenous leukemia (CML) is 1.5 per 100,000 people per year, and the age-adjusted incidence is higher in men than in women (2.0 versus 1.2). The incidence of CML increases slowly with age until the middle forties, when it starts to rise rapidly. CML incidence decreased slightly between 1973 and 1999 (1.9 versus 1.5).

**DEFINITION** The diagnosis of CML is established by identifying a clonal expansion of a hematopoietic stem cell possessing a reciprocal translocation between chromosomes 9 and 22. This translocation results in the head-to-tail fusion of the breakpoint cluster region (BCR) gene on chromosome 22q11 with the ABL (named after the abelson murine leukemia virus) gene located on chromosome 9q34. Untreated, the disease is characterized by the inevitable transition from a chronic phase to an accelerated phase and on to blast crisis.

**ETIOLOGY** No clear correlation with exposure to cytotoxic drugs, such as alkylating agents, has been found, and there is no direct evidence of a viral etiology. Cigarette smoking has been shown to accelerate the progression to blast crisis and therefore has an adverse effect on survival in CML. The effect of radiation was demonstrated in a study of the atomic bomb survivors, where it has been estimated that the development of a CML cell mass of 10,000/μl takes 6.3 years. No increase in CML incidence was found in the survivors of the Chernobyl accident, suggesting that only large doses of radiation can induce CML.

**PATHOPHYSIOLOGY** The product of the fusion gene resulting from the t(9;22) plays a central role in the development of CML. This chimeric gene is transcribed into a hybrid BCR/ABL mRNA in which exon 1 of ABL is replaced by variable numbers of 5′ BCR exons. Bcr/Abelson fusion proteins, p210BCR/ABL, are produced that contain NH2-terminal domains of Bcr and the COOH-terminal domains of Abl. A rare breakpoint, occurring within the 3′ region of the BCR gene, yields a fusion protein of 230 kDa, p230BCR/ABL. Bcr/Abelson fusion proteins can transform hematopoietic progenitor cells in vitro. Furthermore, reconstituting lethally irradiated mice with bone marrow cells infected with retrovirus carrying the gene encoding the p210BCR/ABL leads to the development of a myeloproliferative syndrome resembling CML in 50% of the mice. Specific antisense oligomers to the BCR/ABL junction inhibit the growth of t(9;22)-positive leukemic cells without affecting normal colony formation.

The mechanism(s) by which p210BCR/ABL promotes the transition from the benign state to the fully malignant one is still unclear. Messenger RNA for BCR/ABL can occasionally be detected in normal individuals. However, attachment of the BCR sequences to ABL results in three critical functional changes: (1) the Abelson protein becomes constitutively active as a tyrosine kinase enzyme, subsequently activating downstream kinases that prevent apoptosis; (2) the DNA-protein-binding activity of Abelson is attenuated; and (3) the binding of Abelson to cytoskeletal actin microfilaments is enhanced.

**Disease Progression** The events associated with transition to the acute phase are poorly understood. Chromosomal instability of the malignant clone, resulting, for example, in the acquisition of an additional t(9;22), trisomy 8, or 17p- (p53 loss), is a fundamental characteristic of CML. Acquisition of these additional genetic and/or molecular abnormalities is critical to the phenotypic transformation. Large deletions adjacent to the translocation breakpoint on the derivative 9 chromosome, detected by microsatellite polymerase chain reaction (PCR) or FISH, are associated with shorter survival time. Heterogeneous structural alterations of the p53 gene, as well as structural alterations and lack of protein production of the retinoblastoma gene, have been associated with disease progression in a subset of patients. Rare patients show alterations in RAS. Sporadic reports also document the presence of an altered MYC (named after the myelocytomatosis virus) gene. Progressive de novo DNA methylation at the BCR/ABL locus has also been shown to herald blast crisis transformation. Finally, interleukin (IL)-1β may be involved in the progression of CML to the blastic phase. Multiple pathways to disease transformation exist, but the exact timing and relevance of each remain unclear.

**CLINICAL PRESENTATION**

**Symptoms** The clinical onset of the chronic phase is generally insidious. Accordingly, some patients are diagnosed while still asymptomatic, during health screening tests; other patients present with fatigue, malaise, and weight loss or have symptoms resulting from splenic enlargement, such as early satiety and left upper quadrant pain or mass. Less common are features related to granulocytic and monocytic proliferation, such as purpura, splenomegaly, priapism, visual disturbances, and pulmonary insufficiency. Patients with p210BCR/ABL-positive CML have a more indolent course.

Progression of CML is associated with worsening symptoms. Unexplained fever, significant weight loss, increasing dose requirement of the drugs controlling the disease, bone and joint pain, bleeding, thrombosis, and infections suggest transformation into accelerated or blastic phases. Fewer than 10 to 15% of newly diagnosed patients present with accelerated disease or with de novo blastic phase CML.

**Physical Findings** In most patients the abnormal finding on physical examination at diagnosis is minimal to moderate splenomegaly; mild hepatomegaly is found occasionally. Persistent splenomegaly despite continued therapy is a sign of disease acceleration. Lymphadenopathy and myeloid sarcomas are unusual except late in the course of the disease; when they are present, the prognosis is poor.

**Hematologic Findings** Elevated white blood cell counts, with various degrees of immaturity of the granulocytic series, are present at diag-
nosis. Usually <5% circulating blasts and <10% blasts and promyelocytes are noted. Cycling of the counts may be observed in patients followed without treatment. Platelet counts are almost always elevated at diagnosis, and a mild degree of normochromic normocytic anemia is present. Leukocyte alkaline phosphatase is characteristically low in CML cells. Serum levels of vitamin B12 and vitamin B6,−binding proteins are generally elevated. Phagocytic functions are usually normal at diagnosis and remain normal during the chronic phase. Histamine production secondary to basophilia is increased in later stages, causing pruritus, diarrhea, and flushing.

At diagnosis, bone marrow cellularity, primarily of the myeloid and megakaryocytic lineages, with a greatly altered myeloid to erythroid ratio, is increased in almost all patients with CML. The marrow blast percentage is generally normal or slightly elevated. Marrow or blood basophilia, eosinophilia, and monocytosis may be present. While collagen fibrosis in the marrow is unusual at presentation, significant degrees of reticulin stain—measured fibrosis are noted in about half of the patients.

Disease acceleration is defined by the development of increasing degrees of anemia unaccounted for by bleeding or chemotherapy; cytogenetic clonal evolution; or blood or marrow blasts between 10 and 20%, blood or marrow basophils ≥20%, or platelet count <100,000/μl. Blast crisis is defined as acute leukemia, with blood or marrow blasts ≥20%. Hyposedent neutrophils may appear (Pelger-Huet anomaly). Blast cells can be classified as myeloid, lymphoid, erythroid, or undifferentiated, based on morphologic, cytochemical, and immunologic features. About half the cases are myeloid, one-third lymphoid, 10% erythroid, and the rest are undifferentiated.

Chromosomal Findings The cytogenetic hallmark of CML, found in 90 to 95% of patients, is the t(9;22)(q34;q11.2). Originally, this was recognized by the presence of a shortened chromosome 22 (22q−), designated as the Philadelphia chromosome, that arises from the reciprocal 9;22 translocation. Some patients may have complex translocations (designated as variant translocations) involving three, four, or five chromosomes (usually including chromosomes 9 and 22). However, the molecular consequences of these changes appear similar to those resulting from the typical t(9;22). All patients should have evidence of the translocation either by cytogenetics, FISH, or molecularly to make a diagnosis of CML.

Prognostic Factors The clinical outcome of patients with CML is variable. Before imatinib mesylate, death was expected in 10% of patients within 2 years and in about 20% yearly thereafter and the median survival time was ~4 years. Therefore, several prognostic models that identify different risk groups in CML have been developed. The most commonly used staging systems have been derived from multivariate analyses of prognostic factors. The Sokal index identified percentage of circulating blasts, spleen size, platelet count, cytogenetic clonal evolution, and age as the most important prognostic indicators. This system was based on chemotherapy-treated patients. The Hasford system was developed on interferon-α-treated patients. It identified age, spleen size, percentage of circulating blasts, platelet count, and percentage of eosinophils and basophils as the most important prognostic indicators. This system differs from the Sokal index by ignoring clonal evolution and incorporating percentage of eosinophils and basophils. When applied to a data set of 272 patients treated with interferon-α (IFN-α), the Hasford system was more potent than the Sokal score for predicting survival time; it identified more low-risk patients but left only a small number of cases in the high-risk group. The Hasford system has not yet been validated in patients undergoing transplantation. However, preliminary results suggest that it is applicable to imatinib-treated patients.

The therapy of CML is rapidly undergoing evolution because we have a curative treatment (allogeneic transplantation) that has significant toxicity and a new targeted treatment (imatinib) without long-term follow-up data. Therefore, physician experience and patient preference must be factored into the treatment selection process. Discussion of both treatment options with a patient is indicated. The decision should focus on the outcomes, risks, and toxicities of the various approaches.

At present, the goal of therapy in CML is to achieve prolonged, durable, nonneoplastic, nonclonal hematopoiesis, which entails the eradication of any residual cells containing the BCR/ABL transcript. Hence the goal is complete molecular remission and cure (Table 96-4). A proposed treatment plan for the newly diagnosed patient with CML is presented in Fig. 96-2.

* Complete hematologic response requires the disappearance of splenomegaly.

1 Up to 15% normal metaphases are occasionally seen at diagnosis (when 30 metaphases are analyzed).

Note: RT-PCR, reverse transcriptase polymerase chain reaction.

**FIGURE 96-2** Flow chart for the therapy of newly diagnosed CML. Patients with an HLA-compatible donor have the possibility to undergo allogeneic stem cell transplant (SCT) as initial therapy or treatment with imatinib. The asterisk denotes that some centers employ allogeneic SCT only if imatinib fails to induce a response. Broken lines denote lack of long-term survival data. IFN, interferon.
and histocompatible donor. Furthermore, survival after SCT in the accelerated and blastic phases of the disease is significantly diminished and is associated with a very high rate of relapse. The Seattle pre-imatinib data demonstrate that bone marrow transplantation (BMT) early in the chronic phase (1 to 2 years from diagnosis) is superior to later BMT.

**THE DONOR** Transplantation from a family donor, who is either fully matched or mismatched at only one HLA locus, should be considered the only curative therapy for any patient with CML who is a candidate for an HLA-related sibling transplant. Syngeneic BMT in patients with chronic phase CML has been reported from the Seattle group to result in 7-year disease-free survival in 55% of the patients, with a 30% relapse rate. With HLA-identical sibling BMT in the chronic phase, many groups have reported 5-year disease-free survival in 40 to 70% of patients, with a 25% relapse rate. BMT from an HLA-matched unrelated donor in chronic phase <1 year from diagnosis and <30 years resulted in similar 5-year disease-free survival as matched sibling donor transplantation. For all other groups, patients receiving transplants from unrelated individuals have higher rates of graft failure and acute and chronic GVHD and prolonged convalescence after treatment, compared to those who receive allogeneic transplants from related individuals. Peripheral blood is now being studied as a source of hematopoietic progenitor cells; it may offer rapid engraftment and less risk for the donor. With unrelated donors, some studies demonstrated no difference in GVHD and improved disease-free survival when comparing peripheral blood to bone marrow stem cells. No such data are available using matched sibling donors to date. At the current time, some centers collect bone marrow and some peripheral blood from siblings donors for newly diagnosed CML patients. Umbilical-cord blood may permit mismatched SCT with notably less GVHD; GVL effects do not appear to be impaired. A problem with cord blood is obtaining a sufficient number of progenitor cells to reconstitute hematopoiesis in an adult.

**PREPARATIVE REGIMENS** These regimens have been studied by several groups. A randomized study by the Seattle group compared cyclophosphamide and total-body irradiation with busulphan and cyclophosphamide. They found no significant differences in the 3-year probabilities of survival, relapse, event-free survival, speed of engraftment, or incidence of venoocclusive disease of the liver. Significantly more patients in the total-body irradiation arm experienced major elevations of creatinine, acute GVHD, longer periods of fever, positive blood cultures, hospital admissions, and longer inpatient hospital stays. However, increased chronic GVHD, obstructive broncholitis, and alopecia were noted with busulphan. Measurement of busulphan levels revealed no significant association between busulphan levels and regimen-related toxicity, but low levels were associated with an increased risk of relapse. Intravenous busulphan allows better control of serum levels. We tend to favor the use of busulphan and cyclophosphamide. Nonmyeloblative transplants in which the preparative regimen is aimed at eliminating host lymphocytes rather than bone marrow are being tested. Reduced toxicity with preserved antitumor efficacy is the goal.

**DEVELOPMENT AND TYPE OF GVHD** Development of grade I GVHD, as compared to no GVHD, decreases the risk of relapse. A lower relapse rate was observed also in patients with grade II GVHD but was accompanied by a substantially higher transplant-related mortality rate. The decreased relapse rate may be caused by a GVL effect. Depletion of T lymphocytes from donor marrow can prevent GVHD but results in an increased risk of relapse, which exceeds the relapse rate after syngeneic SCT. Thus, T lymphocytes from the donor marrow mediate a significant antileukemic, or GVL, effect, and even syngeneic marrow may exhibit limited GVL activity in CML.

**POSTTRANSPLANTATION TREATMENT** Further support for the existence of an immunologically mediated GVL effect came from the observation that donor leukocyte infusions (without any preparative chemotherapy or GVHD prophylaxis) can induce hematologic and cytogenetic remissions in patients with CML who have relapsed after allogeneic SCT.

Imatinib’s effect in the chronic phase of the disease prompted its study in patients who relapse after allogeneic SCT. Studies with small numbers of patients have proved that imatinib can control CML that has recurred after allogeneic SCT but is associated with myelosuppression and recurrence of severe GVHD. Imatinib studies after allogeneic SCT to prevent relapse in patients with advanced disease at the time of transplantation (patients at high risk for relapse) or patients undergoing non-myeloblative transplants are under way.

The activity of IFN-α in patients with early chronic-phase CML was the basis for the use of IFN-α after SCT, either to induce cytogenetic remissions in relapsed patients or to prevent relapse after SCT for high-risk patients. The main concern about IFN-α use after allogeneic SCT has been the development or worsening of GVHD, because IFN-α acts as an immunomodulator. IFN-α has also been combined with mononuclear cells obtained from donor blood to induce cytogenetic remissions in relapsed patients. Cytogenetic remissions have been achieved, but the exact role of IFN-α as opposed to the mononuclear cells is unclear.

**Imatinib Mesylate** Imatinib mesylate (Gleevec, STI571) functions through competitive inhibition at the adenosine triphosphate (ATP) binding site of the Abl kinase, which leads to inhibition of tyrosine phosphorylation of proteins involved in Bcr/Abl signal transduction. It shows a high degree of specificity for Bcr/Abl, the receptor for platelet-derived growth factor, and c-kit tyrosine kinases. Imatinib induces apoptosis in cells expressing Bcr/Abl. Based on its antileukemic activity in vitro it was tested in clinical trials.

Most patients with CML in chronic phase have a rapid hematologic response to imatinib therapy. In the initial studies with imatinib in patients with chronic-phase CML who were intolerant to IFN-α, 95% of patients achieved complete hematologic remission, and 60% achieved major cytogenetic remission, with a complete cytogenetic remission rate of 41%. Those who did not achieve at least a major cytogenetic remission following 3 months of therapy had a higher risk of disease progression to the accelerated/blastic phases of the disease. Patients in the accelerated/blastic phases of the disease are less sensitive to imatinib, and the treatment outcome is less favorable. In newly diagnosed CML, a recent randomized phase III study of imatinib (400 mg/d) versus IFN-α and cytarabine revealed the complete hematologic remission rate, at 18 months, of patients treated with imatinib to be 97% as compared to 69% in patients treated with IFN-α and cytarabine. Similarly, the complete cytogenetic remission rate was 76% in patients treated with imatinib as compared to 14% in patients treated with IFN-α and cytarabine. Progression to accelerated/blastic phases of the disease was noted in 3% of patients treated with imatinib as compared to 8.5% of patients treated with IFN-α and cytarabine. These results led to rapid Food and Drug Administration approval of imatinib for all stages of CML.

Imatinib is administered orally and has an acceptable toxicity profile. The main side effects are fluid retention, nausea, muscle cramps, diarrhoea, and skin rashes. The management of these side effects is usually supportive. Myelosuppression is the most common hematologic side effect, and patients who received busulphan are at a greater risk than patients who were treated with IFN-α. It seems to result from the eradication of the malignant clone and delayed recovery of the normal nonclonal progenitor cells. Blood and platelet support should be provided, and therefore dose reduction is rarely recommended in the absence of infection. Doses <300 mg/d seem ineffective and may lead to development of resistance.

Four mechanisms of resistance to imatinib have been described to date. These are (1) gene amplification, (2) mutations at the kinase site, (3) enhanced expression of multidrug exporter proteins, and (4) alternative signaling pathways functionally compensating for the imatinib-sensitive mechanisms. The unfavorable prognosis associated with
Imatinib-resistance was shown in the accelerated and blast crisis phases of the disease. Specifically, patients who do not achieve major cytogenetic remission within 3 months of initiation of imatinib have shorter survival than patients who achieve that level of remission. Therefore, all four mechanisms are being targeted in clinical trials.

The encouraging results with imatinib have led many clinicians to offer it as a first-line therapy for newly diagnosed CML patients, including those who otherwise would have benefited from transplant (e.g., young patients with a sibling matched donor). This may be unwise since the clinical studies so far have very short follow-up, thus limiting knowledge regarding the curative potential of imatinib. Delaying transplantation until after development of imatinib resistance may worsen outcome.

Interferons When allogeneic SCT is not feasible, IFN-α therapy used to be the treatment of choice before imatinib became available. Only longer follow-up of patients treated with imatinib will prove whether IFN-α will still have a role in the treatment of CML. The interferons are a complex group of naturally occurring proteins produced by eukaryotic cells in response to viruses, antigens, and mitogens. Three distinct groups of IFN species have been identified: IFN-α, -β and -γ. Although various interferons have become available for clinical investigation, most data have been generated with IFN-α preparations.

Interferons have potent, pleiotropic biologic effects, spanning a spectrum of antiviral, microbicidal, immunomodulatory, and antiproliferative properties. While interferons downregulate the expression of several oncoproteins and cytokines, they also upregulate the expression of IFN regulatory factor-1 (a transcriptional activator with antioncogenic activity), adhesion molecules, and the histocompatibility genes. Interferons also inhibit angiogenesis and induce a cellular immune response. However, the mode(s) of action in CML is still unknown.

In randomized studies comparing IFN-α and chemotherapy, patients treated with IFN-α survived longer than patients treated with hydroxyurea or busulphan. The 5-year survival rate was 51% with IFN-α and 42% with chemotherapy. Of note, achieving complete cytogenetic or molecular response after IFN-α therapy is associated with a 10-year survival rate as high as 78%.

Patients develop both acute and chronic side effects from IFN-α therapy. Acute side effects (flu-like symptoms) appear early in the course of the treatment. Most flu-like symptoms respond to acetaminophen, and tachyphylaxis develops within 1 to 2 weeks. Chronic reactions, such as fatigue and lethargy, depression, weight loss, myalgias, and arthralgias, occur in about half of the patients and often require dose reduction. Patients also report cough, postnasal drip, and dryness of the skin. Infrequently, immune-mediated thrombocytopenia and anemia develop. In addition, long-term therapy has been associated with late autoimmune side effects, such as hypothyroidism and occasionally generalized autoimmune phenomena.

The most important persistent side effects in patients with CML who are treated with IFN-α are neurologic. All patients treated with IFN-α are subject to some neurologic toxicity, the most common symptom being lethargy. Up to 20% of patients have neurologic side effects that are associated with compromised quality of life and reduced ability to carry out their regular activity, such as full-time work. In addition, at the required doses, impotence in men is not infrequent. The combination of IFN-α with cytarabine has produced better results in one study but not in another.

Chemotherapy Innovative approaches are still important in CML; the exact role of imatinib in the armamentarium of CML remains undefined. Initial management of patients with chemotherapy is currently reserved for rapid lowering of white blood cell counts, reduction of symptoms, and reversal of symptomatic splenomegaly. Hydroxyurea, a ribonucleotide reductase inhibitor, induces rapid disease control. The initial dose is 1 to 4 g/d; the dose should be halved with each 50% reduction of the leukocyte count. Unfortunately, cytogenetic remissions with hydroxyurea are uncommon. Busulphan, an alkylating agent that acts on early progenitor cells, has a more prolonged effect. However, we do not recommend its use because of its serious side effects, which include unexpected and occasionally fatal, myelosuppression in 5 to 10% of patients; pulmonary, endocardial, and marrow fibrosis; and an Addison-like wasting syndrome.

Homoharringtonine (HHT) is a plant alkaloid derived from a tree, Cephalotaxus fortunei sp. harringtonii. HHT blocks peptide bond formation after binding of the aminoacyl-transfer RNA to the ribosome. In patients whose disease progressed during treatment with IFN-α or who were in later chronic phase (>1 year from diagnosis), HHT induced 72% complete hematologic responses and 15% major cytogenetic responses. The use of HHT before IFN-α in early chronic phase resulted in a 92% complete hematologic response rate and a 27% major cytogenetic response rate. Toxicity is mainly related to myelosuppression. In vitro synergism between arsenic trioxide and imatinib have led to the development of combination trials.

Arsenic trioxide gained recognition as a therapeutic agent following reports from China of a high incidence of favorable hematologic responses in patients with APL. The mechanism(s) of action of arsenic trioxide in non-APL leukemias is unknown. Initial studies of arsenic trioxide in Bcr/Abl-expressing cell lines demonstrated downregulation of Bcr/Abl expression as well as activation of apoptosis. More recent studies have demonstrated an initial effect of arsenic trioxide on Bcr/Abl expression prior to activation of the apoptotic pathway. In vitro synergism between arsenic trioxide and imatinib have led to the clinical investigation of this combination.

Intensive combination chemotherapy has also been used in chronic-phase CML, with 30 to 50% of patients achieving complete cytogenetic responses. However, these cytogenetic remissions have been short-lived. Consequently, intensive combination chemotherapy regimens are being used today only to mobilize normal progenitors in the blood in order to collect circulating stem cells for autologous transplantation.

Autologous SCT Autologous SCT could potentially cure CML if a means to select the residual normal progenitors, which coexist with their malignant counterparts, could be developed. As a source of autologous hematopoietic stem cells for transplantation, blood offers certain advantages over marrow (e.g., faster engraftment for the patient and no general anesthesia for the donor). Normal hematopoietic stem cells appear with increased frequency in the blood of patients with CML during the recovery phase after chemotherapy and G-CSF. A role for imatinib before stem cell collection to achieve minimal residual disease and following transplantation to maintain this status is currently being investigated. However, only a few cases have been reported to successfully engraft following imatinib therapy. Therefore such approaches should be performed only in clinical trials.

Leukapheresis and Splenectomy Intensive leukapheresis may control the blood counts in chronic-phase CML; however, it is expensive and cumbersome. It is useful in emergencies where leukostasis-related complications such as pulmonary failure or cerebrovascular accidents are likely. It may also have a role in the treatment of pregnant women in whom it is important to avoid potentially teratogenic drugs.

Splenectomy was used in CML in the past because of the suggestion that evolution to the acute phase might occur in the spleen. However, this does not appear to be the case, and splenectomy is now reserved for symptomatic relief of painful splenomegaly unresponsive to chemotherapy or for significant anemia or thrombocytopenia associated with hypersplenism. Splenic radiation is used rarely to reduce the size of the spleen.

Minimal Residual Disease After allogeneic SCT, RT-PCR analysis may be positive for residual disease during the first 6 months in patients who subsequently achieve a long-lasting remission. However, late persistence of RT-PCR positivity appears to indicate a reduced probability of cure. RT-PCR positivity at any single time point is not predictive of imminent relapse. After allogeneic SCT, patients are often divided according to RT-PCR results into one of three groups: (1) persistently positive, (2) intermittently negative, and (3) persistently negative.

have been developed based on the effect of IFN-α in the chronic phase of the disease, imatinib with IFN-α or with its long-acting (pegylated) member are being studied. Likewise, based on the combined effect of cytarabine and IFN-α, a regimen of imatinib and cytarabine is being evaluated. The results from these trials are premature at this point. However, they will most probably lead to a randomized trial of ima-
tinib versus imatinib with IFN-α versus imatinib with cytarabine.

After IFN-α therapy, residual disease was found in all samples tested from patients with complete cytogenetic remissions. More recent studies have demonstrated the eventual elimination of the BCR/

ABL mRNA transcript after more prolonged IFN-α treatment in some cases.

Future Directions Abrogation of DNA methylation with 5-aza-2’deoxy-
cytidine (decitabine) has shown clinical activity in the advanced stages of the disease. Inhibition of Ras with a farnesyl transferase inhibitor that blocks its insertion into the membrane may have anti-
tumor activity in CML on the basis of early clinical trials. Preclinical efforts to use Bcr/Abl peptides as a tumor vaccine appear promising. The use of BCR/ABL antisense oligonucleotides to purge residual leukemic cells from autologous hematopoietic progenitors before rein-
fusion, as well as new approaches to induce GVL in the setting of minimal residual disease without inducing GVHD, are under way. All these agents and others are being or will be studied in combination with imatinib. Further, treatment with the histone deacetylase inhibitor suberoylanilide hydroxamic acid (SAHA) was shown to enhance im-
atinib-induced apoptosis of Bcr/Abl-positive cell lines, and the heat-

BIOLOGY OF LYMPHOID MALIGNANCIES: CONCEPTS OF THE WHO CLASSIFICATION OF LYMPHOID MALIGNANCIES

The classification of lymphoid cancers evolved steadily throughout the twentieth century. The distinction between leukemia and lymphoma was made early, and separate classification systems were developed for each. Leukemias were first divided into acute and chronic subtypes based on average survival. Chronic leukemias were easily subdivided into those of lymphoid or myeloid origin based on morphologic characteristics. However, in recent years, a spectrum of diseases that were formerly all called chronic lymphoid leukemia has become apparent (Table 97-1). The acute leukemias were usually malignancies of blast cells with few identifying characteristics. When cytochemical stains became available, it was possible to divide these objectively into myeloid malignancies and acute leukemias of lymphoid cells. Acute leu-
kemias of lymphoid cells have been subdivided based on morphologic characteristics by the French-American-British (FAB) group (Table 97-2). Using this system, lymphoid malignancies of small uniform blasts (e.g., typical childhood acute lymphoblastic leukemia) were called L1, lymphoid malignancies with larger and more variable size cells were called L2, and lymphoid malignancies of uniform cells with basophilic and sometimes vacuolated cytoplasm were called L3 (e.g., typical Burkitt’s lymphoma cells). Acute leukemias of lymphoid cells have also been subdivided based on immunologic (i.e., T cell vs. B cell) and cytogenetic abnormalities (Table 97-2). Major cytogenetic subgroups include the t(9;22) (e.g., Philadelphia chromosome–positive acute lymphoblastic leukemia) and the t(8;14) found in the L3 or Burkitt’s leukemia.

Non-Hodgkin’s lymphomas were separated from Hodgkin’s disease by recognition of the Sternberg-Reed cells early in the twentieth century. The histologic classification for non-Hodgkin’s lymphomas was has been one of the most contentious issues in oncology. Imperfect morphologic systems were supplanted by imperfect immunologic systems, and poor reproducibility of diagnosis has hampered progress. In 1999, the World Health Organization (WHO) classification of lymphoid malignancies was devised through a process of consensus development among international leaders in hematopathology and clinical oncology. The WHO classification takes into account morphologic, clinical, immunologic, and genetic information and attempts to divide non-Hodgkin’s lymphomas and other lymphoid malignancies into clinical/pathologic entities that have clinical and therapeutic relevance. This system is presented in Table 97-3. Clinical studies have shown that this new system is clinically relevant and has a higher degree of diagnostic accuracy than those used previously. The possibilities for subdividing lymphoid malignancies are extensive. However, Table 97-3 presents in bold those malignancies that occur in at least 1% of patients. Specific lymphoma subtypes will be dealt with in more detail below.

Etiology and Epidemiology

Chronic lymphoid leukemia (CLL) is the most prevalent form of leukemia in western countries. It occurs most frequently in older adults and is exceedingly rare in children. In 2004, 8190 new cases were diagnosed in the United States, but because of the prolonged survival associated with this disorder, the total prevalence is many times higher. CLL is more common in men than in women and more common in whites than in blacks. This is an uncommon malignancy in Asia. The etiologic factors for typical CLL are unknown.

In contrast to CLL, acute lymphoid leukemias (ALLs) are predominantly cancers of children and young adults. The L3 or Burkitt’s leukemia occurring in children in developing countries seems to be associated with infection by the Epstein-Barr virus (EBV) in infancy. However, the explanation for the etiology of more common subtypes of ALL is much less certain. Childhood ALL occurs more often in higher socioeconomic subgroups. Children with trisomy 21 (Downs syndrome) have an increased risk for childhood acute lymphoblastic leukemia as well as acute myeloid leukemia. Exposure to high-energy radiation in early childhood increases the risk of developing T cell acute lymphoblastic leukemia.

The etiology of ALL in adults is also uncertain. ALL is unusual in middle-aged adults but increases in incidence in the elderly. However, acute myeloid leukemia is still much more common in older patients. Environmental exposures including certain industrial exposures, exposure to agricultural chemicals, and smoking might increase the risk of developing ALL as an adult.

The preponderance of evidence suggests that Hodgkin’s disease is of B cell origin. The incidence of Hodgkin’s disease appears fairly stable, with ~7800 new cases diagnosed in 2004 in the United States. Hodgkin’s disease is more common in whites than in blacks and more common in males than in females. A bimodal distribution of age at diagnosis has been observed, with one peak incidence occurring in patients in their 20s and the other in those in their 80s.
Some of the late age peak may be attributed to confusion among entities with similar appearance such as anaplastic large cell lymphoma and T cell–rich B cell lymphoma. Patients in the younger age groups diagnosed in the United States have the nodular sclerosing subtype of Hodgkin’s disease. Elderly patients, patients infected with HIV, and patients in third world countries more commonly have mixed-cellularity Hodgkin’s disease or lymphocyte-depleted Hodgkin’s disease. Infection by HIV is a risk factor for developing Hodgkin’s disease. In addition, an association between infection by EBV and Hodgkin’s disease has been demonstrated. A monoclonal or oligoclonal proliferation of EBV-infected cells in 20 to 40% of the patients with Hodgkin’s disease has led to proposals for this virus having an etiologic role in Hodgkin’s disease. However, the matter is not settled definitively.

For unknown reasons, non-Hodgkin’s lymphomas increased in frequency in the United States at the rate of 4% per year between 1950 and the late 1990s. For uncertain reasons, the rate of increase in the past few years seems to be decreasing. About 54,000 new cases of non-Hodgkin’s lymphoma were diagnosed in the United States in the year 2004. Non-Hodgkin’s lymphomas are more frequent in the elderly and more frequent in men. Patients with both primary and secondary immunodeficiency states are predisposed to developing non-Hodgkin’s lymphomas. These include patients with HIV infection; patients who have undergone organ transplantation; and patients with inherited immune deficiencies, the sicca syndrome, and rheumatoid arthritis.

The incidence of non-Hodgkin’s lymphomas and the patterns of expression of the various subtypes differ geographically. T cell lymphomas are more common in Asia than in western countries, while certain subtypes of B cell lymphomas such as follicular lymphoma are more common in western countries. A specific subtype of non-Hodgkin’s lymphoma known as the angiocentric nasal T/natural killer (NK) cell lymphoma has a striking geographic occurrence, being most frequent in Southern Asia and parts of Latin America. Another subtype of non-Hodgkin’s lymphoma associated with infection by human T cell lymphotropic virus (HTLV) I is seen particularly in southern Japan and the Caribbean (Chap. 172).

A number of environmental factors have been implicated in the occurrence of non-Hodgkin’s lymphoma, including infectious agents, chemical exposures, and medical treatments. Several studies have demonstrated an association between exposure to agricultural chemicals and an increased incidence in non-Hodgkin’s lymphoma. Patients treated for Hodgkin’s disease can develop non-Hodgkin’s lymphoma; it is unclear whether this is a consequence of the Hodgkin’s disease or its treatment. However, the infectious etiology of non-Hodgkin’s lymphoma is the area where evidence has been expanding most rapidly in recent years. Table 97-4 illustrates those infectious agents associated with the development of non-Hodgkin’s lymphoma. HTLV-I infects T cells and leads directly to the development of adult T cell lymphoma (ATL) in a small percentage of infected patients. The cumulative lifetime risk of developing lymphoma in an infected patient is 2.5%. The virus is transmitted by infected lymphocytes ingested by nursing babies of infected mothers, blood-borne transmission, or sexually. The median age of patients with ATL is about 56 years, emphasizing the long latency. HTLV-I is also the cause of tropical spastic paraparesis—a neurologic disorder that occurs somewhat more frequently than lymphoma and with shorter latency.

EBV is associated with the development of Burkitt’s lymphoma in Central Africa and the occurrence of aggressive non-Hodgkin’s lymphomas in immunosuppressed patients in western countries. The majority of primary central nervous system (CNS) lymphomas are associated with EBV. EBV infection is strongly associated with the occurrence of extranodal nasal T/NK cell lymphomas in Asia and South America. Infection with HIV predisposes to the development of aggressive, B cell non-Hodgkin’s lymphoma. This may be through overexpression of interleukin 6 by infected macrophages. Infection of the stomach by the bacterium Helicobacter pylori induces the development of gastric MALT (mucosa-associated lymphoid tissue) lymphomas. This association is supported by evidence that patients treated with antibiotics to eradicate Helicobacter pylori have regression of their MALT lymphoma. The bacterium does not transform lymphocytes to produce the lymphoma; instead, a vigorous immune response is made to the bacterium and the chronic antigenic stimulation leads to the neoplasia. MALT lymphomas of the skin may be related to Borrelia sp. infections.

Chronic hepatitis C virus infection has been associated with the development of lymphoplasmycatic lymphoma. Human herpesvirus 8 is associated with primary effusion lymphoma in HIV-infected persons and multicentric Castleman’s disease, a diffuse lymphadenopathy associated with systemic symptoms of fever, malaise, and weight loss.

In addition to infectious agents, a number of other diseases or exposures may predispose to developing lymphoma (Table 97-5).

**IMMUNOLOGY**

All lymphoid cells are derived from a common hematopoietic progenitor that gives rise to lymphoid, myeloid, erythroid, monocye, and megakaryocyte lineages. Through the ordered and sequential activation of a series of transcription factors, the cell first becomes committed to the lymphoid lineage and then gives rise to B and T cells. About 75% of all lymphoid leukemias and 90% of all lymphomas are of B cell origin. A cell becomes committed to B cell development when it begins to rearrange its immunoglobulin genes. The sequence of cellular changes, including changes in cell-surface phenotype, that characterizes normal B cell development is shown in Fig. 97-1. A cell becomes committed to T cell differentiation upon migration to the thymus and rearrangement of T cell antigen receptor genes. The sequence of the events that characterize T cell development is depicted in Fig. 97-2.

Although lymphoid malignancies often retain the cell-surface phenotype of lymphoid cells at particular stages of differentiation, this information is of little consequence. The so-called stage of differentiation of a malignant lymphoma does not predict its natural history. For example, the clinically most aggressive lymphoid leukemia is

Antigen-independent differentiation

Burkitt’s leukemia, which has the phenotype of a mature follicle center IgM-bearing B cell. Leukemias bearing the immunologic cell-surface phenotype of more primitive cells (e.g., pre-B ALL, CD10+) are less aggressive and more amenable to curative therapy than the “more mature” appearing Burkitt’s leukemia cells. Furthermore, the apparent stage of differentiation of the malignant cell does not reflect the stage at which the genetic lesions that gave rise to the malignancy developed. For example, follicular lymphoma has the cell-surface phenotype of a follicle center cell, but its characteristic chromosomal translocation, the t(14;18), which involves juxtaposition of the anti-immunoglobulin heavy chain gene rearrangement (HCR) and light chain gene rearrangement or deletion (κ R or D, λ R or D) occur early in B cell development. The approximate normal stage of differentiation associated with particular lymphomas is shown. ALL, acute lymphoid leukemia; CLL, chronic lymphoid leukemia; SL, small lymphocytic lymphoma.

Malignancies of lymphoid cells are associated with recurring genetic abnormalities. While specific genetic abnormalities have not been identified for all subtypes of lymphoid malignancies, it is presumed that they exist. Genetic abnormalities can be identified at a variety of levels including gross chromosomal changes (i.e., translocations, additions, or deletions); rearrangement of specific genes that may or may not be apparent from cytogenetic studies; and overexpression, underexpression, or mutation of specific oncogenes. Altered expression or mutation of specific proteins is particularly important. Many lymphomas contain balanced chromosomal translocations involving the antigen receptor genes; immunoglobulin genes on chromosomes 2, 14, and 22 in B cells; and T cell antigen receptor genes on chromosomes 7 and 14 in T cells. The rearrangement of chromosome segments to generate mature antigen receptors must create a site of vulnerability to aberrant recombination. B cells are even more susceptible to acquiring mutations during their maturation in germinal centers; the generation of antibody of higher affinity requires the introduction of mutations into the variable region genes in the germinal centers. Other nonimmunoglobulin genes, for example bcl-6, may acquire mutations as well.

In the case of diffuse large B cell lymphoma, the translocation t(14;18) occurs in ~30% of patients and leads to overexpression of the bcl-2 gene found on chromosome 18. Some other patients without the translocation also overexpress the BCL-2 protein. This protein is involved in suppressing apoptosis—i.e., the mechanism of cell death most often induced by cytotoxic chemotherapeutic agents. A higher relapse rate has been observed in patients whose tumors overexpress the BCL-2 protein, but not in those patients whose lymphoma cells show only the translocation. Thus, particular genetic mechanisms have clinical ramifications.

Table 97-6 presents the best documented translocations and associated oncogenes for various subtypes of lymphoid malignancies. In some cases, such as the association of the t(14;18) in follicular lymphoma, the t(2;5) in anaplastic large T/null-cell lymphoma, the t(8;14) in Burkitt’s lymphoma, and the t(11;14) in mantle cell lymphoma, the great majority of tumors in patients with these diagnoses display these abnormalities. In other types of lymphoma where a minority of the patients have tumors expressing specific genetic abnormalities, the defects may have prognostic significance. No specific genetic abnormalities have been identified in Hodgkin’s disease other than aneuploidy.

In typical B cell CLL, trisomy 12 conveys a poorer prognosis. In ALL in both adults and children, genetic abnormalities have important prognostic significance. Patients whose tumor cells display the t(9;22) have a much poorer outlook than patients who do not have this translocation. Other genetic abnormalities that occur frequently in adults with ALL include the t(4;11) and the t(8;14). The t(4;11) is associated with younger age, female predominance, high white cell counts, and L1 morphology. The t(8;14) is associated with older age, male predominance, frequent CNS involvement, and L3 morphology. Both are associated with a poor prognosis. In childhood ALL, hyperdiploidy has been shown to have a favorable prognosis.

Gene profiling using array technology allows the simultaneous assessment of the expression of thousands of genes. This technology provides the possibility to identify new genes with pathologic importance in lymphomas, the identification of patterns of gene expression with diagnostic and/or prognostic significance, and the identification of genetic expression, the identification of patterns of gene expression with diagnostic and/or prognostic significance, and the identification of genetic.
of new therapeutic targets. Recognition of patterns of gene expression is complicated and requires sophisticated mathematical techniques. Early successes using this technology in lymphoma include the identification of previously unrecognized subtypes of diffuse large B cell lymphoma. The challenge remains to provide information from such studies, and to determine if these subgroups of patients provide the opportunity to identify better treatments for these subgroups of patients. Similar information is being generated in follicular lymphoma and mantle cell lymphoma. The challenge remains to provide information from such techniques in a clinically useful time frame.

Regardless of the type of lymphoid malignancy, the initial evaluation of the patient should include performance of a careful history and physical examination. These will help confirm the diagnosis, identify those manifestations of the disease that might require prompt attention, and aid in the selection of further studies to optimally characterize the patient’s status to allow the best choice of therapy. It is difficult to overemphasize the importance of a carefully done history and physical examination. They might provide observations that lead to reconsidering the diagnosis, provide hints at etiology, clarify the stage, and allow the physician to establish rapport with the patient that will make it possible to develop and carry out a therapeutic plan.

For patients with ALL, evaluation is usually completed after a complete blood count, chemistry studies reflecting major organ function, a bone marrow biopsy with genetic and immunologic studies, and a lumbar puncture. The latter is necessary to rule out occult CNS involvement. At this point, most patients would be ready to begin therapy. In ALL, prognosis is dependent upon the genetic characteristics of the tumor, the patient’s age, the white cell count, and the patient’s overall clinical status and major organ function.

In CLL, the patient evaluation should include a complete blood count, chemistry tests to measure major organ function, serum protein electrophoresis, and a bone marrow biopsy. However, some physicians believe that the diagnosis would not always require a bone marrow biopsy. Patients often have imaging studies of the chest and abdomen looking for pathologic lymphadenopathy. Patients with typical B cell CLL can be subdivided into three major prognostic groups. Those patients with only blood and bone marrow involvement by leukemia but no lymphadenopathy, organomegaly, or signs of bone marrow failure have the best prognosis. Those with lymphadenopathy and organomegaly have an intermediate prognosis, and patients with bone marrow failure, defined as hemoglobin <100 g/L (10 g/dL) or platelet count <100,000/μL, have the worst prognosis. The pathogenesis of the anemia or thrombocytopenia is important to discern. The prognosis is adversely affected when either or both of these abnormalities are due to progressive marrow infiltration and loss of productive marrow. However, either or both may be due to autoimmune phenomena or to hypersplenism that can develop during the course of the disease. These destructive mechanisms are usually completely reversible (glucocorticoids for autoimmune disease; splenectomy for hypersplenism) and do not influence disease prognosis.

Two popular staging systems have been developed to reflect these prognostic groupings (Table 97-7). Patients with typical B cell CLL can have their course complicated by immunologic abnormalities including autoimmune hemolytic anemia, autoimmune thrombocytopenia, and hypogammaglobulinemia. Patients with hypogammaglobulinemia benefit from regular (monthly) γ globulin administration. Because of expense, γ globulin is often withheld until the patient experiences a significant infection. These abnormalities do not have a clear prognostic significance and should not be used to assign a higher stage.

The initial evaluation of a patient with Hodgkin’s disease or non-Hodgkin’s lymphoma is similar. In both situations, the determination of an accurate anatomic stage is an important part of the evaluation. The staging system is the Ann Arbor staging system originally developed for Hodgkin’s disease (Table 97-8).
FIGURE 97-3  Relationship of different gene expression patterns to outcome of treatment for diffuse large B cell lymphoma. The top panel reveals the pattern of expression of a large number of lymphocyte-expressed genes in tumors from patients with diffuse large B cell lymphoma, a lymphoma recognized as morphologically heterogeneous but before now not classifiable reproducibly. Two dominant patterns are seen, one mimicking germinal center B cells and one mimicking activated peripheral blood B cells.

The bottom panels show the relationship between gene expression pattern and clinical outcome. A. Kaplan-Meier survival plots of all patients according to gene profile showing significant differences between follicular center and activated B cell types. B. Kaplan-Meier survival of patients based upon the IPI scores. C. Kaplan-Meier survival plots showing that among patients with IPI low risk, the gene expression profile has prognostic significance. (IPI, International Prognostic Index.)

| A     | No symptoms |
| B     | Unexplained weight loss of >10% of the body weight during the 6 months before staging investigation |
|       | Unexplained, persistent, or recurrent fever with temperatures >38°C during the previous month |
|       | Recurrent drenching night sweats during the previous month |
| E     | Localized, solitary involvement of extralymphatic tissue, excluding liver and bone marrow |

Evaluation of patients with Hodgkin’s disease will typically include a complete blood count; erythrocyte sedimentation rate; chemistry studies reflecting major organ function; computed tomography (CT) scans of the chest, abdomen, and pelvis; and a bone marrow biopsy. Neither a positron emission tomography (PET) scan nor a gallium scan is absolutely necessary for primary staging, but one performed at the completion of therapy allows evaluation of persisting radiographic abnormalities, particularly the mediastinum. Knowing that the PET scan or gallium scan is abnormal before treatment is initiated can help in this assessment. In most cases, these studies will allow assignment of anatomic stage and the development of a therapeutic plan.

In patients with non-Hodgkin’s lymphoma, the same evaluation described for patients with Hodgkin’s disease is usually carried out. In addition, serum levels of lactate dehydrogenase (LDH) and β₂-microglobulin and serum protein electrophoresis are often included in the evaluation. Anatomic stage is assigned in the same manner as used for Hodgkin’s disease. However, the prognosis of patients with non-Hodgkin’s lymphoma is best assigned using the International Prognostic Index (IPI) (Table 97-9). This is a powerful predictor of outcome in all subtypes of non-Hodgkin’s lymphoma. Patients are assigned an IPI score based on the presence or absence of five adverse prognostic factors. Figure 97-4 shows the prognostic significance of this score in 1300 patients with all types of non-Hodgkin’s lymphoma. CT scans are routinely used in the evaluation of patients with all subtypes of non-Hodgkin’s lymphoma but PET and gallium scans are much more useful in aggressive subtypes such as diffuse large B cell lymphoma than in more indolent subtypes such as a follicular lymphoma or small lymphocytic lymphoma.

Patients are assigned a number for each risk factor they have. Patients are grouped differently based upon the type of lymphoma. For diffuse large B cell lymphoma:

- 0,1 factor = low risk
- 2 factors = low-intermediate risk
- 3 factors = high-intermediate risk
- 4,5 factors = high risk

CLINICAL FEATURES, TREATMENT, AND PROGNOSIS OF SPECIFIC LYMPHOID MALIGNANCIES

PRECURSOR CELL B CELL NEOPLASMS Pre-B cell Lymphoblastic Leukemia/Lymphoma The most common cancer in childhood is B cell ALL. Although this disorder can also present as a lymphoma in either adults or children, presentation as lymphoma is quite rare. The malignant cells in patients with precursor B cell lymphoblastic leukemia are most commonly of pre-B cell origin. Patients typically present with signs of bone marrow failure such as pallor, fatigue, bleeding, fever, and infection related to peripheral blood cytopenias. Peripheral blood counts regularly show anemia and thrombocytopenia but might show leukopenia, a normal leukocyte count, or leukocytosis based largely on the number of circulating malignant cells (Fig. 97-5). Extranodal sites of disease are frequently involved in patients who...
MATURE (PERIPHERAL) B CELL NEOPLASMS

I high cure rate has been reported. Few patients who present with the disease confined to lymph nodes, as are used in patients presenting with leukemia, are appropriate. In the precursor B cell lymphoblastic malignancy. These patients often have cytogenetic abnormalities seen in adults with precursor B cell leukemia.

The evaluation of a new patient with typical B cell CLL/small lymphocytic lymphoma based on morphologic findings and immunophenotype. However, even in these patients, ~70 to 75% will be found to have bone marrow involvement and the search for circulating monoclonal B lymphocytes is often positive.

The differential diagnosis of typical B cell CLL is extensive and presented in Table 97-1. Immunophenotyping will eliminate the T cell disorders and can often help sort out other B cell malignancies. For example, only mantle cell lymphoma and typical B cell CLL are usually CD5 positive. Typical B cell small lymphocytic lymphoma can be confused with other B cell disorders including lymphoplasmacytic lymphoma (i.e., the tissue manifestation of Waldenström’s macroglobulinemia), nodal marginal zone B cell lymphoma, and mantle cell lymphoma. In addition, some small lymphocytic lymphomas have areas of large cells that can lead to confusion with diffuse large B cell lymphoma. An expert hematopathologist is vital for making this distinction.

Typical B cell CLL is often found incidentally when a complete blood count is done for another reason. However, complaints that might lead to the diagnosis include fatigue, frequent infections, and new lymphadenopathy. The diagnosis of typical B cell CLL should be considered in a patient presenting with an autoimmune hemolytic anemia or autoimmune thrombocytopenia. B cell CLL has also been associated with red cell aplasia. When this disorder presents as lymphoma, the most common abnormality is asymptomatic new lymphoma. In addition, some small lymphocytic lymphomas have areas of large cells that can lead to confusion with diffuse large B cell lymphoma. An expert hematopathologist is vital for making this distinction.

phocytic lymphoma will include many of the studies included in Table 97-11, which describes the initial evaluation of a new patient with non-Hodgkin’s lymphoma. In addition, particular attention needs to be given to detecting immune abnormalities such as autoimmune hemolytic anemia, autoimmune thrombocytopenia, hypogammaglobulinemia, and red cell aplasia. Molecular analysis of immunoglobulin gene sequences in CLL has demonstrated that about half the patients have tumors expressing mutated immunoglobulin genes and half have tumors expressing unmutated or germ-line immunoglobulin sequences. Patients with unmutated immunoglobulins tend to have a more aggressive clinical course and are less responsive to therapy. Unfortunately, immunoglobulin gene sequencing is not routinely available. CD38 expression is said to be low in the better-prognosis patients expressing mutated immunoglobulin and high in poorer-prognosis patients expressing unmutated immunoglobulin, but this test has not been confirmed as a reliable means of distinguishing the two groups.

**TREATMENT**

Patients whose presentation is typical B cell CLL with no manifestations of the disease other than bone marrow involvement and lymphocytosis (i.e., Rai stage 0 and Binet stage A; Table 97-7) can be followed without specific therapy for their malignancy. These patients have a median survival >10 years, and some will never require therapy for this disorder. If the patient has an adequate number of circulating normal blood cells and is asymptomatic, many physicians would not initiate therapy for patients in the intermediate stage of the disease manifested by lymphadenopathy and/or hepatosplenomegaly. However, the median survival for these patients is ~7 years, and most will require treatment in the first few years of follow-up. Patients who present with bone marrow failure (i.e., Rai stage III or IV or Binet stage C) will require initial therapy in almost all cases. These patients have a serious disorder with a median survival of only 1.5 years. It must be remembered that immune manifestations of typical B cell CLL should be managed independently of specific antileukemia therapy. For example, glucocorticoid therapy for autoimmune cytopenias and γ globulin replacement for patients with hypogammaglobulinemia should be used whether or not antileukemia therapy is given.

Patients who present primarily with lymphoma and have a low IPI score have a 5-year survival of ~75%, but those with a high IPI score have a 5-year survival of <40% and are more likely to require early therapy.

The most common treatments for patients with typical B cell CLL/small lymphocytic lymphoma have been single-agent chlorambucil or fludarabine alone or in combination. Chlorambucil can be administered orally with few immediate side effects, while fludarabine is administered intravenously and is associated with significant immune suppression. However, fludarabine is by far the more active agent and is the only drug associated with a significant incidence of complete remission. The combination of rituximab (375 to 500 mg/m² day 1), fludarabine (25 mg/m² days 2 to 4 on cycle 1 and 1 to 3 in subsequent cycles), and cyclophosphamide (250 mg/m² with fludarabine) achieves complete responses in 69% of patients and those responses are associated with molecular remissions in half of the cases. Half the patients experience grade III or IV neutropenia. For young patients presenting with leukemia requiring therapy, regimens containing fludarabine are today the treatment of choice. Because fludarabine is an effective second-line agent in patients with tumors unresponsive to chlorambucil, the latter agent is often chosen in elderly patients who require therapy. Many patients who present with lymphoma will receive a combination chemotherapy regimen used in other lymphomas such as CVP (cyclophosphamide, vincristine, and prednisone), or CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) although fludarabine-containing regimens may be preferable. Alemtuzumab (anti-CD52) is another antibody with activity in the disease, but it kills both B and T cells and is associated with more immune compromise that rituximab. Young patients with this disease can be candidates for bone marrow transplantation. Allogeneic bone marrow transplantation can be curative but is associated with a significant treatment-related mortality. The use of autologous transplantation in patients with this disorder has been discouraging.

**Extranodal Marginal Zone B Cell Lymphoma of MALT Type**

Extranodal marginal zone B cell lymphoma of MALT type makes up ~8% of non-Hodgkin’s lymphomas. This small-cell lymphoma presents in extranodal sites. It was previously considered a small lymphocytic lymphoma or sometimes a pseudolymphoma. The recognition that the gastric presentation of this lymphoma was associated with *H. pylori* infection was an important step in recognizing it as a separate entity. The clinical characteristics of extranodal marginal zone B cell lymphoma of MALT type are presented in Table 97-10.

The diagnosis of extranodal marginal zone B cell lymphoma of MALT type can be made accurately by an expert hematopathologist based on a characteristic pattern of infiltration of small lymphocytes that are monoclonal B cells and CD5 negative. In some cases, transformation to diffuse large B cell lymphoma occurs, and both diagnoses may be made in the same biopsy. The differential diagnosis includes benign lymphocytic infiltration of extranodal organs and other small-cell B cell lymphomas.

Extranodal marginal zone B cell lymphoma of MALT type may occur in the stomach, orbit, intestine, lung, thyroid, salivary gland, skin, soft tissues, bladder, kidney, and CNS. It may present as a new mass, be found on routine imaging studies, or be associated with local symptoms such as upper abdominal discomfort in gastric lymphoma. Most MALT lymphomas are gastric in origin. At least two genetic forms of gastric MALT exist: one (accounting for ~50% of cases) characterized by t(11;18)(q21;q21) that juxtaposes the amino terminal of the API2 gene with the carboxy terminal of the MALT1 gene creating an API2/MALT1 fusion product, and the other characterized by multiple sites of genetic instability including trisomies of chromosomes 3, 7, 12, and 18. Ninety-five percent of gastric MALT lymphomas are associated with *H. pylori* infection, and those that are not usually express t(11;18). The t(11;18) usually results in activation of NF-κB, which acts as a survival factor for the cells. Lymphomas with t(11;18) translocations are genetically stable and do not evolve to diffuse large B cell lymphoma. By contrast, t(11;18)-negative MALT lymphomas
lymphomas often acquire BCL6 mutations and progress to aggressive histology lymphoma. MALT lymphomas are localized to the organ of origin in ~40% of cases and to the organ and regional lymph nodes in ~30% of patients. However, distant metastasis can occur—particularly with transformation to diffuse large B cell lymphoma. Many patients who develop this lymphoma will have an autoimmune or inflammatory process such as Sjögren’s syndrome (salivary gland MALT), Hashimoto’s thyroiditis (thyroid MALT), or Helicobacter gastritis (gastric MALT).

Evaluation of patients with extranodal marginal zone B cell lymphoma of MALT type follows the pattern set forth in Table 97-11 for staging a patient with non-Hodgkin’s lymphoma. In particular, patients with gastric lymphoma need to have studies performed to document the presence or absence of H. pylori infection. Endoscopic studies including ultrasound can help define the extent of gastric involvement. Most patients with extranodal marginal zone B cell lymphoma of MALT type have a good prognosis, with a 5-year survival of ~75%. In patients with a low IPI score, the 5-year survival is ~90%, while it drops to ~40% in patients with a high IPI score.

**TREATMENT**

Extranodal marginal zone B cell lymphoma of MALT type is curable when localized. Local therapy such as radiation or surgery can effect cure, and this is one of the few times where surgery might be a reasonable primary therapy for a patient with non-Hodgkin’s lymphoma. Patients with gastric MALT lymphomas who are infected with H. pylori can achieve remission in the majority of cases with eradication of the infection. These remissions can be durable, but molecular evidence of persisting neoplasia is frequent and the long-term outcome is uncertain. Patients who present with more extensive disease are most often treated with single-agent chemotherapy such as chlorambucil. Coexistent diffuse large B cell lymphoma must be treated with combination chemotherapy. The additional acquired mutations that mediate the histologic progression also convey Helicobacter independence to the growth.

**Mantle Cell Lymphoma**  
Mantle cell lymphoma makes up ~6% of all non-Hodgkin’s lymphomas. Recognized as a separate entity only in the past decade, this lymphoma was previously placed in a number of other subtypes. Its existence was confirmed by the recognition that these lymphomas have a characteristic chromosomal translocation, t(11;14), between the immunoglobulin heavy chain gene on chromosome 14 and the bcl-1 gene on chromosome 11, and regularly overexpress the BCL-1 protein. The clinical characteristics of mantle cell lymphoma are presented in Table 97-10.

The diagnosis of mantle cell lymphoma can be made accurately by an expert hematopathologist based on morphologic findings and proof that the tumor is a B cell lymphoma. As with all subtypes of lymphoma, an adequate biopsy is important. The differential diagnosis of mantle cell lymphoma includes other small-cell B cell lymphomas. In particular, mantle cell lymphoma and small lymphocytic lymphoma share a characteristic expression of CD5. Mantle cell lymphoma usually has a slightly indented nucleus.

The most common presentation of mantle cell lymphoma is with palpable lymphadenopathy, frequently accompanied by systemic symptoms. Approximately 70% of patients will be stage IV at the time of diagnosis, with frequent bone marrow and peripheral blood involvement. Of the extranodal organs that can be involved, gastrointestinal involvement is particularly important to recognize. Patients who present with lymphomatosis polyposis in the large intestine usually have mantle cell lymphoma. The evaluation of patients with mantle cell lymphoma involves the studies presented in Table 97-11 for staging of patients with non-Hodgkin’s lymphoma. Patients who present with gastrointestinal tract involvement often have Waldeyer’s ring involvement, and vice versa. The 5-year survival for all patients with mantle cell lymphoma is ~25%, with only occasional patients who present with a high IPI score surviving 5 years and ~50% of patients with a low IPI score surviving 5 years.

**Follicular Lymphoma**  
Follicular lymphomas make up 22% of non-Hodgkin’s lymphomas worldwide and at least 30% of non-Hodgkin’s lymphomas diagnosed in the United States. This type of lymphoma can be diagnosed accurately on morphologic findings alone and has been the diagnosis in the majority of patients in therapeutic trials for “low-grade” lymphoma in the past. The clinical characteristics of follicular lymphoma are presented in Table 97-10.

Evaluation of an adequate biopsy by an expert hematopathologist is sufficient to make a diagnosis of follicular lymphoma. The tumor is composed of small cleaved and large cells in varying proportions organized in a follicular pattern of growth (Fig. 97-7). Confirmation of B cell immunophenotype and the existence of the t(14;18) and abnormal expression of BCL-2 protein are confirmatory. The major differential diagnosis is between lymphoma and reactive follicular hyperplasia. The coexistence of diffuse large B cell lymphoma must be considered. Patients with follicular lymphoma are often subclassified into those with predominantly small cells, those with a mixture of small and large cells, and those with predominantly large cells. While this distinction cannot be made simply or very accurately, these subdivisions do have prognostic significance. Patients with follicular lymphoma with predominantly large cells have a higher proliferative fraction, progress more rapidly, and have a shorter overall survival with simple chemotherapy regimens.

The most common presentation for follicular lymphoma is with new, painless lymphadenopathy. Multiple sites of lymphoid involvement are typical, and unusual sites such as epiploic nodules are sometimes seen. However, essentially any organ can be involved, and extranodal presentations do occur. Most patients do not have fevers, sweats, or weight loss, and an IPI score of 0 or 1 is found in ~50% of patients. Fewer than 10% of patients have a high (i.e., 4 or 5) IPI score. The staging evaluation for patients with follicular lymphoma should include the studies included in Table 97-11 for the staging of patients with non-Hodgkin’s lymphoma.

**TREATMENT**

Follicular lymphoma is one of the malignancies most responsive to chemotherapy and radiotherapy. In addition, as many as 25% of the patients undergo spontaneous regression—usually transient—when followed without therapy. In an asymptomatic patient, no initial treatment and watchful waiting can be an appropriate management strategy and is particularly likely to be adopted for older patients. For patients who do require treatment, single-agent chlorambucil or cyclophosphamide or combination chemotherapy with CVP or CHOP are most frequently used. With adequate treatment, 50 to 75% of patients will achieve a complete remission. While most patients relapse (median response duration is ~2 years), at least 20% of complete responders...
will remain in remission for >10 years. For the rare patient with localized follicular lymphoma, involved field radiotherapy produces an excellent treatment result.

A number of new therapies have been shown to be active in the treatment of patients with follicular lymphoma. These include new cytotoxic agents such as fludarabine, and biologic agents such as interferon α, monoclonal antibodies with or without radionuclides, and lymphoma vaccines. In patients treated with a doxorubicin-containing combination chemotherapy regimen, interferon α given to patients in complete remission seems to prolong survival. The monoclonal antibody rituximab can cause objective responses in 35 to 50% of patients with relapsed follicular lymphoma, and radiolabeled antibodies appear to have response rates well in excess of 50%. Trials with tumor vaccines have been encouraging. Both autologous and allogeneic hematopoietic stem cell transplantation yield high complete response rates in patients with relapsed follicular lymphoma, and long-term remissions can occur.

Patients with follicular lymphoma with a predominance of large cells have a shorter survival when treated with single-agent chemotherapy but seem to benefit from receiving an anthracycline-containing combination chemotherapy regimen. When their disease is treated aggressively, the overall survival for such patients is no lower than for patients with follicular lymphomas, and the failure-free survival is superior.

Patients with follicular lymphoma have a high rate of histologic transformation to diffuse large B cell lymphoma (~7% per year). This is recognized ~40% of the time during the course of the illness by repeat biopsy and is present in almost all patients at autopsy. This transformation is usually heralded by rapid growth of lymph nodes—often localized—and the development of systemic symptoms such as fevers, sweats, and weight loss. Although these patients have a poor prognosis, aggressive combination chemotherapy regimens can sometimes cause a complete remission in the diffuse large B cell lymphoma, often leaving the patient with persisting follicular lymphoma.

**Diffuse Large B Cell Lymphoma**

Diffuse large B cell lymphoma is the most common type of non-Hodgkin’s lymphoma, representing approximately one-third of all cases. This lymphoma makes up the majority of cases in previous clinical trials of “aggressive” or “intermediate-grade” lymphoma. The clinical characteristics of diffuse large B cell lymphoma are presented in Table 97-10. The diagnosis of diffuse large B cell lymphoma can be made accurately by an expert hematopathologist when review of an adequate biopsy and proof of B cell immunophenotype are available (Fig. 97-8). Cytogenetic and molecular genetic studies are not necessary for diagnosis, but some evidence has accumulated that patients who overexpress the BCL-2 protein might be more likely to relapse than others. Patients with prominent mediastinal involvement are sometimes diagnosed as a separate subgroup having primary mediastinal diffuse large B cell lymphoma. This latter group of patients has a younger median age (i.e., 37 years) and a female predominance (66%). Subtypes of diffuse large B cell lymphoma, including those with an immunoblastic subtype and tumors with extensive fibrosis, are recognized by pathologists but do not appear to have important, independent treatment significance.

Diffuse large B cell lymphoma can present as either primary lymph node disease or at extranodal sites. More than 50% of patients will have some site of extranodal involvement at diagnosis, with the most common sites being the gastrointestinal tract and bone marrow, each being involved in 15 to 20% of patients. Essentially any organ can be involved, making a diagnostic biopsy imperative. For example, diffuse large B cell lymphoma of the pancreas has a much better prognosis than pancreatic carcinoma but would be missed without biopsy. Primary diffuse large B cell lymphoma of the brain is being diagnosed with increasing frequency. Other unusual subtypes of diffuse large B cell lymphoma such as pleural effusion lymphoma and intravascular lymphoma have been difficult to diagnose and associated with a very poor prognosis.

The initial evaluation of patients with diffuse large B cell lymphoma involves the studies presented in Table 97-11 for staging of patients with non-Hodgkin’s lymphoma. After a careful staging evaluation, ~50% of patients will be found to have stage I or II disease and ~50% will have widely disseminated lymphoma. Bone marrow biopsy shows involvement by lymphoma in about 15% of cases, with marrow involvement by small cells more frequent than with large cells.

**TREATMENT**

The initial treatment of all patients with diffuse large B cell lymphoma should be with a combination chemotherapy regimen. The most popular regimen in the United States is CHOP, sometimes in combination with rituximab, although a variety of other anthracycline-containing combination chemotherapy regimens appear to be equally efficacious. Patients with stage I or nonbulky stage II can be effectively treated with three to four cycles of combination chemotherapy followed by involved field radiotherapy. The results are at least equal and probably superior to six to eight cycles of combination therapy, and cure rates of 60 to 70% in stage II disease and 80 to 90% in stage I disease can be expected.

For patients with bulky stage II, stage III, or stage IV, six to eight cycles of a combination chemotherapy regimen such as CHOP, often in combination with rituximab, are usually administered. A large randomized trial showed the superiority of CHOP combined with rituximab over CHOP alone in elderly patients. A frequent approach would be to administer four cycles of therapy and then reevaluate. If the patient has achieved a complete remission after four cycles, two more cycles of treatment might be given and then therapy discontinued. Using this approach, 70% of patients can be expected to achieve a complete remission, and 50 to 70% of complete responders will be cured. The chances for a favorable response to treatment are predicted by the IPI. In fact, the IPI was developed specifically to predict outcome in patients with diffuse large B cell lymphoma. For the 35% of patients with a low IPI score of 0 to 1, the 5-year survival is >70%, while for the 20% of patients with a high IPI score of 4 to 5, the 5-year survival is ~20%. A number of other factors, including molecular features of the tumor, levels of circulating cytokines and soluble receptors, and other surrogate markers, have been shown to influence prognosis. However, they have not been validated as rigorously as the IPI and have not been uniformly applied clinically.

Because a large number of patients with diffuse large B cell lymphoma are either initially refractory to therapy or relapse after apparently effective chemotherapy, nearly half of patients will be candidates for salvage treatment at some point. Alternative combination chemo-
therapy regimens can induce complete remission in as many as 50% of these patients, but long-term disease-free survival is seen in <10%. Autologous bone marrow transplantation has been shown to be superior to salvage chemotherapy at usual doses and leads to long-term disease-free survival in ~40% of patients whose lymphomas remain chemotherapy-sensitive after relapse.

**Burkitt’s Lymphoma/Leukemia** Burkitt’s lymphoma/leukemia is a rare disease in adults in the United States, making up <1% of non-Hodgkin’s lymphomas, but it makes up ~30% of childhood non-Hodgkin’s lymphoma. Burkitt’s leukemia, or L3 ALL, makes up a small proportion of childhood and adult acute leukemias. The clinical features of Burkitt’s lymphoma occurring in adults are presented in Table 97-10.

Burkitt’s lymphoma can be diagnosed morphologically by an expert hematopathologist with a high degree of accuracy. The cells are homogeneous in size and shape (Fig. 97-9). Demonstration of a very high proliferative fraction and the presence of the t(8;14) or one of its variants, t(2;8) and the α light chain gene), can be confirmatory. Burkitt’s cell leukemia is recognized by the typical monotonous mass of medium-sized cells with round nuclei, multiple nucleoli, and basophilic cytoplasm with cytoplasmic vacuoles. Demonstration of a B cell immunophenotype and one of the above-noted cytogenetic abnormalities is confirmatory.

The three distinct clinical forms of Burkitt’s lymphoma that are recognized are endemic, sporadic, and immunodeficiency-associated. Endemic and sporadic Burkitt’s lymphomas occur frequently in children in Africa, and the sporadic form in western countries. Immuno-deficiency-associated Burkitt’s lymphoma is seen in patients with HIV infection. Pathologists sometimes have difficulty distinguishing between Burkitt’s lymphoma and diffuse large B cell lymphoma. In the past, a separate subgroup of non-Hodgkin’s lymphoma intermediate between the two was recognized. When tested, this subgroup could not be diagnosed accurately. Distinction between the two major types of B cell aggressive non-Hodgkin’s lymphomas can sometimes be made based on the extremely high proliferative fraction seen in patients with Burkitt’s lymphoma (i.e., essentially 100% of tumor cells are in cycle) caused by c-myc deregulation.

Most patients in the United States with Burkitt’s lymphoma present with peripheral lymphadenopathy or an intraabdominal mass. The disease is typically rapidly progressive and has a propensity to metastasize to the CNS. Initial evaluation should always include an examination of cerebral spinal fluid to rule out metastasis in addition to the other staging evaluations noted in Table 97-11. Once the diagnosis of Burkitt’s lymphoma is suspected, a diagnosis must be made promptly and staging evaluation must be accomplished expeditiously. This is the most rapidly progressive human tumor, and any delay in initiating therapy can adversely affect the patient’s prognosis.

### TREATMENT

Treatment of Burkitt’s lymphoma in both children and adults should begin within 48 h of diagnosis and involves the use of intensive combination chemotherapy regimens incorporating high doses of cyclophosphamide. Prophylactic therapy to the CNS is mandatory. Burkitt’s lymphoma was one of the first cancers shown to be curable by chemotherapy. Today, cure can be expected in 70 to 80% of both children and young adults when effective therapy is administered precisely. Salvage therapy has been generally ineffective in patients failing the initial treatment, emphasizing the importance of the initial treatment approach.

**Other B Cell Lymphoid Malignancies** B-cell prolymphocytic leukemia involves blood and marrow infiltration by large lymphocytes with prominent nucleoli. Patients typically have a high white cell count, splenomegaly, and minimal lymphadenopathy. The chances for a complete response to therapy are poor.

Hairy cell leukemia is a rare disease that presents predominantly in older males. Typical presentation involves pancytopenia, although occasional patients will have a leukemic presentation. Splenomegaly is usual. The malignant cells appear to have “hairy” projections on light and electron microscopy and show a characteristic staining pattern with tartrate-resistant acid phosphatase. Bone marrow is typically not able to be aspirated, and biopsy shows a pattern of fibrosis with diffuse infiltration by the malignant cells. Patients with this disorder are prone to unusual infections including infection by Mycobacterium avium intracellulare, and vasculitic syndromes have been described. Hairy cell leukemia is responsive to chemotherapy with interferon α, pentostatin, or cladribine, with the latter being the usually preferred treatment. Clinical complete remissions with cladribine occur in the majority of patients, and long-term disease-free survival is frequent.

Splenical marginal zone lymphoma involves infiltration of the splenic white pulp by small, monoclonal B cells. This is a rare disorder that can present as leukemia as well as lymphoma. Definitive diagnosis is often made at splenectomy, which is also an effective therapy. This is an extremely indolent disorder, but when chemotherapy is required, the most usual treatment has been chlorambucil.

Lymphoplasmacytic lymphoma is the tissue manifestation of Waldenström’s macroglobulinemia (Chap. 98). This type of lymphoma has been associated with chronic hepatitis C virus infection, and an etiologic association has been proposed. Patients typically present with lymphadenopathy, splenomegaly, bone marrow involvement, and occasionally peripheral blood involvement. The tumor cells do not express CD5. Patients often have a monoclonal IgM protein, high levels of which can dominate the clinical picture with the symptoms of hyperviscosity. Treatment of lymphoplasmacytic lymphoma can be aimed primarily at reducing the abnormal protein, if present, but will usually also involve chemotherapy. Chlorambucil, fludarabine, and cladribine have been utilized. The median 5-year survival for patients with this disorder is ~60%.

Nodal marginal zone lymphoma, also known as monocytoid B cell lymphoma, represents ~1% of non-Hodgkin’s lymphomas. This lymphoma has a slight female predominance and presents with disseminated disease (i.e., stage III or IV) in 75% of patients. Approximately one-third of patients have bone marrow involvement, and a leukemic presentation occasionally occurs. The staging evaluation and therapy should use the same approach as used for patients with follicular lymphoma. Approximately 60% of the patients with nodal marginal zone lymphoma will survive 5 years after diagnosis.

PRECURSOR T CELL MALIGNANCIES

**Precursor T Cell Lymphoblastic Leukemia/Lymphoma** Precursor T cell malignancies can present either as ALL or as an aggressive lymphoma. These malignancies are more common in children and young adults, with males more frequently affected than females.

Precursor T cell ALL can present with bone marrow failure, although the severity of anemia, neutropenia, and thrombocytopenia is often less than in precursor B cell ALL. These patients sometimes have very high white cell counts, a mediastinal mass, lymphadenopathy, and hepatosplenomegaly. Precursor T cell lymphoblastic lymphoma is most often found in young men presenting with a large mediastinal mass and pleural effusions. Both presentations have a propensity to metastasize to the CNS, and CNS involvement is often present at diagnosis.
MATURE (PERIPHERAL) T CELL DISORDERS

Mycosis Fungoides

Mycosis fungoides is also known as cutaneous T cell lymphoma. This lymphoma is more often seen by dermatologists than internists. The median age of onset is in the mid-fifties, and the disease is more common in males and in blacks.

Mycosis fungoides is an indolent lymphoma with patients often having several years of eczematous or dermatitic skin lesions before the diagnosis is finally established. The skin lesions progress from patch stage to plaque stage to cutaneous tumors. Early in the disease, biopsies are often difficult to interpret, and the diagnosis may only become apparent by observing the patient over time. In advanced stages, the lymphoma can metastasize to lymph nodes and visceral organs. A particular syndrome in patients with this lymphoma involves erythroderma and circulating tumor cells. This is known as Sézary’s syndrome.

Rare patients with localized early stage mycosis fungoides can be cured with radiotherapy, often total-skin electron beam irradiation. More advanced disease has been treated with topical glucocorticoids, topical nitrogen mustard, phototherapy, psoralen with ultraviolet A (PUVA), electron beam radiation, interferon, antibodies, fusion toxins, and systemic cytotoxic therapy. Unfortunately, these treatments are palliative.

Adult T Cell Lymphoma/Leukemia

Adult T cell lymphoma/leukemia is one manifestation of infection by the HTLV-I retrovirus. Patients can be infected through transplacental transmission, blood transfusion, and by sexual transmission of the virus. Patients who acquire the virus from their mother through breast milk are most likely to develop lymphoma, but the risk is still only 2.5% and the latency averages 55 years. Nationwide testing for HTLV-I antibodies and the aggressive implementation of public health measures could theoretically lead to the disappearance of adult T cell lymphoma/leukemia. Tropical spastic paraparesis, another manifestation of HTLV-I infection (Chap. 172), occurs after a shorter latency (1 to 3 years) and is most common in people who acquire the virus during adulthood from transfusion or sex.

The diagnosis of adult T cell lymphoma/leukemia is made when an expert hematopathologist recognizes the typical morphologic picture, a T cell immunophenotype (i.e., CD4 positive) of malignant cells has been demonstrated, and the existence of antibodies to HTLV-I is proven. Examination of the peripheral blood will usually reveal characteristic, pleomorphic abnormal CD4-positive cells with indented nuclei, which have been called “flower” cells (Fig. 97-10).

A subset of patients have a smoldering clinical course and long survival, but most patients present with an aggressive disease mani-

Treatment

Children with precursor T cell ALL seem to benefit from very intensive remission induction and consolidation regimens. The majority of patients treated in this manner can be cured. Older children and young adults with precursor T cell lymphoblastic lymphoma are also often treated with “leukemia-like” regimens. Patients who present with localized disease have an excellent prognosis. However, advanced age is an adverse prognostic factor. Adults with precursor T cell lymphoblastic lymphoma who present with high LDH levels or bone marrow or CNS involvement are often offered bone marrow transplantation as part of their primary therapy.

Anaplastic Large T/Null Cell Lymphoma

Anaplastic large T/null cell lymphoma was previously usually diagnosed as undifferentiated carcinoma or malignant histiocytosis. Discovery of the CD30, or Ki-1, antigen and the recognition that some patients with previously unclassified malignancies displayed this antigen led to the identification of a new type of lymphoma. Subsequently, discovery of the t(2;5) and the resultant frequent overexpression of the anaplastic lymphoma kinase (ALK) protein confirmed the existence of this entity. This lymphoma accounts for ~2% of all non-Hodgkin’s lymphomas. The clinical characteristics of patients with anaplastic large T/null cell lymphoma are presented in Table 97-10.

The diagnosis of anaplastic large T/null cell lymphoma is made when an expert hematopathologist recognizes the typical morphologic picture and a T cell or null cell immunophenotype is demonstrated along with CD30 positivity. Documentation of the t(2;5) and/or overexpression of ALK protein confirm the diagnosis. Some diffuse large B cell lymphomas can also have an anaplastic appearance but have the same clinical course or response to therapy as other diffuse large B cell lymphomas.

Patients with anaplastic large T/null cell null lymphoma are typically young (median age, 33 years) and male (~70%). Some 50% of patients present in stage I/II, and the remainder with more extensive disease. Systemic symptoms and elevated LDH levels are seen in about one-half of patients. Bone marrow and the gastrointestinal tract are rarely involved, but skin involvement is frequent. Some patients with disease confined to the skin have a different and more indolent disorder that has been termed cutaneous anaplastic large T/null cell lymphoma and might be related to lymphomatoid papulosis.
demonstration of a monoclonal T cell population using T cell receptor gene rearrangement studies will be required to make a diagnosis.

The initial evaluation of a patient with a peripheral T cell lymphoma should include the studies in Table 97-11 for staging patients with non-Hodgkin’s lymphoma. Unfortunately, patients with peripheral T cell lymphoma usually present with adverse prognostic factors, with >80% of patients having an IPI score ≥2 and >30% having an IPI score ≥4. As this would predict, peripheral T cell lymphomas are associated with a poor outcome, and only 25% of the patients survive 5 years after diagnosis. Treatment regimens are the same as those used for diffuse large B cell lymphoma, but patients with peripheral T cell lymphoma have a poorer response to treatment. Because of this poor treatment outcome, hematopoietic stem cell transplantation is often considered early in the care of young patients.

A number of specific clinical syndromes are seen in the peripheral T cell lymphomas. Angioimmunoblastic T cell lymphoma is one of the more common subtypes, making up ~20% of T cell lymphomas. These patients typically present with generalized lymphadenopathy, fever, weight loss, skin rash, and polycytemia. In some cases, it is difficult to separate patients with a reactive disorder from those with true lymphoma.

Enteropathy-type intestinal T cell lymphoma is a rare disorder that occurs in patients with untreated gluten-sensitive enteropathy. Patients are frequently wasted and sometimes present with intestinal perforation. The prognosis is poor. Hepatosplenic γδ T cell lymphoma is a systemic illness that presents with sinusoidal infiltration of the liver, spleen, and bone marrow by malignant T cells. Tumor masses generally do not occur. The disease is associated with systemic symptoms and is often difficult to diagnosis. Treatment outcome is poor. Subcutaneous panniculitis-like T cell lymphoma is a rare disorder that is often confused with panniculitis. Patients present with multiple subcutaneous nodules, which progress and can ulcerate. Hemophagocytic syndrome is common. Response to therapy is poor. The development of the hemophagocytic syndrome (profound anemia, ingestion of erythrocytes by monocytes and macrophages) in the course of any peripheral T cell lymphoma is generally associated with a fatal outcome.

HODGKIN’S DISEASE — Classic Hodgkin’s Disease

Hodgkin’s disease occurs in 7600 patients in the United States each year, and the disease does not appear to be increasing in frequency. Most patients present with palpable lymphadenopathy that is nontender; in most patients, these lymph nodes are in the neck, supraclavicular area, and axilla. More than half the patients will have mediastinal adenopathy at diagnosis, and this is sometimes the initial manifestation. Subdiaphragmatic presentation of Hodgkin’s disease is unusual and more common in older males. Approximately one-third of patients present with fevers, night sweats, and/or weight loss—B symptoms in the Ann Arbor staging classification (Table 97-8). Occasionally, Hodgkin’s disease can present as a fever of unknown origin. This is more common in older patients who are found to have mixed-cellularity Hodgkin’s disease in an abdominal site. Rarely, the fevers persist for days to weeks, followed by febrile intervals and then recurrence of the fever. This pattern is known as Pel-Ebstein fever. Hodgkin’s disease can occasionally present with unusual manifestations. These include severe and unexplained itching, cutaneous disorders such as erythema nodosum and ichthyosiform atrophy, paraneoplastic cerebellar degeneration and other distant effects on the CNS, nephrotic syndrome, immune hemolytic anemia and thrombocytopenia, hypercalcemia, and pain in lymph nodes on alcohol ingestion.

The diagnosis of Hodgkin’s disease is established by review of an adequate biopsy specimen by an expert hematopathologist. In the United States, most patients would be classified as having nodular sclerosing Hodgkin’s disease, with a minority of patients having mixed-cellularity Hodgkin’s disease. Lymphocyte-predominant and lymphocyte-depleted Hodgkin’s disease are rare. Mixed-cellularity Hodgkin’s disease or lymphocyte-depletion Hodgkin’s disease are seen more frequently in patients infected by HIV (Fig. 97-11). The differential diagnosis of a lymph node biopsy suspicious for Hodgkin’s disease includes inflammatory processes, mononucleosis, non-Hodgkin’s lymphoma, phenytoin-induced lymphadenopathy, and nonlymphomatous malignancies.

The staging evaluation for a patient with Hodgkin’s disease would typically include a careful history and physical examination; complete blood count; erythrocyte sedimentation rate; serum chemistry studies including LDH; chest radiograph; CT scan of the chest, abdomen, and pelvis; and bone marrow biopsy. Many patients would also have a PET scan or a gallium scan. Although rarely utilized, a bipedal lymphangiogram can be helpful. PET and gallium scans are most useful at the completion of therapy to document remission. Staging laparotomies were once popular for most patients with Hodgkin’s disease but are now done rarely because of an increased reliance on systemic rather than local therapy.

Patients with localized Hodgkin’s disease are cured >90% of the time. In patients with good prognostic factors, extended field radiotherapy has a high cure rate. Increasingly, patients with all stages of Hodgkin’s disease are treated initially with chemotherapy. Patients with localized or good-prognosis disease receive a brief course of chemotherapy followed by radiotherapy to sites of node involvement. Patients with more extensive disease or those with B symptoms receive a complete course of chemotherapy. The most popular chemotherapy regimens used in the treatment of Hodgkin’s disease include doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) and mechlorethamine, vincristine, procarbazine, and prednisone (MOPP), or combinations of the drugs in these two regimens. Today, most patients in the United States receive ABVD, but a weekly chemotherapy regimen administered for 12 weeks called Stanford V is becoming increasingly popular, but includes radiation therapy, which has been associated with life-threatening late toxicities such as premature coronary artery disease and second solid tumors. In Europe a high-dose regimen called BEACOPP incorporating alkylating agents has become popular and might have a better response rate in very high risk patients. Long-term disease-free survival in patients with advanced disease can be achieved in >75% of patients who lack systemic symptoms and in 50 to 70% of patients with systemic symptoms.

Patients who relapse after primary therapy of Hodgkin’s disease can frequently still be cured. Patients who relapse after initial treatment only with radiotherapy have an excellent outcome when treated with chemotherapy. Patients who relapse after an effective chemotherapy regimen are usually not curable with subsequent chemotherapy administered at standard doses. However, patients with a long initial

**Figure 97-11** Mixed cellularity Hodgkin’s disease. A Reed-Sternberg cell is present near the center of the field; a large cell with a bilobed nucleus and prominent nucleoli giving an “owl’s eyes” appearance. The majority of the cells are normal lymphocytes, neutrophils, and eosinophils that form a pleomorphic cellular infiltrate.
Nodular Lymphocyte-Predominant Hodgkin’s Disease  Nodular lymphocyte-predominant Hodgkin’s disease is now recognized as an entity distinct from classic Hodgkin’s disease. Previous classification systems recognized that biopsies from a subset of patients diagnosed as having Hodgkin’s disease contained a predominance of small lymphocytes and rare Reed-Sternberg cells. A subset of these patients have tumors with nodular growth pattern and a clinical course that varied from that of patients with classic Hodgkin’s disease. This is an unusual clinical entity and represents <5% of cases of Hodgkin’s disease.

Nodular lymphocyte-predominant Hodgkin’s disease has a number of characteristics that suggest its relationship to non-Hodgkin’s lymphoma. These include a clonal proliferation of B cells and a distinctive immunophenotype; tumor cells express J chain and display CD45 and epithelial membrane antigen (ema) and do not express two markers normally found on Sternberg-Reed cells, CD30 and CD15. This lymphoma tends to have a chronic, relapsing course and sometimes transforms to diffuse large B cell lymphoma.

The treatment of patients with nodular lymphocyte-predominant Hodgkin’s disease is controversial. Some clinicians favor no treatment and merely close follow-up. In the United States, most physicians will treat localized disease with radiotherapy and disseminated disease with regimens utilized for patients with classic Hodgkin’s disease. Regardless of the therapy utilized, most series report a long-term survival of >80%.

LYMPHOMA-LIKE DISORDERS

The most common condition that pathologists and clinicians might confuse with lymphoma is reactive, atypical lymphoid hyperplasia. Patients might have localized or disseminated lymphadenopathy and might have the systemic symptoms characteristic of lymphoma. Underlying causes include a drug reaction to phenytoin or carbamazepine. Immune disorders such as rheumatoid arthritis and lupus erythematosus, viral infections such as cytomegalovirus and EBV, and bacterial infections such as cat-scratch disease may cause adenopathy (Chap. 54). In the absence of a definitive diagnosis after initial biopsy, continued follow-up, further testing, and repeated biopsies, if necessary, are the appropriate approach rather than instituting therapy.

Specific conditions that can be confused with lymphoma include Castleman’s disease, which can present with localized or disseminated lymphadenopathy; some patients have systemic symptoms. The disseminated form is often accompanied by anemia and polycytemia. The condition has been associated with overproduction of interleukin 6, possibly produced by human herpesvirus 8. Patients with localized disease can be treated effectively with local therapy, while the initial treatment for patients with disseminated disease is usually with systemic glucocorticoids.

Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman’s disease) usually presents with bulky lymphadenopathy in children or young adults. The disease is usually nonprogressive and self-limited, but patients can manifest autoimmune hemolytic anemia. Lymphomatoid papulosis is a cutaneous lymphoproliferative disorder that is often confused with anaplastic large-cell lymphoma involving the skin. The cells of lymphomatoid papulosis are similar to those seen in lymphoma and stain for CD30, and T cell receptor gene rearrangements are sometimes seen. However, the condition is characterized by waxing and waning skin lesions that usually heal, leaving small scars. In the absence of effective communication between the clinician and the pathologist regarding the clinical course in the patient, this disease will be misdiagnosed. Since the clinical picture is usually benign, misdiagnosis is a serious mistake.

GENERAL PRINCIPLES

The plasma cell disorders are monoclonal neoplasms related to each other by virtue of their development from common progenitors in the B lymphocyte lineage. Multiple myeloma, Waldenström’s macroglobulinemia, primary amyloidosis (Chap. 310), and the heavy chain diseases comprise this group and may be designated by a variety of synonyms such as monoclonal gammopathies, paraproteinemias, plasma cell dyscrasias, and dysproteinemias. Mature B lymphocytes destined to produce IgG bear surface immunoglobulin molecules of both M and G heavy chain isotypes with both isotypes having identical idiootypes (variable regions). Under normal circumstances, maturation to antibody-secreting plasma cells is stimulated by exposure to the antigen for which the surface immunoglobulin is specific; however, in the plasma cell disorders the control over this process is lost. The clinical manifestations of all the plasma cell disorders relate to the expansion of the neoplastic cells, to the secretion of cell products (immunoglobulin molecules or subunits, lymphokines), and to some extent to the host’s response to the tumor. Normal development of B lymphocytes is discussed in Chap. 295.

There are three categories of structural variation among immunoglobulin molecules that form antigenic determinants, and these are used to classify immunoglobulins (Chap. 295). Isotypes are those determinants that distinguish among the main classes of antibodies of a given species and are the same in all normal individuals of that species. Therefore, isotypic determinants are, by definition, recognized by antibodies from a distinct species (heterologous sera) but not by antibodies from the same species (homologous sera). There are five heavy chain isotypes (M, G, A, D, E) and two light chain isotypes (k, λ). Allotypes are distinct determinants that reflect regular small differences between individuals of the same species in the amino acid sequences of otherwise similar immunoglobulins. These differences are determined by alleles; by definition, they are detected by antibodies made in the same species. Idiotypes are the third category of antigenic determinants. They are unique to the molecules produced by a given clone of antibody-producing cells. Idiotypes are formed by the unique structure of the antigen-binding portion of the molecule.

Antibody molecules (Fig. 295-9) are composed of two heavy chains (mol wt ~50,000) and two light chains (mol wt ~25,000). Each chain has a constant portion (limited amino acid sequence variability) and a variable region (extensive sequence variability). The light and heavy chains are linked by disulfide bonds and are aligned so that their variable regions are adjacent to one another. This variable region forms the antigen recognition site of the antibody molecule; its unique structural features form a particular set of determinants, or idiotypes, that are reliable markers for a particular clone of cells because each antibody is formed and secreted by a single clone. Each chain is specified by distinct genes, synthesized separately, and assembled into an intact antibody molecule after translation (Fig. 98-1). Because of the mechanics of the gene rearrangements necessary to specify the immunoglobulin variable regions (VDJ joining for the heavy chain, VJ joining for the light chain), a particular clone rearranges only one of the two chromosomes to produce an immunoglobulin molecule of only one light chain isotype and only one allotype (allelic exclusion). After exposure to antigen, the variable region may become associated with a new heavy chain isotype (class switch). Each clone of cells performs these sequential gene arrangements in a unique way. This results in each clone producing a unique immunoglobulin molecule. In most cells, light chains are synthesized in slight excess, are secreted as free light chains by plasma cells, and are cleared by the kidney, but <10 mg of such light chains is excreted per day.

Electrophoretic analysis of components of the serum proteins permits determination of the amount of immunoglobulin in the serum (Fig. 98-2). The variety of immunoglobulins move heterogeneously in an electric field and form a broad peak in the gamma region. The γ globulin region of the electrophoretic pattern is usually increased in the sera of patients and animals with plasma cell tumors. There is a sharp spike in this region called an M component (M for monoclonal). Less commonly, the M component may appear in the β, or α1 globulin region. The antibody must be present at a concentration of at least 5 g/L (0.5 g/dL) to be detectable by this method. This corresponds to approximately 10⁷ cells producing the antibody. Confirmation that such an M component is truly monoclonal relies on the use of immunoelectrophoresis that shows a single light and heavy chain type. Hence immunoelectrophoresis and electrophoresis provide qualitative and quantitative assessment of the M component, respectively. Once the presence of an M component has been confirmed, electrophoresis provides the more practical information for managing patients with monoclonal gammopathies. In a given patient, the amount of M component in the serum is a reliable measure of the tumor burden. This makes the M component an excellent tumor marker, yet it is not specific enough to be used to screen asymptomatic patients. In addition

Multiple Myeloma

**Definition**

Multiple myeloma represents a malignant proliferation of plasma cells derived from a single clone. The terms multiple myeloma and myeloma may be used interchangeably.

- The tumor, its products, and the host response to it result in a number of organ dysfunctions and symptoms of bone pain or fracture, renal failure, susceptibility to infection, anemia, hypercalcemia, and occasionally clotting abnormalities, neurologic symptoms, and vascular manifestations of hyperviscosity.

**Etiology**

The cause of myeloma is not known. Myeloma occurred with increased frequency in those exposed to the radiation of nuclear warheads in World War II after a 20-year latency. A variety of chromosomal alterations have been found in patients with myeloma; 1q14 deletions, 17p13 deletions, and 11q abnormalities predominate. The most common translocation is t(11;14)(q13;q32), and evidence is strong that errors in switch recombination—participate in the transformation pathway. Overexpression of myc or ras genes has been noted in some cases. Mutations in p53 and Rb-1 have also been described, but no common molecular pathogenesis has yet emerged.

Myeloma has been seen more commonly than expected among farmers, wood workers, leather workers, and those exposed to petroleum products. The neoplastic event in myeloma may involve cells to the plasma cell disorders, M components may be detected in other lymphoid neoplasms such as chronic lymphocytic leukemia and lymphomas of B or T cell origin; nonlymphoid neoplasms such as chronic myeloid leukemia, breast cancer, and colon cancer; a variety of non-neoplastic conditions such as cirrhosis, sarcoidosis, parasitic diseases, Gaucher disease, and pyoderma gangrenosum; and a number of autoimmune conditions, including rheumatoid arthritis, myasthenia gravis, and cold agglutinin disease. A very rare skin disease known as lichen myxinatosus or papular mucinosis is associated with a monoclonal gammopathy. Highly cationic IgG is deposited in the dermis of patients with this disease. This organ specificity may reflect the specificity of the antibody for some antigenic component of the dermis.

The nature of the M component is variable in plasma cell disorders. It may be an intact antibody molecule of any heavy chain subclass, or it may be an altered antibody or fragment. Isolated light or heavy chains may be produced. In some plasma cell tumors such as extramedullary or solitary bone plasmacytomas, less than 1/3 of patients will have an M component. In about 20% of myelomas, only light chains are produced and in most cases are secreted in the urine as Bence Jones proteins. The frequency of myelomas of a particular heavy chain class produced and in most cases are secreted in the urine as Bence Jones proteins. In about 20% of myelomas, only light chains are produced and in most cases are secreted in the urine as Bence Jones proteins.

**Etiology**

The cause of myeloma is not known. Myeloma occurred with increased frequency in those exposed to the radiation of nuclear warheads in World War II after a 20-year latency. A variety of chromosomal alterations have been found in patients with myeloma; 1q14 deletions, 17p13 deletions, and 11q abnormalities predominate. The most common translocation is t(11;14)(q13;q32), and evidence is strong that errors in switch recombination—participate in the transformation pathway. Overexpression of myc or ras genes has been noted in some cases. Mutations in p53 and Rb-1 have also been described, but no common molecular pathogenesis has yet emerged.

Myeloma has been seen more commonly than expected among farmers, wood workers, leather workers, and those exposed to petroleum products. The neoplastic event in myeloma may involve cells earlier in B cell differentiation than the plasma cell. Circulating B cells bearing surface immunoglobulin that share the idiotype of the M component are present in myeloma patients. Interleukin (IL) 6 may play a role in driving myeloma cell proliferation; a large fraction of myeloma cells exposed to IL-6 in vitro respond by proliferating. The IL-6 dependency of myeloma is controversial. It remains difficult to distinguish benign from malignant plasma cells on the basis of morphologic criteria in all but a few cases (Fig. 98-3).

**Incidence and Prevalence**

About 15,270 cases of myeloma were diagnosed in 2004, and 11,070 people died from the disease. Myeloma increases in incidence with age. The median age at diagnosis is 68 years; it is rare under age 40. The yearly incidence is around 4 per 100,000 and remarkably similar throughout the world. Males are slightly more commonly affected than females, and blacks have nearly twice the incidence of whites. In the age group over 25 the incidence is 30 per 100,000. Myeloma accounts for about 1% of all malignancies in whites and 2% in blacks; 13% of all hematologic cancers in whites and 33% in blacks.

**Pathogenesis and Clinical Manifestations**

Table 98-1

**Bone Pain**

Bone pain is the most common symptom in myeloma, affecting nearly 70% of patients. The pain usually involves the back and ribs, and unlike the pain of metastatic carcinoma, which often is worse at night, the pain of myeloma is precipitated by movement. Persistent localized pain in a patient with myeloma usually signifies a pathologic fracture. The bone lesions of myeloma are caused by the proliferation of tumor cells and the activation of osteoclasts that destroy the bone. The osteoclasts respond to osteoclast activating factors (OAIF) made by the myeloma cells [OAIF activity can be mediated by several cytokines, including IL-1, lymphotoxin, vascular endothelial growth factor (VEGF), receptor activator of NF-κB (RANK) ligand, macrophage inhibitory factor (MIF)-1α, and tumor necrosis factor (TNF)]. However, production of these factors decreases following administration of glucocorticoids or interferon (IFN)-α. The bone lesions are lytic in nature and are rarely associated with osteoblastic new bone formation. Therefore, radioisotopic bone scanning is less useful in diagnosis than is plain radiography. The bony lysis results in substantial mobilization of calcium from bone, and serious acute and chronic complications of hypercalcemia may dominate the clinical picture (see below). Localized bone lesions may expand to the point that mass lesions may be palpated, especially on the skull (Fig. 98-4), clavicles, and sternum, and the collapse of vertebrae may lead to spinal cord compression.

The next most common clinical problem in patients with myeloma is susceptibility to bacterial infections. The most common infections are pneumonias and pyelonephritis, and the most frequent pathogens are Streptococcus pneumoniae, Staphylococcus aureus, and Klebsiella pneumoniae in the lungs and Escherichia coli and other gram-negative organisms in the urinary tract. In about 25% of patients, recurrent infections are the presenting features, and over 75% of patients will have a serious infection at some time in their course. The susceptibility to infection has several contributing causes. First, patients with myeloma have diffuse hypogammaglobulinemia if the M component is excluded. The hypogammaglobulinemia is related to both decreased production and increased destruction of normal antibodies. Moreover, some patients generate a population of circulating regulatory cells in response to their myeloma that can suppress normal antibody synthe-
Bony lesions in multiple myeloma. The skull demonstrates the typical osteolytic lesion with little or no osteoblastic activity. (Courtesy of Dr. Geraldine Schechter.)

Renal failure occurs in nearly 25% of myeloma patients, and some renal pathology is noted in over half. Many factors contribute to this. Hypercalcemia is the most common cause of renal failure. Glomerular deposits of amyloid, hyperuricemia, recurrent infections, and occasional infiltration of the kidney by myeloma cells all may contribute to renal dysfunction. However, tubular damage associated with the excretion of light chains is almost always present. Normally, light chains are filtered, reabsorbed in the tubules, and catabolized. With the increase in the amount of light chains presented to the tubule, the tubular cells become overloaded with these proteins, and tubular damage results either directly from light chain toxic effects or indirectly from the release of intracellular lysosomal enzymes. The earliest manifestation of this tubular damage is the adult Fanconi syndrome (a type 2 proximal renal tubular acidosis), with loss of glucose and amino acids, as well as defects in the ability of the kidney to acidify and concentrate the urine. The proteinuria is not accompanied by hypertension, and the protein is nearly all light chains. Generally, very little albumin is in the urine because glomerular function is usually normal. When the glomeruli are involved, the proteinuria is nonselective. Patients with myeloma also have a decreased anion gap [i.e., \(Na^+ - (Cl^- + HCO_3^-)\)] because the M component is cationic, resulting in retention of chloride. This is often accompanied by hyponatremia that is felt to be artificial (pseudohyponatremia) because each volume of serum has less water as a result of the increased protein. Myeloma patients are susceptible to developing acute renal failure if they become dehydrated.

Anemia occurs in about 80% of myeloma patients. It is usually normocytic and normochromic and related both to the replacement of normal marrow by expanding tumor cells and to the inhibition of hematopoiesis by factors made by the tumor. In addition, mild hemolysis may contribute to the anemia. A larger than expected fraction of patients may have megaloblastic anemia due to either folate or vitamin \(B_12\) deficiency. Granulocytopenia and thrombocytopenia are very rare. Clotting abnormalities may be seen due to the failure of antibody-coated platelets to function properly or to the interaction of the M component with clotting factors I, II, V, VII, or VIII. Raynaud’s phenomenon and impaired circulation may result if the M component forms cryoglobulins, and hyperviscosity syndromes may develop depending on the physical properties of the M component (most common with IgM, IgG3, and IgA paraproteins). Hyperviscosity is defined on the basis of the relative viscosity of serum as compared with water. Normal relative serum viscosity is 1.8 (i.e., serum is normally almost twice as viscous as water). Symptoms of hyperviscosity occur at a level of 5 to 6, a level usually reached at paraprotein concentrations of around 40 g/L (4 g/dL) for IgM, 50 g/L (5 g/dL) for IgG3, and 70 g/L (7 g/dL) for IgA.

Although neurologic symptoms occur in a minority of patients, they may have many causes. Hypercalcemia may produce lethargy, weakness, depression, and confusion. Hyperviscosity may lead to headache, fatigue, visual disturbances, and retinopathy. Bony damage and collapse may lead to cord compression, radicular pain, and loss of bowel and bladder control. Infiltration of peripheral nerves by amyloid can be a cause of carpal tunnel syndrome and other sensorimotor mono- and polyneuropathies.

Many of the clinical features of myeloma, e.g., cord compression, pathologic fractures, hyperviscosity, sepsis, and hypercalcemia, can present as medical emergencies. Despite the widespread distribution of plasma cells in the body, tumor expansion is dominantly within bone and bone marrow and, for reasons unknown, rarely causes enlargement of spleen, lymph nodes, or gut-associated lymphatic tissue.

Diagnosis and Staging The classic triad of myeloma is marrow plasmacytosis (>10%), lytic bone lesions, and a serum and/or urine M component results in fractional catabolic rates of 8 to 16% instead of the normal 2%. These patients have very poor antibody responses, especially to polysaccharide antigens such as those on bacterial cell walls. Most measures of T cell function in myeloma are normal, but a subset of CD4+ cells may be decreased. Granulocyte lysozyme content is low, and granulocyte migration is not as rapid as normal in patients with myeloma, probably the result of a tumor product. There are also a variety of abnormalities in complement functions in myeloma patients. All these factors contribute to the immune deficiency of these patients.

Renal failure occurs in nearly 25% of myeloma patients, and some renal pathology is noted in over half. Many factors contribute to this. Hypercalcemia is the most common cause of renal failure. Glomerular deposits of amyloid, hyperuricemia, recurrent infections, and occasional infiltration of the kidney by myeloma cells all may contribute to renal dysfunction. However, tubular damage associated with the excretion of light chains is almost always present. Normally, light chains are filtered, reabsorbed in the tubules, and catabolized. With the increase in the amount of light chains presented to the tubules, the tubular cells become overloaded with these proteins, and tubular damage results either directly from light chain toxic effects or indirectly from the release of intracellular lysosomal enzymes. The earliest manifestation of this tubular damage is the adult Fanconi syndrome (a type 2 proximal renal tubular acidosis), with loss of glucose and amino acids, as well as defects in the ability of the kidney to acidify and concentrate the urine. The proteinuria is not accompanied by hypertension, and the protein is nearly all light chains. Generally, very little albumin is in the urine because glomerular function is usually normal. When the glomeruli are involved, the proteinuria is nonselective. component. The diagnosis may be made in the absence of bone lesions if the plasmacytosis is associated with a progressive increase in the M component over time or if extramedullary mass lesions develop. There are two important variants of myeloma, solitary bone plasmacytoma and extramedullary plasmacytoma. These lesions are associated with an M component in fewer than 30% of the cases, they may affect younger individuals, and both are associated with median survival of 10 or more years. Solitary bone plasmacytoma is a single lytic bone lesion without marrow plasmacytosis. Extramedullary plasmacytomas usually involve the submucosal lymphoid tissue of the nasopharynx or parasanal sinuses without marrow plasmacytosis. Both tumors are highly responsive to local radiation therapy. If an M component is present, it should disappear after treatment. Solitary bone plasmacytomas may recur in other bony sites or evolve into myeloma. Extramedullary plasmacytomas rarely recur or progress.

The most difficult differential diagnosis in patients with myeloma involves their separation from individuals with benign monoclonal gammopathies or monoclonal gammapathies of uncertain significance (MGUS). MGUS are vastly more common than myeloma, occurring in 1% of the population over age 50 and in up to 10% over age 75. Patients with MGUS usually have <10% bone marrow plasma cells; <30 g/L (3 g/dL) of M components; no urinary Bence Jones protein; and no anemia, renal failure, lytic bone lesions, or hypercalcemia. When bone marrow cells are exposed to radioactive thymidine in order to quantitate dividing cells, patients with MGUS always have a labeling index <1%; patients with myeloma always have a labeling index >1%. With long-term follow-up, about 1% per year of patients with MGUS go on to develop myeloma. Typically, patients with MGUS require no therapy. Their survival is about 2 years shorter than age-matched controls without MGUS.

The clinical evaluation of patients with myeloma includes a careful physical examination searching for tender bones and masses. Only a small minority of patients has an enlargement of the spleen and lymph nodes, the physiologic sites of antibody production. Chest and bone radiographs may reveal lytic lesions or diffuse osteoporosis. MRI offers a sensitive means to document cord or root compression in patients with pain syndromes. A complete blood count with differential may reveal anemia. Erythrocyte sedimentation rate is elevated. Rare patients (~2%) may have plasma cell leukemia with more than 2000 plasma cells/μL. This may be seen in disproportionate frequency in IgD (12%) and IgE (25%) myelomas. Serum calcium, urea nitrogen, creatinine, and uric acid levels may be elevated. Protein electrophoresis and measurement of serum immunoglobulins are useful for detecting and characterizing M spikes, supplemented by immunoelectrophoresis, which is especially sensitive for identifying low concentrations of M components not detectable by protein electrophoresis. A 24-h urine specimen is necessary to quantitate protein excretion, and a concentrated aliquot is used for electrophoresis and immunologic typing of any M component. Serum alkaline phosphatase is usually normal even with extensive bone involvement because of the absence of osteoblastic activity. It is also important to quantitate serum β2-microglobulin (see below). Serum soluble IL-6 receptor levels and C-reactive protein may reflect physiologic IL-6 levels in the patient.

The serum M component will be IgG in 53% of patients, IgA in 25%, and IgD in 1%; 20% of patients will have only light chains in serum and urine. Dipsticks for detecting proteinuria are not reliable at identifying light chains, and the heat test for detecting Bence Jones protein is falsely negative in about 50% of patients with light chain myeloma. Fewer than 1% of patients have no identifiable M component; these patients usually have light chain myelomas in which renal catabolism has made the light chains undetectable in the urine. IgD myeloma may also present as light chain myeloma. About two-thirds of patients with serum M components also have urinary light chains. It is not clear whether this is due to some genetically important determinant of cell proliferation or because lambda light chains are more likely to cause renal damage and form amyloid than are kappa light chains. The heavy chain isotype may have an impact on patient management as well. About half of patients with IgM paraproteins develop hyperviscosity compared with only 2 to 4% of patients with IgA and IgG M components. Among IgM myelomas, it is the IgM subclass that has the highest tendency to form both concentration- and temperature-dependent aggregates, leading to hyperviscosity and cold agglutination at lower serum concentrations.

The staging system for patients with myeloma is a functional system for predicting survival and is based on a variety of clinical and laboratory tests, unlike the anatomic staging systems for solid tumors. Details of the staging system are given in Table 98-2. Based on the hemoglobin, calcium, M component, and degree of skeletal involvement, the total-body tumor burden is estimated to be low (stage I, <0.6 × 1012 cells/m²), intermediate (stage II, 0.6 to 1.2 × 1012 cells/m²), or high (stage III, >1.2 × 1012 cells/m²), and the stages are further subdivided on the basis of renal function [A if serum creatinine <177 mol/L (<2 mg/dL), B if >177 (>2)]. Patients in stage IA have a median survival of more than 5 years and those in stage IIIB about 15 months. β2-Microglobulin is a protein of 11,000 mol wt with homologies with the constant region of immunoglobulins that is the light chain of the class I major histocompatibility antigens (HLA-A, -B, -C) on the surface of every cell. Serum β2-microglobulin is the single most powerful predictor of survival and can substitute for staging. Patients with β2-microglobulin levels <0.004 g/L have a median survival of 43 months and those with levels >0.004 g/L only 12 months. It is also felt that once the diagnosis of myeloma is firm, histologic features of atypia may also exert an influence on prognosis. IL-6 may be an autocrine and/or paracrine growth factor for myeloma cells; el-

evated levels are associated with more aggressive disease. High labeling index and high levels of lactate dehydrogenase and thymidine kinase are also associated with poor prognosis.

Other factors that may influence prognosis are the number of cytogenetic abnormalities, chromosome 13q deletion, % plasma cells in the marrow, circulating plasma cells, performance status, and serum levels of IL-6, soluble IL-6 receptors, C-reactive protein, hepatocyte growth factor, C-terminal cross-linked telopeptide of collagen I, TGF-β, and syndecan-1.

**TREATMENT**

About 10% of patients with myeloma will have an indolent course demonstrating only very slow progression of disease over many years. Such patients only require antitumor therapy when the serum myeloma protein level rises above 50 g/L (5 g/dL) or progressive bone lesions develop. Patients with solitary bone plasmacytomas and extramedullary plasmacytomas may be expected to enjoy prolonged disease-free survival after local radiation therapy to a dose of around 40 Gy. There is a low incidence of occult marrow involvement in patients with solitary bone plasmacytoma. Such patients are usually detected because their serum M component falls slowly or disappears initially only to return after a few months. These patients respond well to systemic chemotherapy.

The vast majority of patients with myeloma require therapeutic intervention. In general, such therapy is of two sorts: systemic chemotherapy to control the progression of myeloma, and symptomatic supportive care to prevent serious morbidity from the complications of the disease. All patients with stage II or III disease and stage I patients exhibiting Bence Jones proteinuria, progressive lytic bone lesions, vertebral compression fractures, recurrent infections, or rising serum M component should be treated with systemic combination chemotherapy. Therapy can prolong and improve the quality of life for myeloma patients.

The standard treatment has consisted of intermittent pulses of an alkylating agent [L-phenylalanine mustard (L-PAM), melphanal, cyclophosphamide, or chlorambucil] and prednisone administered for 4 to 7 days every 4 to 6 weeks. The alkylating agents appear to be roughly equally active, but resistance to one agent is often accompanied by resistance to the others. The usual doses are as follows: melphalan, 8 mg/m² per day; cyclophosphamide, 200 mg/m² per day; chlorambucil, 8 mg/m² per day; prednisone, 25 to 60 mg/m² per day. Melphalan is used most commonly, but because of their near equivalence in antitumor efficacy, we favor cyclophosphamide as the alkylating agent because it is less toxic to the marrow stem cell compartment and results in a lower incidence of myelodysplastic syndromes than do the other alkylating agents. Doses may need adjustment based on marrow tolerance. However, there are few constraints on the dose of the steroid pulse, and it appears that more is better. Patients responding to therapy generally have a prompt and gratifying reduction in bone pain, hypercalcemia, and anemia, and often have fewer infections. The serum M component lags substantially behind the symptomatic improvement, often taking 4 to 6 weeks to fall. This fall depends on the rate of tumor cell kill and the fractional catabolic rate of immunoglobulin, which in turn depends on the serum concentration (for IgG). Light chain excretion, with a functional half-life of approximately 6 h, may fall within the first week of treatment. However, since urine light chain levels may relate to renal tubular function, they are not a reliable measure of tumor cell kill. Calculations of tumor cell kill are made by extrapolation of the serum M component level and rely heavily on the assumption that every tumor cell produces immunoglobulin at a constant rate. About 60% of patients will achieve at least a 75% reduction in serum M component level and tumor cell mass in response to an alkylating agent and prednisone. Although this is a tumor reduction of less than 1 log, clinical responses may last many months. The important feature of the level of the M protein is not how far or how fast it falls, but the rate of its increase after therapy. Efforts to improve the fraction of patients responding and the degree of response have involved adding other active chemotherapeutic agents to the treatment program. Patients with more advanced disease may benefit most from such an approach. High-dose therapy with hematopoietic stem cell support can modestly extend progression-free and overall survival but few, if any, patients are cured. Sequential treatment with combination chemotherapy regimens followed by two successive high-dose melphalan treatments, each supported with peripheral blood stem cell transplants, have achieved complete responses in 50% of patients treated within a year of diagnosis. Complete responses are rare (<10%) with standard therapy. Long-term follow-up is not yet available. Allogeneic transplants may also produce high response rates, but treatment-related mortality may be as high as 40%. Nonmyeloablative allogeneic transplantation is now under evaluation to reduce toxicity while permitting an immune graft-vs-tumor effect.

The ideal duration of therapy has not been determined. Most physicians treat every 4 to 6 weeks for 1 or 2 years. Cessation of therapy is followed by relapse, usually within a year. Retreatment may be associated with a second response in up to 80% of patients. Maintenance therapy (e.g., with IFN-α) may prolong the duration of response, but this therapy is toxic and has generally not prolonged survival. Oral prednisone maintenance therapy appears to improve response duration and survival. The regrowth rate of the tumor during relapse accelerates with each relapse. This observation suggests that kinetic resistance to therapy (i.e., increase in cycling cells) is perhaps more important than drug resistance controlled by mdr-1 expression. Patients often respond to treatment, but the length of the response progressively shortens. Patients primarily resistant to initial therapy have a median survival of less than a year. High-dose pulsed glucocorticoids used alone (200 mg prednisone every other day or 1 g/m² per day methylprednisolone for 5 days) or VAD combination chemotherapy (vincristine, 0.4 mg/ d in a 4-day continuous infusion; doxorubicin, 9 mg/m² per day in a 4-day continuous infusion; dexamethasone, 40 mg/d for 4 days per week for 3 weeks) may offer useful palliation in patients resistant to primary therapy. High-dose melphalan has activity in patients with refractory disease. Thalidomide, which inhibits angiogenesis, also produces responses in refractory cases, but at doses that may cause somnolence. Novel agents, including immunomodulatory derivatives of thalidomide (IMiDs) and the proteasome inhibitor, PS-341, target not only the tumor cell but also the tumor cell-bone marrow interaction and production of myeloma growth, survival, drug resistance, and migration factors. These agents can achieve responses in relapsed refractory disease and are under evaluation for efficacy earlier in the disease course.

About 15% of patients die within the first 3 months after diagnosis; subsequently, the death rate is about 15% per year. The disease usually follows a chronic course for 2 to 5 years before developing an acute terminal phase, usually marked by the development of pancytopenia with a cellular marrow that is refractory to treatment. Widespread organ infiltration by myeloma cells occurs, and survival is less than 6 months. About 46% of patients die in the chronic phase of disease from progressive myeloma (16%) and renal failure (10%), sepsis (14%), or both (6%). Death in the acute terminal phase (26%) is chiefly from progressive myeloma (13%) and sepsis (9%). Five percent of patients die of acute leukemia, myeloblastic or monocytic. Although it has been debated that this is related to the primary disease, it appears more likely to be the result of chronic therapy with alkylating agents. Nearly 23% of patients die of myocardial infarction, chronic lung disease, diabetes, or stroke, all intercurrent illnesses related more to the age of the patient group than to the tumor.

Supportive care directed at the anticipated complications of the disease may be as important as primary antitumor therapy. The hypercalcemia generally responds well to bisphosphonates, glucocorticoid therapy, hydration, and natriuresis. Calcitonin may add to the inhibitory effects of steroids on bone resorption. Bisphosphonates (e.g., pamidronate 90 mg or zoledronate 4 mg once a month) reduce osteoclastic bone resorption and preserve performance status and qual-
lymphocytes are usually present in the peripheral blood. About 10% of macroglobulins are cryoglobulins. These are pure M components and are not the mixed cryoglobulins seen in rheumatoid arthritis and other autoimmune diseases. Mixed cryoglobulins are composed of IgM or IgA complexed with IgG, for which they are specific. In both cases, Raynaud’s phenomenon and serious vascular symptoms precipitated by the cold may occur, but mixed cryoglobulins are not commonly associated with malignancy. Patients suspected of having a cryoglobulin based on history and physical examination should have their blood drawn into a warm syringe and delivered to the laboratory in a container of warm water to avoid errors in quantitating the cryoglobulin.

**POEMS Syndrome** The features of this syndrome are polyneuropathy, organomegaly, endocrinopathy, multiple myeloma, and skin changes (POEMS). Patients usually have a severe, progressive sensorimotor polyneuropathy associated with sclerotic bone lesions from myeloma. Polyneuropathy occurs in about 14% of myelomas, but the POEMS syndrome is only a rare subset of that group. Unlike typical myeloma, hepatomegaly and lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in one-third. The lymphadenopathy frequently resembles Castleman’s disease histologically, a condition that has been linked to IL-6 overproduction. The endocrine manifestations include amenorrhea in women and impotence and gynecomasia in men. Hyperprolactinemia due to loss of normal inhibitory control by the hypothalamus may be associated with other central nervous system manifestations such as papilledema and elevated cerebrospinal fluid pressure and protein. Type 2 diabetes mellitus occurs in about one-third of patients. Hypothyroidism and adrenal insufficiency are occasionally noted. Skin changes are diverse: hyperpigmentation, hypertrichosis, skin thickening, and digital clubbing. Other manifestations include peripheral edema, ascites, pleural effusions, fever, and thrombocytosis.

The pathogenesis of the disease is unclear, but high circulating levels of the proinflammatory cytokines IL-1, IL-6, VEGF, and TNF have been documented and levels of the inhibitory cytokine transforming growth factor (TGF-β) are lower than expected. Treatment of the myeloma may result in an improvement in the other disease manifestations.

**HEAVY CHAIN DISEASES** The heavy chain diseases are rare lymphoplasma cytoid malignancies. Their clinical manifestations vary with the heavy chain isotype. Patients secrete a defective heavy chain that usually has an intact Fc fragment and a deletion in the Fe region. Gamma, alpha, and mu heavy chain diseases have been described, but no reports of delta or epsilon heavy chain diseases have appeared. Molecular biologic analysis of these tumors has revealed structural genetic defects that may account for the aberrant chain secreted.

**Gamma Heavy Chain Disease (Franklin’s Disease)** This disease affects people of widely different age groups and countries of origin. It is characterized by lymphadenopathy, fever, anemia, malaise, hepatosplenomegaly, and weakness. Its most distinctive symptom is palatal edema, resulting from node involvement of Waldeyer’s ring, and this may progress to produce respiratory compromise. The diagnosis depends on the demonstration of an anomalous serum M component [often <20 g/L (<2 g/dL) that reacts with anti-IgG but not anti-light chain rea-
gents. The M component is typically present in both serum and urine. Most of the paraproteins have been of the gamma, subclass, but other subclasses have been seen. The patients may have thrombocytopenia, eosinophilia, and nondiagnostic bone marrow. Patients usually have a rapid downhill course and die of infection; however, some patients have survived 5 years with chemotherapy.

**Alpha Heavy Chain Disease (Seligmann’s Disease)** This is the most common of the heavy chain diseases. It is closely related to a malignancy known as Mediterranean lymphoma, a disease that affects young people in parts of the world where visceral parasites are common, such as the Mediterranean, Asia, and South America. The disease is characterized by an infiltration of the lamina propria of the small intestine with lymphoplasmacytoid cells that secrete truncated alpha chains. Demonstrating alpha heavy chains is difficult because the alpha chains tend to polymerize and appear as a smear instead of a sharp peak on electrophoretic profiles. Despite the polymerization, hyperviscosity is not a common problem in alpha heavy chain disease. Without J chain—facilitated dimerization, viscosity does not increase dramatically. Light chains are absent from serum and urine. The patients present with chronic diarrhea, weight loss, and malabsorption and have extensive mesenteric and para-aortic adenopathy. Respiratory tract involvement occurs rarely. Patients may vary widely in their clinical course. Some may develop diffuse aggressive histologies of malignant lymphoma. Chemotherapy may produce long-term remissions. Rare patients appear to have responded to antibiotic therapy, raising the question of the etiologic role of antigenic stimulation, perhaps by some chronic intestinal infection. Chemotherapy plus antibiotics may be more effective than chemotherapy alone.

**Mu Heavy Chain Disease** The secretion of isolated mu heavy chains into the serum appears to occur in a very rare subset of patients with chronic lymphocytic leukemia. The only features that may distinguish patients with mu heavy chain disease are the presence of vacuoles in the malignant lymphocytes and the excretion of kappa light chains in the urine. The diagnosis requires ultracentrifugation or gel filtration to confirm the nonreactivity of the paraprotein with the light chain reagents, because some intact immunoglobulins fail to interact with these sera. The tumor cells seem to have a defect in the assembly of light and heavy chains, because they appear to contain both in their cytoplasm. There is no evidence that such patients should be treated differently from other patients with chronic lymphocytic leukemia (Chap. 97).

**FURTHER READING**

with type O blood can donate to essentially all recipients because their cells are not recognized by any ABO isoagglutinins. The rare individuals with Bombay phenotype produce antibodies to H substance (which is present on all red cells except those of hh phenotype) as well as to both A and B antigens and are therefore compatible only with other hh donors.

In most people, A and B antigens are secreted by the cells and are present in the circulation. Nonsecretors are susceptible to a variety of infections (e.g., Candida albicans, Neisseria meningitidis, Streptococcus pneumoniae, Haemophilus influenzae) as many organisms may bind to polysaccharides on cells. Soluble blood group antigens may block this binding.

**Rh SYSTEM** The Rh system is the second most important blood group system in pretransfusion testing. The Rh antigens are found on a 30- to 32-kDa RBC membrane protein that has no defined function. Although >40 different antigens in the Rh system have been described, five determinants account for the vast majority of phenotypes. The presence of the D antigen confers Rh “positivity,” while persons who lack the D antigen are Rh negative. Two allelic antigen pairs, E/e and C/c, are also found on the Rh protein. The three Rh genes, E/e, D, and C/c, are arranged in tandem on chromosome 1 and inherited as a haplotype, i.e., CDE or Cde. Two haplotypes can result in the phenotypic expression of two to five Rh antigens.

The D antigen is a potent alloantigen. About 15% of individuals lack this antigen. Exposure of these Rh-negative people to even small amounts of Rh-positive cells, by either transfusion or pregnancy, can result in the production of anti-D alloantibody.

**OTHER BLOOD GROUP SYSTEMS AND ALLOANTIBODIES** More than 100 blood group systems are recognized, composed of more than 500 antigens. The presence or absence of certain antigens has been associated with various diseases and anomalies; antigens also act as receptors for infectious agents. Alloantibodies of importance in routine clinical practice are listed in Table 99-1.

Antibodies to Lewis system carbohydrate antigens are the most common cause of incompatibility during pretransfusion screening. The Lewis gene product is a fucosyl transferase and maps to chromosome 19. The antigen is not an integral membrane structure but is adsorbed to the RBC membrane from the plasma. Antibodies to Lewis antigens are usually IgM and cannot cross the placenta. Lewis antigens may be adsorbed onto tumor cells and may be targets of therapy.

I system antigens are also oligosaccharides related to H, A, B, and Le, I and i are not allelic pairs but are carbohydrate antigens that differ only in the extent of branching. The i antigen is an unbranched chain that is converted by the I gene product, a glycosyltransferase, into a branched chain. The branching process affects all the ABH antigens, which become progressively more branched in the first 2 years of life. Some patients with cold agglutinin disease or lymphomas can produce anti-I autoantibodies that cause RBC destruction. Occasional patients with mononucleosis or Mycoplasma pneumonia may develop cold agglutinins of either anti-I or anti-i specificity. Most adults lack i expression; thus, finding a donor for patients with anti-i is not difficult.

Note: RBC, red blood cell; HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction.

Even though most adults express I antigen, binding is generally low at body temperature. Thus, administration of warm blood prevents isoagglutination.

The P system is another group of carbohydrate antigens controlled by specific glycosyltransferases. Its clinical significance is in rare cases of syphilis and viral infection that lead to paroxysmal cold hemoglobinuria. In these cases, an unusual autoantibody to P is produced that binds to RBCs in the cold and fixes complement upon warming. Antibodies with these biphasic properties are called Donath–Landeinsteiner antibodies. The P antigen is the cellular receptor of parvovirus B19 and also may be a receptor for Escherichia coli binding to urothelial cells.

The MNSsU system is regulated by genes on chromosome 4. M and N are determinants on glycoprotein A, an RBC membrane protein, and S and s are determinants on glycoprotein B. Anti-S and anti-s IgG antibodies may develop after pregnancy or transfusion and lead to hemolysis. Anti-U antibodies are rare but problematic; virtually every donor is incompatible because nearly all persons express U.

The Kell protein is very large (720 amino acids) and its secondary structure contains many different antigenic epitopes. The immunogenicity of Kell is third behind the ABO and Rh systems. The absence of the Kell precursor protein (controlled by a gene on X) is associated with acanthocytosis, shortened RBC survival, and a progressive form of muscular dystrophy that includes cardiac defects. This rare condition is called the McLeod phenotype. The K_ gene is linked to the 91-kDa component of the NADPH-oxidase on the X chromosome, deletion or mutation of which accounts for about 60% of cases of chronic granulomatous disease.

The Duffy antigens are codominant alleles, Fy⁺ and Fy⁻, that also serve as receptors for Plasmodium vivax. More than 70% of persons in malaria-endemic areas lack these antigens, probably from selective influences of the infection on the population.

The Kidd antigens, Jk⁻ and Jk⁺, may elicit antibodies transiently. A delayed hemolytic transfusion reaction that occurs with blood tested as compatible is often related to delayed appearance of anti-Jk⁻.

**PRETRANSFUSION TESTING**

Pretransfusion testing of a potential recipient consists of the “type and screen.” The “forward type” determines the ABO and Rh phenotype of the recipient’s RBC by using antisera directed against the A, B, and D antigens. The “reverse type” detects isoagglutinins in the patient’s serum and should correlate with the ABO phenotype, or forward type.

The alloantibody screen identifies antibodies directed against other RBC antigens. The alloantibody screen is performed by mixing patient serum with type O RBCs that contain the major antigens of most blood group systems and whose extended phenotype is known. The specificity of the alloantibody is identified by correlating the presence or absence of antigen with the results of the agglutination.

Cross-matching is ordered when there is a high probability that the patient will require a packed RBC (PRBC) transfusion. Blood selected for cross-matching must be ABO compatible and lack antigens for which the patient has alloantibodies. Nonreactive cross-matching confirms the absence of any major incompatibility and reserves that unit for the patient.

In the case of Rh-negative patients, every attempt must be made to provide Rh-negative blood components to prevent alloimmunization to the D antigen. In an emergency, Rh-positive blood can be safely transfused to a Rh-negative patient who lacks anti-D; however, the recipient is likely to become alloimmunized and produce anti-D. Rh-negative women of childbearing age who are transfused with products containing Rh-positive RBCs should receive passive immunization with anti-D (RhoGam or WinRho) to reduce or prevent sensitization.

**BLOOD COMPONENTS**

Blood products intended for transfusion are routinely collected as whole blood (450 mL) in various anticoagulants. Most donated blood is processed into components: PRBCs, platelets, and fresh-frozen
plasma (FFP) or cryoprecipitate (Table 99-2). Whole blood is first separated into PRBCs and platelet-rich plasma by slow centrifugation. The platelet-rich plasma is then centrifuged at high speed to yield one unit of random donor (RD) platelets and one unit of FFP. Cryoprecipitate is produced by thawing FFP to precipitate the plasma proteins, then separated by centrifugation.

Apheresis technology is used for the collection of multiple units of platelets from a single donor. These single-donor apheresis platelets (SDAP) contain the equivalent of at least six units of RD platelets and have fewer contaminating leukocytes than pooled RD platelets.

Plasma may also be collected by apheresis. Plasma derivatives such as albumin, intravenous immunoglobulin, antithrombin, and coagulation factor concentrates are prepared from pooled plasma from many donors and are treated to eliminate infectious agents.

**WHOLE BLOOD** Whole blood provides both oxygen-carrying capacity and volume expansion. It is the ideal component for patients who have sustained acute hemorrhage of ≥25% total blood volume loss. Whole blood is stored at 4°C to maintain erythrocyte viability, but platelet dysfunction and degradation of some coagulation factors occurs. In addition, 2,3-bisphosphoglycerate levels fall over time, leading to an increase in the oxygen affinity of the hemoglobin and a decreased capacity to deliver oxygen to the tissues, a problem with all red cell products.

Whole blood is not readily available since it is routinely processed into components.

**PACKED RED BLOOD CELLS** This product increases oxygen-carrying capacity in the anemic patient. Adequate oxygenation can be maintained with a hemoglobin content of 70 g/L in the normovolemic patient without cardiac disease; however, comorbid factors often necessitate transfusion at a higher threshold. The decision to transfuse should be guided by the clinical situation and not by an arbitrary laboratory value. In the critical care setting, liberal use of transfusions to maintain near normal levels of hemoglobin may have unexpected negative effects on survival. In most patients requiring transfusion, levels of hemoglobin of 100 g/L are sufficient to keep oxygen supply from being critically low.

PRBCs may be modified to prevent certain adverse reactions. Leukocyte reduction of cellular blood products is increasingly common, and universal prestorage leukocyte reduction has been recommended. Prestorage filtration appears superior to bedside filtration as smaller amounts of cytokines are generated in the stored product. These PRBC units contain <5 × 10⁶ donor white blood cells (WBCs), and their use lowers the incidence of posttransfusion fever, cytomegalovirus (CMV) infections, and alloimmunization. Other theoretical benefits include less immunosuppression in the recipient and lower risk of infections. Plasma, which may cause allergic reactions, can be removed from cellular blood components by washing.

**PLATELETS** Thrombocytopenia is a risk factor for hemorrhage, and platelet transfusion reduces the incidence of bleeding. The threshold for prophylactic platelet transfusion is 10,000/µL. In patients without fever or infections, a threshold of 5000/µL may be sufficient to prevent spontaneous hemorrhage. For invasive procedures, 50,000/µL platelets is the usual target level.

Platelets are given either as pools prepared from five to eight RDs or as SDAPs from a single donor. In an unsensitized patient without increased platelet consumption [splenomegaly, fever, disseminated intravascular coagulation (DIC)], six to eight units of RD platelets (about 1 unit per 10 kg body weight) are transfused, and each unit is anticipated to increase the platelet count 5000 to 10,000/µL. Patients who have received multiple transfusions may be alloimmunized to many HLA- and platelet-specific antigens and have little or no increase in their posttransfusion platelet counts. Patients who may require multiple transfusions are best served by receiving SDAP and leukocyte-reduced components to lower the risk of alloimmunization.

Refractoriness to platelet transfusion may be evaluated using the corrected count increment (CCI):

\[
CCI = \frac{\text{posttransfusion count} - \text{pretransfusion count}}{\text{number of platelets transfused} \times 10^{11}} \times \text{BSA}
\]

where BSA is body surface area measured in square meters. The platelet count performed 1 h after the transfusion is acceptable if the CCI is 10 × 10⁹/mL, and after 18 to 24 h an increment of 7.5 × 10⁹/mL is expected. Patients who have suboptimal responses are likely to have received multiple transfusions and have antibodies directed against class I HLA antigens. Refractoriness can be investigated by detecting anti-HLA antibodies in the recipient’s serum. Patients who are sensitized will often react with 100% of the lymphocytes used for the HLA-antibody screen, and HLA-matched SDAPs should be considered for those patients who require transfusion. Although ABO-identical HLA-matched SDAPs provide the best chance for increasing the platelet count, locating these products is difficult. Platelet cross-matching is available in some centers. Additional clinical causes for a low platelet CCI include fever, bleeding, splenomegaly, DIC, or medications in the recipient.

**FRESH-FROZEN PLASMA** FFP contains stable coagulation factors and plasma proteins: fibrinogen, antithrombin, albumin, as well as proteins C and S. Indications for FFP include correction of coagulopathies, including the rapid reversal of warfarin; supplying deficient plasma proteins; and treatment of thrombotic thrombocytopenic purpura. FFP should not be routinely used to expand blood volume. FFP is an acellular component and does not transmit intracellular infections, e.g., CMV. Patients who are IgA-deficient and require plasma support should receive FFP from IgA-deficient donors to prevent anaphylaxis (see below).

**CRYOPRECIPITATE** Cryoprecipitate is a source of fibrinogen, factor VIII, and von Willebrand factor (vWF). It is ideal for supplying fibrinogen to the volume-sensitive patient. When factor VIII concentrates are not available, cryoprecipitate may be used since each unit contains approximately 80 units of factor VIII. Cryoprecipitate may also supply vWF to patients with dysfunctional (type II) or absent (type III) von Willebrand disease.

**PLASMA DERIVATIVES** Plasma from thousands of donors may be pooled to derive specific protein concentrates, including albumin, intravenous immunoglobulin, antithrombin, and coagulation factors. In addition, donors who have high-titer antibodies to specific agents or antigens provide hyperimmune globulins, such as anti-D (RhoGam, WinRho),

**ADVERSE REACTIONS TO BLOOD TRANSFUSION**

Adverse reactions to transfused blood components occur despite multiple tests, inspections, and checks. Fortunately, the most common reactions are not life-threatening, although serious reactions can present with mild symptoms and signs. Some reactions can be reduced or prevented by modified (filtered, washed, or irradiated) blood components. When an adverse reaction is suspected, the transfusion should be stopped and reported to the blood bank for investigation.

Transfusion reactions may result from immune and nonimmune mechanisms. Immune-mediated reactions are often due to preformed donor or recipient antibody; however, cellular elements may also cause adverse effects. Nonimmune causes of reactions are due to the chemical and physical properties of the stored blood component and its additives.

Transfusion-transmitted infections are increasingly rare due to improved screening and testing. As the risk of viral infection is reduced, the relative risk of other reactions increases, such as hemolytic transfusion reactions and sepsis from bacterially contaminated components. More effort is being directed at improving pretransfusion quality assurance to further increase the safety of transfusion therapy. Infections, like any adverse transfusion reaction, must be brought to the attention of the blood bank for appropriate studies (Table 99-3).

**IMMUNE-MEDIATED REACTIONS**

Immune-mediated hemolysis occurs when the recipient has preformed antibodies that lyse donor erythrocytes. The ABO isoagglutinins are responsible for the majority of these reactions, although allolgorithms directed against other RBC antigens, i.e., Rh, Kell, and Duffy, may result in hemolysis.

Acute hemolytic reactions may present with hypotension, tachypnea, tachycardia, fever, chills, hemoglobinemia, hemoglobinuria, chest and/or flank pain, and discomfort at the infusion site. Monitoring the patient’s vital signs before and during the transfusion is important to identify reactions promptly. When acute hemolysis is suspected, the transfusion must be stopped immediately, intravenous access maintained, and the reaction reported to the blood bank. A correctly labeled posttransfusion blood sample and any untransfused blood should be sent to the blood bank for analysis. The laboratory evaluation for hemolysis includes the measurement of serum haptoglobin, lactate dehydrogenase (LDH), and indirect bilirubin levels.

*Infectious agents rarely associated with transfusion, theoretically possible or of unknown risk include: Hepatitis A virus, parvovirus B-19, Babesia microti (babesiosis), Borrelia burgdorferi (Lyme disease), Trypanosoma cruzi (Chagas disease), and Trepomonema pallidum, human herpesvirus-8 and hepatitis G virus.

**Note:** FNHTR, febrile nonhemolytic transfusion reaction; TRALI, transfusion-related acute lung injury; HTLV, human T lymphotropic virus; RBC, red blood cell.

Adverse reactions to transfused blood components occur despite multiple tests, inspections, and checks. Fortunately, the most common reactions are not life-threatening, although serious reactions can present with mild symptoms and signs. Some reactions can be reduced or prevented by modified (filtered, washed, or irradiated) blood components. When an adverse reaction is suspected, the transfusion should be stopped and reported to the blood bank for investigation.

Transfusion reactions may result from immune and nonimmune mechanisms. Immune-mediated reactions are often due to preformed donor or recipient antibody; however, cellular elements may also cause adverse effects. Nonimmune causes of reactions are due to the chemical and physical properties of the stored blood component and its additives.

Transfusion-transmitted infections are increasingly rare due to improved screening and testing. As the risk of viral infection is reduced, the relative risk of other reactions increases, such as hemolytic transfusion reactions and sepsis from bacterially contaminated components. More effort is being directed at improving pretransfusion quality assurance to further increase the safety of transfusion therapy. Infections, like any adverse transfusion reaction, must be brought to the attention of the blood bank for appropriate studies (Table 99-3).

**IMMUNE-MEDIATED REACTIONS**

Immunemediated hemolysis occurs when the recipient has preformed antibodies that lyse donor erythrocytes. The ABO isoagglutinins are responsible for the majority of these reactions, although allolgorithms directed against other RBC antigens, i.e., Rh, Kell, and Duffy, may result in hemolysis.

Acute hemolytic reactions may present with hypotension, tachypnea, tachycardia, fever, chills, hemoglobinemia, hemoglobinuria, chest and/or flank pain, and discomfort at the infusion site. Monitoring the patient’s vital signs before and during the transfusion is important to identify reactions promptly. When acute hemolysis is suspected, the transfusion must be stopped immediately, intravenous access maintained, and the reaction reported to the blood bank. A correctly labeled posttransfusion blood sample and any untransfused blood should be sent to the blood bank for analysis. The laboratory evaluation for hemolysis includes the measurement of serum haptoglobin, lactate dehydrogenase (LDH), and indirect bilirubin levels.

The immune complexes that result in RBC lysis can cause renal dysfunction and failure. Diuresis should be induced with intravenous fluids and furosemide or mannitol. Tissue factor released from the lysed erythrocytes may initiate DIC. Coagulation studies including prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen, and platelet count should be monitored in patients with hemolytic reactions.

Errors at the patient’s bedside, such as mislabeling the sample or transfusing the wrong patient, are responsible for the majority of these reactions. The blood bank investigation of these reactions includes examination of the pre- and posttransfusion samples for hemolysis and repeat typing of the patient samples; direct antiglobulin test (DAT), sometimes called the direct Coombs test, of the posttransfusion sample; repeating the cross-matching of the blood component; and checking all clerical records for errors. DAT detects the presence of antibody or complement bound to RBCs in vivo.

**Delayed Hemolytic and Serologic Transfusion Reactions**

Delayed hemolytic transfusion reactions (DHTRs) are not completely preventable. These reactions occur in patients previously sensitized to RBC alloantigens who have a negative alloantibody screen due to low antibody levels. When the patient is transfused with antigen-positive blood, an anamnestic response results in the early production of alloantibody that binds donor RBCs. The alloantibody is detectable 1 to 2 weeks following the transfusion, and the posttransfusion DAT may become positive due to circulating donor RBCs coated with antibody or complement. The transfused, alloantibody-coated erythrocytes are cleared by the reticuloendothelial system. These reactions are detected most commonly in the blood bank when a subsequent patient sample reveals a positive alloantibody screen or a new alloantibody in a recently transfused recipient.

No specific therapy is usually required, although additional RBC transfusions may be necessary. Delayed serologic reactions are similar to DHTR, as the DAT is positive and alloantibody is detected; however, RBC clearance is not increased.

**Febrile Nonhemolytic Transfusion Reaction**

The most frequent reaction associated with the transfusion of cellular blood components is a febrile nonhemolytic transfusion reaction (FNHTR). These reactions are characterized by chills and rigors and a ≥1°C rise in temperature. FNHTR is diagnosed when other causes of fever in the transfused patient are ruled out. Antibodies directed against donor leukocyte and HLA antigens may mediate these reactions; thus, multiple transfused patients and multiparous women are felt to be at increased risk. Although antibodies may be demonstrated in the recipient’s serum, investigation is not routinely done because of the mild nature of most FNHTR. The use of leukocyte-reduced blood products may prevent or delay sensitization to leukocyte antigens and thereby reduce the incidence of these febrile episodes. Cytokines released from cells within stored blood components may mediate FNHTR; thus, leukoreduction before storage may prevent these reactions. The incidence and severity of these reactions can be decreased in patients with recurrent reactions by premedicating with acetaminophen or other antipyretic agents.

**Allergic Reactions**

Urticarial reactions are related to plasma proteins found in transfused components. Mild reactions may be treated symptomatically by temporarily stopping the transfusion and administering antihistamines (diphenhydramine, 50 mg orally or intramuscularly). The transfusion may be completed after the signs and/or symptoms resolve. Patients with a history of allergic transfusion reaction should be premedicated with an antihistamine. Cellular components can be washed to remove residual plasma for the extremely sensitized patient.

**Anaphylactic Reaction**

This severe reaction presents after transfusion of only a few milliliters of the blood component. Symptoms and signs include difficulty breathing, coughing, nausea and vomiting, hypotension, bronchospasm, loss of consciousness, respiratory arrest, and shock. Treatment includes stopping the transfusion, maintaining vas-
cular access, and administering epinephrine (0.5 to 1.0 mL of 1:1000 dilution subcutaneously). Glucocorticoids may be required in severe cases.

Patients who are IgA-deficient may be sensitized to this Ig class and are at risk for anaphylactic reactions associated with plasma transfusion. Individuals with severe IgA deficiency should therefore receive only IgA-deficient plasma and washed cellular blood components. Patients who have anaphylactic or repeated allergic reactions to blood components should be tested for IgA deficiency.

**Graft-versus-Host Disease**  Graft-versus-host disease (GVHD) is a frequent complication of allogeneic stem cell transplantation, in which lymphocytes from the donor attack and cannot be eliminated by an immunodeficient host. Transfusion-related GVHD is mediated by donor T lymphocytes that recognize host HLA antigens as foreign and mount an immune response, which is manifested clinically by the development of fever, a characteristic cutaneous eruption, diarrhea, and liver function abnormalities. GVHD can also occur when blood components that contain viable T lymphocytes are transfused to immunodeficient recipients or to immunocompetent recipients who share HLA antigens with the donor (e.g., a family donor). In addition to the aforementioned clinical features of GVHD, transfusion-associated GVHD (TA-GVHD) is characterized by marrow aplasia and pancytopenia. TA-GVHD is highly resistant to treatment with immunosuppressive therapies, including glucocorticoids, cyclosporine, antilymphocyte globulin, and ablative therapy followed by allogeneic bone marrow transplantation. Clinical manifestations appear at 8 to 10 days, and death occurs at 3 to 4 weeks posttransfusion.

TA-GVHD can be prevented by irradiation of cellular components (minimum of 2500 cGy) before transfusion to patients at risk. Patients at risk for TA-GVHD include fetuses receiving intratransfusions, selected immunocompetent (e.g., lymphoma patients) or immunocompromised recipients, recipients of donor units known to be from a blood relative, and recipients who have undergone marrow transplantation. Directed donations by family members should be discouraged (they are not less likely to transmit infection); lacking other options, the blood products from family members should always be irradiated.

**Transfusion-Related Acute Lung Injury**  This uncommon reaction results from the transfusion of donor plasma that contains high-titer anti-HLA antibodies that bind recipient leukocytes. The leukocytes aggregate in the pulmonary vasculature and release mediators that increase capillary permeability. The recipient develops symptoms of respiratory compromise and signs of noncardiogenic pulmonary edema, including bilateral interstitial infiltrates on chest x-ray. Treatment is supportive, and patients usually recover without sequelae. Testing the donor’s plasma for anti-HLA antibodies can support this diagnosis. The implicated donors are frequently multiparous women, and transfusion of their plasma component should be avoided.

**Posttransfusion Purpura**  This reaction presents as thrombocytopenia 7 to 10 days after platelet transfusion and occurs predominantly in women. Platelet-specific antibodies are found in the recipient’s serum, and the most frequently recognized antigen is HPAl-1a found on the platelet glycoprotein IIIa receptor. The delayed thrombocytopenia is due to the production of antibodies that react to both donor and recipient platelets. Additional platelet transfusions can worsen the thrombocytopenia and should be avoided. Treatment with intravenous immunoglobulin may neutralize the effector antibodies, or plasmapheresis can be used to remove the antibodies.

**Alloimmunization**  A recipient may become alloimmunized to a number of antigens on cellular blood elements and plasma proteins. Alloantibodies to RBC antigens are detected during pretransfusion testing, and their presence may delay finding antigen-negative cross-match-compatible products for transfusion. Women of childbearing age who are sensitized to certain RBC antigens (i.e., D, C, E, Kell, or Duffy) are at risk for bearing a fetus with hemolytic disease of the newborn. Matching for D antigen is the only pretransfusion selection test to prevent RBC alloimmunization.

Alloimmunization to antigens on leukocytes and platelets can result in refractoriness to platelet transfusions. Once alloimmunization has developed, HLA-compatible platelets from donors who share similar antigens with the recipient may be difficult to find. Hence, prudent transfusion practice is directed at preventing sensitization through the use of leukocyte-reduced cellular components, as well as limiting antigenic exposure by the judicious use of transfusions and use of SDFAs.

**NONIMMUNOLOGIC REACTIONS**  **Fluid Overload**  Blood components are excellent volume expanders, and transfusion may quickly lead to volume overload. Monitoring the rate and volume of the transfusion, along with the use of a diuretic, can minimize this problem.

**Hypothermia**  Refrigerated (4°C) or frozen (−18°C or below) blood components can result in hypothermia when rapidly infused. Cardiac dysrhythmias can result from exposing the sinoatrial node to cold fluid. Use of an in-line warmer will prevent this complication.

**Electrolyte Toxicity**  RBC leakage during storage increases the concentration of potassium in the unit. Neonates and patients in renal failure are at risk for hyperkalemia. Preventive measures, such as using fresh or washed RBCs, are warranted for neonatal transfusions because this complication can be fatal.

Citrated, commonly used to anticoagulate blood components, chelates calcium and thereby inhibits the coagulation cascade. Hypocalcemia, manifested by circumoral numbness and/or tingling sensation of the fingers and toes, may result from multiple rapid transfusions. Because citrate is quickly metabolized to bicarbonate, calcium infusion is seldom required in this setting. If calcium or any other intravenous infusion is necessary, it must be given through a separate intravenous line.

**Iron Overload**  Each unit of RBCs contains 200 to 250 mg of iron. Symptoms and signs of iron overload affecting endocrine, hepatic, and cardiac function are common after 100 units of RBCs have been transfused (total body iron load of 20 g). Preventing this complication by using alternative therapies (e.g., erythropoietin) and judicious transfusion is preferable and cost effective. Deferoxamine and other chelating agents are available, but the response is often suboptimal.

**Hypotensive Reactions**  Transient hypotension may be noted among transfused patients who take angiotensin-converting enzyme (ACE) inhibitors. Since blood products contain bradykinin that is normally degraded by ACE, patients on ACE inhibitors may have increased bradykinin levels that cause hypotension. The blood pressure typically returns to normal without intervention.

**Immunomodulation**  Transfusion of allogeneic blood is immunosuppressive. Multiply transfused renal transplant recipients are less likely to reject the graft, and transfusion may result in poorer outcomes in cancer patients and increase the risk of infections. Transfused leukocytes are thought to mediate the immunosuppression. Leukocyte-depleted cellular products may cause less immunosuppression, though controlled data have not been obtained and are unlikely to be obtained as the blood supply becomes universally leukocyte-depleted.

**INFECTIOUS COMPLICATIONS**  **Nucleic acid amplification testing (NAT)** has been used since 1999 to screen donated blood for the presence of HIV and hepatitis C virus RNA.

**Viral Infections**  **Hepatitis C virus (HCV)**  Fewer than 150 donors have been found to be HCV RNA positive in the absence of HCV antibodies, and the risk of acquiring HCV through transfusion is now 1 in 1,600,000 units. Infection with HCV may be asymptomatic or lead to chronic active hepatitis, cirrhosis, and liver failure.
Only eight seronegative donors have been shown to harbor HIV RNA. The risk of HIV-1 infection per transfusion episode is 1 in 1.9 million. Antibodies to HIV-2 are also measured in donated blood. No cases of HIV-2 infection have been reported in the United States since 1992.

**HEPATITIS B VIRUS**  Donated blood is screened for HBV using assays for hepatitis B surface antigen (HbsAg). NAT testing is not practical because of slow viral replication and lower levels of viremia. The risk of transfusion-associated HBV infection is 1 in 63,000 units, twenty-fold greater than for HCV. Vaccination of individuals who require long-term transfusion therapy can prevent this complication.

**OTHER HEPATITIS VIRUSES**  Hepatitis A virus is rarely transmitted by transfusion, and the disease is typically asymptomatic and does not lead to chronic infection. Hepatitis G virus, now called GBV-C, along with two other transfusion-transmitted viruses, TTV and SEN-V, do not cause chronic hepatitis or other disease states. Routine testing does not appear to be warranted.

**CYTOMEGALOVIRUS**  This ubiquitous virus infects ≅50% of the general population and is transmitted by the infected “passenger” WBCs found in transfused PRBCs or platelet components. Cellular components that are leukocyte-reduced have a decreased risk of transmitting CMV, regardless of the serologic status of the donor. Groups at risk for CMV infections include immunosuppressed patients, CMV-seronegative transplant recipients, and neonates; these patients should receive leukocyte-depleted components or CMV seronegative products.

**HUMAN T LYMPHOTROPIC VIRUS (HTLV) TYPE I**  Assays to detect HTLV-I and -II are used to screen all donated blood. HTLV-I is associated with adult T cell leukemia/lymphoma and tropical spastic paraparesis in a small percentage of infected persons (Chap. 172). The risk of HTLV-I infection via transfusion is 1 in 641,000 transfusion episodes. HTLV-II is not clearly associated with any disease.

**PARVOLVIRUS B-19**  Blood components and products derived from pooled plasma can transmit this virus, the etiologic agent of erythema infectiosum, or fifth disease, in children. Parvovirus B-19 shows tropism for erythroid precursors and inhibits both erythrocyte production and maturation. Pure red cell aplasia, presenting either as acute aplastic crisis or chronic anemia with shortened RBC survival, may occur in individuals with an underlying hematologic disease, such as sickle cell disease or thalassemia (Chap. 94). The fetus of a seronegative woman is at risk for developing hydrops from this virus. NAT testing has reduced the risk of transfusion transmission.

**Bacterial Contamination**  Most bacteria do not grow well at cold temperatures; thus, PRBCs and FFP are not common sources of bacterial contamination. However, some gram-negative bacteria, notably *Yersinia* and *Pseudomonas* species, can grow at 1°C to 6°C. Platelet concentrates, which are stored at room temperature, are more likely to contain skin contaminants such as gram-positive organisms, including coagulase-negative staphylococci.

Recipients of transfusions contaminated with bacteria may develop fever and chills, which can progress to septic shock and DIC. These reactions may occur abruptly, within minutes of initiating the transfusion, or after several hours. The onset of symptoms and signs is often sudden and fulminating, which distinguishes bacterial contamination from a FNHTR. The reactions, particularly those related to gram-negative contaminants, are the result of infused endotoxins formed within the contaminated stored component.

When contaminated transfusions are suspected (i.e., when there is sudden development of shock), the transfusion must be stopped immediately. Therapy is directed at supporting the recipient’s blood pressure, cardiac output, oxygenation, and renal function. The laboratory investigation should include cultures of any untransfused component, along with the routine blood bank clerical checks and serologic studies. Broad-spectrum antibiotic coverage should be started immediately and may be adjusted based on culture and sensitivity.

**Other Infectious Agents**  Various parasites including those causing malaria, babesiosis, and Chagas disease can be transmitted by blood transfusion rarely. Geographic migration and travel of donors can shift the incidence of these rare infections. West Nile virus may be transmitted by transfusion. Other agents implicated in transfusion transmission include Lyme disease and varian Creutzfeld-Jakob disease. Because these infections can prove fatal, they should be considered in the transfused patient in the appropriate clinical setting.

**ALTERNATIVES TO TRANSFUSION**  Alternatives to allogeneic blood transfusions that avoid homologous donor exposures with attendant immunologic and infectious risks remain attractive. Autologous blood is the best option when transfusion is anticipated. However, the cost:benefit ratio of autologous transfusion remains high. No transfusion is a zero-risk event; clerical errors and bacterial contamination remain potential complications even with autologous transfusions. Additional methods of autologous transfusion in the surgical patient include preoperative hemodilution, recovery of shed blood from sterile surgical sites, and postoperative drainage collection. Directed or designated donation from friends and family of the potential recipient has not been safer than volunteer donor component transfusions. Such directed donations may in fact place the recipient at higher risk for complications such as GVHD and alloimmunization.

Oxygen-carrying blood substitutes, such as perfluorocarbons and aggregated hemoglobin solution, are presently in various stages of clinical trials. Granulocyte and granulocyte-macrophage colony-stimulating factor are clinically useful to hasten leukocyte recovery in patients with leukopenia related to high-dose chemotherapy. Erythropoietin stimulates erythrocyte production in patients with anemia of chronic renal failure and other conditions, thus avoiding or reducing the need for transfusion. This hormone can also stimulate erythropoiesis in the autologous donor to enable additional donation. Thrombopoietin, a cytokine that promotes megakaryocyte proliferation and maturation, is being tested for its ability to reduce the need for platelet transfusion.

Bone marrow transplantation was the original term used to describe the collection and transplantation of hematopoietic stem cells, but with the recent demonstration that the peripheral blood and umbilical cord blood are also useful sources of stem cells, hematopoietic cell transplantation has become the preferred generic term for this process. The procedure is usually carried out for one of two purposes: (1) to replace an abnormal but nonmalignant lymphohematopoietic system with one from a normal donor, or (2) to treat malignancy by allowing the administration of higher doses of myelosuppressive therapy than would otherwise be possible. The use of bone marrow transplantation has been steadily increasing, both because of its demonstrated effectiveness in selected diseases and because of increasing availability of donors. The International Bone Marrow Transplant Registry (http://www.ibmtr.org) estimates that about 50,000 transplants are performed each year.

THE HEMATOPOIETIC STEM CELL
Several features of the hematopoietic stem cell make transplantation clinically feasible, including its remarkable regenerative capacity, its ability to home to the marrow space following intravenous injection, and the ability of the stem cell to be cryopreserved. Transplantation of a single stem cell can replace the entire lymphohematopoietic system of an adult mouse. In humans, transplantation of a few percent of a donor’s bone marrow volume regularly results in complete and sustained replacement of the recipient’s entire lymphohematopoietic system, including all red cells, granulocytes, B and T lymphocytes, and platelets, as well as cells comprising the fixed macrophage population, including Kupffer cells of the liver, pulmonary alveolar macrophages, osteoclasts, Langerhans cells of the skin, and brain microglial cells. The ability of the hematopoietic stem cell to home to the marrow following intravenous injection is mediated, at least in part, by the interaction of specific cell molecules, termed selectins, on bone marrow endothelial cells with their unique ligands, termed integrins, on early hematopoietic cells. Human hematopoietic stem cells can survive freezing and thawing with little, if any, damage, making it possible to remove and store a portion of the patient’s own bone marrow for later reinfusion following treatment of the patient with high-dose myelotoxic therapy.

CATEGORIES OF HEMATOPOIETIC CELL TRANSPLANTATION
Hematopoietic cell transplantation can be described according to the relationship between the patient and the donor and by the anatomic source of stem cells. In ~1% of cases, patients have identical twins who can serve as donors. Syngeneic donors represent the best source of stem cells; unlike the use of allogeneic donors, there is no risk of graft-versus-host disease (GVHD) and, unlike the use of autologous marrow, there is no risk that the stem cells are contaminated with tumor cells.

Allogeneic transplantation involves a donor and recipient who are not immunologically identical. Following allogeneic transplantation immune cells transplanted with the marrow or developing from it can react against the patient, causing GVHD. Alternatively, if the immunosuppressive preparative regimen used to treat the patient before transplant is inadequate, immunocompetent cells of the patient can cause graft rejection. The risks of these complications are greatly influenced by the degree of matching between donor and recipient for antigens encoded by genes of the major histocompatibility complex.

The human leukocyte antigen (HLA) molecules are responsible for binding antigenic proteins and presenting them to T cells. The antigens presented by HLA molecules may derive from exogenous sources (e.g., during active infections) or may be endogenous proteins produced by the cell. If individuals are not matched for HLA, T cells from one individual will react strongly to the mismatched HLA, or “major antigens,” of the second. Even if the individuals are HLA-matched, the T cells of the donor may react to differing endogenous, or “minor antigens,” presented by the HLA of the recipient. Reactions to minor antigens tend to be less vigorous. The genes of major relevance to transplantation include HLA-A, -B, -C, and -D; they are closely linked and therefore tend to be inherited as haplotypes, with only rare crossovers between them. Thus, the odds that any one full sibling will match a patient are one in four, and the probability that the patient has an HLA-identical sibling is 1 − (0.75)^n, where n equals the number of siblings.

With current techniques, the risk of graft rejection is 1 to 3%, and the risk of severe, life-threatening acute GVHD is ~15% following transplantation between HLA-identical siblings. The incidence of graft rejection and GVHD increases progressively with the use of family member donors mismatched for one, two, or three antigens. While survival following a one-antigen mismatched transplant is not markedly altered, survival following two- or three-antigen mismatched transplants is significantly impaired, and such transplants should be performed only as part of clinical trials.

The formation of the National Marrow Donor Program has allowed for the identification of HLA-matched unrelated donors for many patients. The genes encoding HLA antigens are highly polymorphic, and thus the odds of any two unrelated individuals being HLA-identical are extremely low, somewhat less than 1 in 10,000. However, by identifying and typing >7 million volunteer donors, HLA-matched donors can now be found for ~50% of patients for whom a search is initiated. It takes, on average, 3 to 4 months to complete a search and schedule and initiate an unrelated donor transplant. Results so far suggest that GVHD is somewhat increased and survival somewhat poorer with such donors than with HLA-matched siblings.

Autologous transplantation involves the removal and storage of the patient’s own stem cells with subsequent reinfusion after the patient receives high-dose myelotoxic therapy. Unlike allogeneic transplantation, there is no risk of GVHD or graft rejection with autologous transplantation. On the other hand, autologous transplantation lacks a graft-versus-tumor (GVT) effect, and the autologous stem cell product can be contaminated with tumor cells that could lead to relapse. A variety of techniques have been developed to “purge” autologous products of tumor cells. Some use antibodies directed at tumor-associated antigens plus complement, antibodies linked to toxins, or antibodies conjugated to immunomagnetic beads. In vitro incubation with certain chemotherapeutic agents such as 4-hydroperoxycyclophosphamide and long-term culture of bone marrow have also been shown to diminish tumor cell numbers in stem cell products. Another technique is positive selection of stem cells using antibodies to CD34, with subsequent column adherence or flow techniques to select normal stem cells while leaving tumor cells behind. All these approaches can reduce the number of tumor cells from 1000- to 10,000-fold and are clinically feasible; however, no prospective randomized trials have yet shown that any of these approaches results in a decrease in relapse rates or improvements in disease-free or overall survival.

Bone marrow aspirated from the posterior and anterior iliac crests has traditionally been the source of hematopoietic stem cells for transplantation. Typically, anywhere from 1.5 to 5 × 10^8 nucleated marrow cells per kilogram are collected for allogeneic transplantation. Several recent studies have found improved survival in the settings of both matched sibling and unrelated transplantation by transplanting higher numbers of bone marrow cells.

Hematopoietic stem cells circulate in the peripheral blood but in very low concentrations. Following the administration of certain hematopoietic growth factors, including granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), and during recovery from intensive chemotherapy, the
concentration of hematopoietic progenitor cells in blood, as measured either by colony-forming units or expression of the CD34 antigen, increases markedly. This has made it possible to harvest adequate numbers of stem cells from the peripheral blood for transplantation. Donors are typically treated with 4 or 5 days of hematopoietic growth factor, following which stem cells are collected in one or two 4-h pheresis sessions. In the autologous setting, transplantation of >2.5 × 10^6 CD34 cells per kilogram, a number easily collected in most circumstances, leads to rapid and sustained engraftment in virtually all cases. Compared to the use of autologous marrow, use of peripheral blood stem cells results in more rapid hematopoietic recovery, with granulocytes recovering to 500/µL by day 12 and platelets recovering to 20,000/µL by day 14. While this more rapid recovery diminishes the morbidity of transplantation, no studies show an improvement in survival.

Variations in studying the use of peripheral blood stem cells for allogeneic transplantation was because peripheral blood stem cell products contain as much as one log more T cells than are contained in the typical marrow harvest; in animal models, the incidence of GVHD is related to the number of T cells transplanted. Nonetheless, phase II and randomized phase III trials have shown that the use of growth factor–mobilized peripheral blood stem cells from HLA-matched family members leads to faster engraftment without an increase in acute GVHD. Chronic GVHD may be increased with peripheral blood stem cells, but in trials conducted so far, this has been more than balanced by reductions in relapse rates and nonrelapse mortality, with the use of peripheral blood stem cells resulting in improved overall survival.

Umbilical cord blood contains a high concentration of hematopoietic progenitor cells, allowing for its use as a source of stem cells for transplantation. Cord blood transplantation from family members has been explored in the setting where the immediate need for transplantation precludes waiting the 9 or so months generally required for the baby to mature to the point of donating marrow. Use of cord blood in such settings results in somewhat slower engraftment than seen with marrow but a low incidence of GVHD, perhaps reflecting the low number of T cells in cord blood. Several banks have been developed to harvest and store cord blood for possible transplantation to unrelated patients from material that would otherwise be discarded. A summary of the first 562 unrelated cord blood transplants, facilitated by the New York Blood Center, reported engraftment in ~85% of patients but at a slower pace than seen with marrow. Severe GVHD was seen in 23% of patients. The risk of graft failure was related to the dose of cord blood cells per kilogram infused. The low cell content of most cord blood collections has limited the use of this approach as a source of stem cells for adult patients.

**THE TRANSPLANT PREPARATIVE REGIMEN**

The treatment regimen administered to patients immediately preceding transplantation is designed to eradicate the patient’s underlying disease and, in the setting of allogeneic transplantation, immunosuppress the patient adequately to prevent rejection of the transplanted marrow. The appropriate regimen, therefore, depends on the disease setting and source of marrow. For example, when transplantation is performed to treat severe combined immunodeficiency and the donor is a histocompatible sibling, no treatment is required because no host cells require eradication and the patient is already too immunoincompetent to reject the transplanted marrow. For aplastic anemia, there is no large population of cells to eradicate and high-dose cyclophosphamide plus antithymocyte globulin are sufficient to immunosuppress the patient adequately to accept the marrow graft. In the setting of thalassemia and sickle cell anemia, high-dose busulfan is frequently added to cyclophosphamide in order to eradicate the hyperplastic host hematopoiesis. A variety of different regimens have been developed to treat malignant diseases. Most of these regimens include agents that have high activity against the tumor in question at conventional doses and have myelosuppression as their predominant dose-limiting toxicity. Therefore, these regimens commonly include busulfan, cyclophosphamide, melphalan, thiota, carmustine, etoposide, and total-body irradiation in various combinations.

Although high-dose treatment regimens have typically been used in transplantation, the understanding that much of the antitumor effect of transplantation derives from an immunologically mediated GVT response has led investigators to ask if less intensive “nonmyeloablative” regimens might be effective and more tolerable. Evidence for a GVT effect comes from studies showing posttransplant relapse rates are lowest in patients who develop acute and chronic GVHD, higher in those without GVHD, and higher still in recipients of T cell–depleted allogeneic or syngeneic marrow. The demonstration that complete remissions can be obtained in many patients who have relapsed posttransplant by simply administering viable lymphocytes from the original donor further strengthens the argument for a potent GVT effect. Accordingly, a variety of less intensive nonmyeloablative regimens have been studied, ranging in intensity from the very minimum required to achieve engraftment (e.g., fludarabine plus 200 cGy total-body irradiation) to regimens of more immediate intensity (e.g., fludarabine plus melphalan). Studies to date document that engraftment can be readily achieved with less toxicity than seen with conventional transplantation. Complete sustained responses have been documented in many patients, particularly those with more indolent hematologic malignancies. The precise role of nonmyeloablative transplants in any one disease category, however, has not yet been fully defined.

**ENGRaFTMENT**

Peripheral blood stem cells are collected by leukopheresis after the donor has been treated with hematopoietic growth factors or, in the setting of autologous transplantation, sometimes after treatment with a combination of chemotherapy and growth factors. Stem cells for transplantation are generally infused through a large-bore central venous catheter. Such infusions are usually well tolerated, although occasionally patients develop fever, cough, or shortness of breath. These symptoms usually resolve with slowing of the infusion. When the stem cell product has been cryopreserved using dimethyl sulfoxide, patients more often experience short-lived nausea or vomiting due to the odor and taste of the cryoprotectant.
**Complications Following Hematopoietic Cell Transplant**

**Early Direct Chemoradiotoxicities** The transplant preparative regimens commonly used cause a spectrum of acute toxicities that vary according to the specific regimen but frequently result in nausea, vomiting, and mild skin erythema (Fig. 100-1). Regimens that include high-dose cyclophosphamide can result in hemorrhagic cystitis, which can usually be prevented by bladder irrigation or with the sulfhydryl compound, mercaptopethanesulfonate (MESNA); rarely, acute hemorrhagic carditis is seen. Most preparative regimens will result in oral mucositis, which typically develops 5 to 7 days posttransplant and often requires narcotic analgesia. Use of a patient-controlled analgesic pump provides the greatest patient satisfaction and results in a lower cumulative dose of narcotic. Patients begin losing their hair 5 to 6 days posttransplant and by 1 week are usually profoundly pancytopenic.

Approximately 10% of patients will develop venoocclusive disease of the liver, a syndrome resulting from direct cytotoxic injury to hepatic-venular and sinusoidal endothelium, with subsequent deposition of fibrin and the development of a local hypercoagulable state. This chain of events results in the clinical symptoms of tender hepatomegaly, ascites, jaundice, and fluid retention. These symptoms can develop any time during the first month posttransplant, with the peak incidence at day 16. The mortality of venoocclusive disease is ~30%, with progressive hepatic failure culminating in a terminal hepatorenal syndrome. Both thrombolytic and anti thrombolytic agents, such as tissue plasminogen activator, heparin, and prostaglandin E, have been studied as therapy, but none has proven of consistent major benefit in controlled trials and all have significant toxicity. Early studies with defibrotide, a polypeoxyribonucleotide, seem encouraging.

Although most pneumonias developing posttransplant are caused by infectious agents, in ~5% of patients a diffuse interstitial pneumonitis may develop that is thought to be the result of direct toxicity of the preparative regimen. Bronchialalveolar lavage typically shows alveolar hemorrhage, and biopsies are typically characterized by diffuse alveolar damage, although some cases may have a more clearly interstitial pattern. High-dose glucocorticoids are often used as treatment, although randomized trials testing their utility have not been reported.

**Late Direct Chemoradiotoxicities** Late complications of the preparative regimen include decreased growth velocity in children and delayed development of secondary sex characteristics. These complications can be partly ameliorated with the use of appropriate growth and sex hormone replacement. Most men become azoospermic, and most postpubertal women will develop ovarian failure, which should be treated. Thyroid dysfunction, usually well compensated, is sometimes seen. Cataracts develop in 10 to 20% of patients and are most common in patients treated with total-body irradiation and those who receive glucocorticoid therapy posttransplant for treatment of GVHD. Aseptic necrosis of the femoral head is seen in 10% of patients and is particularly frequent in those receiving chronic glucocorticoid therapy.

**Graft-versus-host disease** GVHD is the result of allogeneic T cells that were either transferred with the donor’s stem cell inoculum or develop from it, reacting with antigenic targets on host cells. GVHD developing within the first 3 months posttransplant is termed **acute GVHD**, while GVHD developing or persisting beyond 3 months posttransplant is termed **chronic GVHD**. Acute GVHD most often first becomes apparent 2 to 4 weeks posttransplant and is characterized by an erythematous maculopapular rash; persistent anorexia or diarrhea, or both; and by liver disease with increased serum levels of bilirubin, alanine and aspartate aminotransferase, and alkaline phosphatase. Since many conditions can mimic acute GVHD, diagnosis usually requires skin, liver, or endoscopic biopsy for confirmation. In all these organs, endothelial damage and lymphocytic infiltrates are seen. In skin, the epidermis and hair follicles are damaged; in liver, the small bile ducts show segmental disruption; and in intestines, destruction of the crypts and mucosal ulceration may be noted. A commonly used rating system for acute GVHD is shown in Table 100-1. Grade I acute GVHD is of little clinical significance, does not affect the likelihood of survival, and does not require treatment. In contrast, grades II to IV GVHD are associated with significant symptoms and a poorer probability of survival and require aggressive therapy. The incidence of acute GVHD is higher in recipients of stem cells from mismatched or unrelated donors, in older patients, and in patients unable to receive full doses of drugs used to prevent the disease.

One general approach to the prevention of GVHD is the administration of immunosuppressive drugs early after transplant. Combinations of methotrexate and either cyclosporine or tacrolimus are among the most effective and widely used regimens. Prednisone, anti–T cell antibodies, mycophenolate mofetil, and other immunosuppressive agents have also been or are being studied in various combinations. A second general approach to GVHD prevention is removal of T cells from the stem cell inoculum. While effective in preventing GVHD, T cell depletion is associated with an increased incidence of graft failure and of tumor recurrence posttransplant; as yet, little evidence suggests that this approach improves cure rates in any specific setting.

Despite prophylaxis, significant acute GVHD will develop in ~30% of recipients of stem cells from matched siblings and in as many as 60% of those receiving stem cells from unrelated donors. The disease is usually treated with glucocorticoids, antithymocyte globulin, or monoclonal antibodies targeted against T cells or T cell subsets. While complete and sustained engraftment are usually seen posttransplant, occasionally marrow function either does not return or, after a brief period of engraftment, is lost. Graft failure after autologous transplantation can be the result of inadequate numbers of stem cells being transplanted, damage during ex vivo treatment or

**Figure 100-1** Major syndromes complicating marrow transplantation. VOD, venoocclusive disease; GVHD, graft-versus-host disease; HSV, herpes simplex virus; CMV, cytomegalovirus; VZV, varicella-zoster virus. The size of the shaded area roughly reflects the risk of the complication.
storage, or exposure of the patient to myelotoxic agents posttransplant. Infections with cytomegalovirus (CMV) or human herpes virus type 6 have also been associated with loss of marrow function. Graft failure after allogeneic transplantation can also be due to immunologic rejection of the graft by immunocompetent host cells. Immunologically based graft rejection is more common following use of less immunosuppressive preparative regimens, in recipients of T cell–depleted stem cell products, and in patients receiving grafts from HLA-mismatched donors.

Treatment of graft failure usually involves removing all potentially myelotoxic agents from the patient’s regimen and attempting a short trial of myeloid growth factor. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. Reinfusion of donor stem cells in such patients is usually unsuccessful unless preceded by a second immuno-suppressive preparative regimen. Standard preparative regimens are generally tolerated poorly if administered within 100 days of a first nosuppressive preparative regimen. Standard preparativeregimensare patients is usually unsuccessful unless preceded by a second immuno-suppressive preparative regimen. Standard preparative regimens are generally tolerated poorly if administered within 100 days of a first transplant because of cumulative toxicities. However, use of regimens combining, for example, anti-CD3 antibodies with high-dose glucocorticoids have been successful in achieving engraftment in >50% of patients.

**INFECTION**

Posttransplant patients, particularly recipients of allogeneic transplantation, require unique approaches to the problem of infection. Early after transplantation, patients are profoundly neutropenic, and because the risk of bacterial infection is so great, most centers initiate antibiotic treatment once the granulocyte count falls to <500/μL. Fluconazole prophylaxis at a dose of 200 to 400 mg/kg per day reduces the risk of candidal infections. Patients seropositive for herpes simplex should receive acyclovir prophylaxis. One approach to infection prophylaxis is shown in Table 100-2. Despite these prophylactic measures, most patients will develop fever and signs of infection posttransplant. The management of patients who become febrile despite bacterial and fungal prophylaxis is a difficult challenge and is guided by individual aspects of the patient and by the institution’s experience. The general problem of infection in the immunocompromised host is discussed in Chap. 117.

Once patients engraft, the incidence of bacterial infection diminishes; however, patients, particularly allogeneic transplant recipients, remain at significant risk of infection. During the period from engraftment until about 3 months posttransplant, the most common causes of infection are Gram-positive bacteria, fungi (particularly Aspergillus) and viruses including CMV. CMV infection, which in the past was an important cause of morbidity and mortality, can be prevented in seronegative patients by the use of seronegative blood products. The use of ganciclovir, either as prophylaxis beginning at the time of engraftment or initiated when CMV first reactivates as evidenced by development of antigenemia, can significantly reduce the risk of CMV disease in seropositive patients. Foscarnet is effective for some patients who develop CMV antigenemia or infection despite the use of ganciclovir or who cannot tolerate the drug.

*Pneumocystis carinii* pneumonia, once seen in 5 to 10% of patients, can be prevented by treating patients with oral trimethoprim-sulfamethoxazole for 1 week pretransplant and resuming the treatment once patients have engrafted.

The risk of infection diminishes considerably beyond 3 months after transplant unless chronic GVHD develops, requiring continuous immunosuppression. Most transplant centers recommend continuing trimethoprim-sulfamethoxazole prophylaxis while patients are receiving any immunosuppressive drugs and also recommend careful monitoring for late CMV reactivation. In addition, many centers recommend prophylaxis against varicella zoster, using acyclovir for 1 year posttransplant.

---

**TREATMENT OF SPECIFIC DISEASES USING HEMATOPOIETIC CELL TRANSPLANTATION**

**NONMALIGNANT DISEASES**

**Immunodeficiency Disorders** By replacing abnormal stem cells with cells from a normal donor, hematopoietic cell transplantation can cure patients of a variety of immunodeficiency disorders including severe combined immunodeficiency, Wiskott-Aldrich syndrome, and Chédiak-Higashi syndrome. The widest experience has been with severe combined immunodeficiency disease, where cure rates of 90% can be expected with HLA-identical donors and success rates of 50 to 70% have been reported using haplotype-mismatched parents as donors (Table 100-3).

**Aplastic Anemia** Transplantation from matched siblings after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin can cure up to 90% of patients <40 years with severe aplastic anemia. Results in older patients and in recipients of mismatched family member or unrelated marrow are less favorable; therefore, a trial of immunosuppressive therapy is generally recommended for such patients before considering transplantation. Transplantation is effective in all forms of aplastic anemia including, for example, the syndromes associated with paroxysmal nocturnal hemoglobinuria and Fanconi’s anemia. Patients with Fanconi’s anemia are abnormally sensitive to the toxic effects of alkylating agents and so less intensive preparative regimens must be used in their treatment (Chap. 94).

**Hemoglobinopathies** Marrow transplantation from an HLA-identical sibling following a preparative regimen of busulfan and cyclophosphamide can cure 70 to 90% of patients with thalassemia major. The best outcomes can be expected if patients are transplanted before they develop hepatomegaly or portal fibrosis and if they have been given effective chelation therapy. Among such patients, the probabilities of 5-year survival and disease-free survival are 95 and 90%, respectively. Although prolonged survival can be achieved with aggressive chelation therapy, transplantation is the only curative treatment for

Note: Other Nonmalignant Diseases

Theoretically, hematopoietic cell transplantation is used as treatment for aplastic anemia, thalassemia, acute myeloid leukemia, and acute lymphocytic leukemia. Transplantation is being studied as a curative approach to patients with sickle cell anemia. Two-year survival and disease-free survival rates of 90 and 80%, respectively, have been reported following matched sibling transplantation. Decisions about patient selection and the timing of transplantation remain difficult, but transplantation seems to represent a reasonable option for younger patients who suffer repeated crises or other significant complications and who have not responded to other interventions (Chap. 91).

Other Nonmalignant Diseases

Theoretically, hematopoietic cell transplantation should be able to cure any disease that results from an inborn error of the lymphohematopoietic system. Transplantation has been used successfully to treat congenital disorders of white blood cells such as Kostmann’s syndrome, chronic granulomatous disease, and leukocyte adhesion deficiency. Congenital anemias such as Blackfan-Diamond anemia can also be cured with transplantation. Infantile malignant osteopetrosis is due to an inability of the osteoclast to resorb bone, and since osteoclasts derive from the marrow, transplantation can cure this rare inherited disorder.

Hematopoietic cell transplantation has been used as treatment for a number of storage diseases caused by enzymatic deficiencies, such as Gaucher’s disease, Hurler’s syndrome, Hunter’s syndrome, and a number of storage diseases caused by enzymatic deficiencies, such as Gaucher’s disease, Hurler’s syndrome, Hunter’s syndrome, and infantile metachromatic leukodystrophy. Transplantation for these diseases has not been uniformly successful, but treatment early in the course of these diseases, before irreversible damage to extramedullary organs has occurred, increases the chance for success. Transplantation is being explored as a treatment for severe acquired autoimmune disorders. These trials are based on studies demonstrating that transplantation can reverse autoimmune disorders in animal models and on the observation that occasional patients with coexisting autoimmune disorders and hematologic malignancies have been cured of both with transplantation.

MALIGNANT DISEASES

Acute Leukemia

Allogeneic hematopoietic cell transplantation cures 15 to 20% of patients who do not achieve complete response from induction chemotherapy for acute myeloid leukemia (AML) and is the only form of therapy that can cure such patients. Cure rates of 30 to 35% are seen when patients are transplanted in second remission or in first relapse. The best results with allogeneic transplantation are achieved when applied during first relapse, with disease-free survival rates averaging 55 to 60%. Chemotherapy alone can cure a portion of AML patients, and so the relative merits of transplanting all patients during first remission versus only transplantsing very high risk patients and those who relapse continue to be discussed. Autologous transplantation is also able to cure a portion of patients with AML. The rates of disease recurrence with autologous transplantation are higher than seen after allogeneic transplantation, and cure rates are generally somewhat less.

Similar to patients with AML, adults with acute lymphocytic leukemia who do not achieve a complete response to induction chemotherapy can be cured in 15 to 20% of cases with immediate transplantation. Cure rates improve to 30 to 50% in second remission, and therefore transplantation can be recommended for adults who have persistent disease after induction chemotherapy or who have subsequently relapsed. Transplantation in first remission results in cure rates around 55%. While transplantation appears to offer a clear advantage over chemotherapy for patients with high-risk disease, such as those with Philadelphia chromosome-positive disease, debate continues about whether adults with standard-risk disease should be transplanted in first remission or whether transplantation should be reserved until relapse. Autologous transplantation is associated with a higher relapse rate but a somewhat lower risk of nonrelapse mortality when compared to allogeneic transplantation. On balance, most experts recommend use of allogeneic stem cells if an appropriate donor is available.

Chronic Leukemia

Allogeneic hematopoietic cell transplantation is the only therapy shown to cure a substantial portion of patients with chronic myeloid leukemia (CML). Five-year disease-free survival rates are 15 to 20% for patients transplanted for blast crisis, 25 to 50% for accelerated-phase patients, and 60 to 70% for chronic phase patients, with cure rates as high as 80% at selected centers. Time from diagnosis to transplantation influences outcome, with best results obtained among patients transplanted within 1 year of diagnosis. Use of unrelated donors results in more GVHD and slightly worse survival than seen with matched siblings, although, at some large centers, 3-year disease-free survival rates of 70% have been reported. Autologous transplantation is being studied; however, few data suggest that this approach has curative potential in this disease. The timing of transplantation in CML has become more complicated with the introduction of imatinib mesylate, a remarkably effective, relatively nontoxic oral agent. Because imatinib does not generally result in complete molecular remissions, many would argue that allogeneic transplantation remains the treatment of choice for younger patients with matched donors. For older patients and those without matched donors, an initial trial of imatinib is appropriate (Chap. 96).

Allogeneic transplantation has been used to only a limited extent for chronic lymphocytic leukemia, in large part because of the chronic nature of the disease and because of the age profile of patients. With allogeneic transplantation, complete remissions have been achieved in the majority of patients so far reported, with disease-free survival rates of ~50% at 3 years. However, treatment-related mortality has been substantial, and further follow-up is needed. There is even less experience with autologous transplantation in this disorder.

Myelodysplasia

Between 40 and 50% of patients with myelodysplasia appear to be cured with allogeneic transplantation. Results are better among younger patients and those with less advanced disease. However, some patients with myelodysplasia can live for extended periods without intervention, and so transplantation is generally recommended only for patients with disease categorized as intermediate risk 1 or greater according to the International Prognostic Scoring System (Chap. 94).

Lymphoma

Patients with disseminated intermediate- or high-grade non-Hodgkin’s lymphoma who have not been cured by first-line chemotherapy and are transplanted in first relapse or second remission can still be cured in 40 to 50% of cases. This represents a clear advantage over results obtained with salvage chemotherapy. It is unsettled whether patients with high-risk disease benefit from transplantation in first remission. Most experts favor the use of autol-

ogous rather than allogeneic transplantation for patients with non-Hodgkin’s lymphoma, because fewer complications occur with this approach and survival appears equivalent. The role of transplantation in patients with indolent non-Hodgkin’s lymphoma is less well defined. Long-term remissions can be obtained in many patients with acceptable toxicity and results with transplantation in patients with recurrent disease generally appear better than one would expect with conventional-dose chemotherapy. However, late relapses are seen after transplantation, and no randomized study has confirmed its superiority.

The role of transplantation in Hodgkin’s disease is similar to that in non-Hodgkin’s lymphoma. With transplantation, 5-year disease-free survival is 20 to 30% in patients who never achieve a first remission with standard chemotherapy and up to 60% for those transplanted in second remission. Transplantation has no defined role in first remission in Hodgkin’s disease.

**Myeloma**  Patients with myeloma who have progressed on first-line therapy can sometimes benefit from allogeneic or autologous transplantation. Autologous transplantation has been studied as part of the initial therapy of patients, and in randomized trials, both disease-free survival as well as overall survival were improved with this approach. A strategy of autologous transplantation followed by nonmyeloablative allogeneic transplantation has shown encouraging results.

**Solid Tumors**  Among women with metastatic breast cancer, 15 to 20% disease-free survival rates at 3 years have been reported, with better results seen in younger patients who have responded completely to standard-dose therapy before undergoing transplantation. Randomized trials have not shown superior survival for patients treated for metastatic disease with high-dose chemotherapy plus stem cell support. Randomized trials evaluating transplantation as treatment for primary breast cancer are being conducted, but final results are not yet available.

Patients with testicular cancer who have failed first-line chemotherapy have been treated with autologous transplantation; ~10 to 20% of such patients apparently have been cured with this approach.

The use of high-dose chemotherapy with autologous stem cell support is being studied for several other solid tumors, including ovarian cancer, small cell lung cancer, neuroblastoma, and pediatric sarcomas. As in most other settings, the best results have been obtained in patients with limited amounts of disease and where the remaining tumor retains sensitivity to conventional-dose chemotherapy. Few randomized trials of transplantation in these diseases have been completed.

Partial and complete responses have been reported following non-myeloablative allogeneic transplantation for several solid tumors, most notably renal cell carcinomas. These results suggest that the GVT effect, well documented in the treatment of hematologic malignancies, may under certain circumstances apply to selected solid tumors.

**Posttransplant Relapse**  Patients who relapse following autologous transplantation sometimes respond to further chemotherapy, particularly if the remission following transplantation was long. More options are available for patients who relapse following allogeneic transplantation. Of particular interest are the response rates seen with infusion of unirradiated donor lymphocytes. Complete responses in as many as 75% of patients with chronic myeloid leukemia, 40% in myelodysplasia, 25% in AML, and 15% in myeloma have been reported. Major complications of donor lymphocyte infusions include transient myelo-suppression and the development of GVHD. These complications appear to be dependent on the number of donor lymphocytes given and the schedule of infusions, with less GVHD seen with lower dose, fractionated schedules.

**Section 3 Disorders of Hemostasis**

**101 Disorders of the Platelet and Vessel Wall**

Robert I. Handin

 Patients with platelet or vessel wall disorders usually bleed into superficial sites such as the skin, mucous membranes, or genitourinary or gastrointestinal tract. Bleeding begins immediately after trauma and either responds to simple measures, such as pressure and packing, or requires systemic therapy with glucocorticoids, desmopressin, plasma fractions, or platelet concentrates. The most common platelet/vessel wall disorders are (1) various forms of thrombocytopenia, (2) von Willebrand’s disease (vWD), and (3) drug-induced platelet dysfunction. This chapter reviews the diagnosis and treatment of quantitative and qualitative platelet disorders as well as vessel wall defects that cause bleeding. For further discussion of the physiology of normal hemostasis and the cardinal manifestations of bleeding arising from hemostatic disorders, see Chap. 53.

**PLATELET DISORDERS**

Platelets arise from the fragmentation of megakaryocytes, which are very large, polyplid bone marrow cells produced by the process of endomitosis. They undergo from three to five cycles of chromosomal duplication without cytoplasmic division. After leaving the marrow space, about one-third of the platelets are sequestered in the spleen, while the other two-thirds circulate for 7 to 10 days. Normally, only a small fraction of the platelet mass is consumed in the process of hemostasis, so most platelets circulate until they become senescent and are removed by phagocytic cells. The normal blood platelet count is 150,000 to 450,000/μL. A decrease in platelet count stimulates an increase in the number, size, and ploidy of megakaryocytes, releasing additional platelets into the circulation. This process is regulated by thrombopoietin (TPO) binding to its megakaryocyte receptor, a proto-oncogene c-mpl. TPO (c-mpl ligand) is secreted continuously at a low level and binds tightly to circulating platelets. A reduction in platelet count increases the level of free TPO and thereby stimulates megakaryocyte and platelet production.

The platelet count varies during the menstrual cycle, rising following ovulation and falling at the onset of menses. It is also influenced by the patient’s nutritional state and can be decreased in severe iron, folic acid, or vitamin B₁₂ deficiency. Platelets are acute-phase reac-
Thrombocytopenia is caused by one of three mechanisms—decreased bone marrow production, increased splenic sequestration, or accelerated destruction of platelets. In order to determine the etiology of thrombocytopenia, each patient should have a careful examination of the peripheral blood film, an assessment of marrow morphology by examination of an aspirate or biopsy, and an estimate of splenic size by bedside palpation supplemented, if necessary, by ultrasonography or computed tomography (CT). Occasional patients have “pseudothrombocytopenia,” a benign condition in which platelets agglutinate or adhere to leukocytes when blood is collected with EDTA as anticoagulant. This is a laboratory artifact, and the actual platelet count in vivo is normal. A scheme for classifying patients with thrombocytopenia based on these clinical observations and laboratory tests is outlined in Fig. 101-1.

### Impaired Production
Disorders that injure stem cells or prevent their proliferation frequently cause thrombocytopenia. They usually affect multiple hematopoietic cell lines so that thrombocytopenia is accompanied by varying degrees of anemia and leukopenia. Diagnosis of a platelet production defect is readily established by examination of a bone marrow aspirate or biopsy, which should show a reduced number of megakaryocytes. The most common causes of decreased platelet production are marrow aplasia, fibrosis, or infiltration with malignant cells, all of which produce highly characteristic marrow abnormalities. Occasionally, thrombocytopenia is the presenting laboratory abnormality in these disorders. Cytoxic drugs impair megakaryocyte proliferation and maturation and frequently cause thrombocytopenia. Rare marrow disorders, such as congenital amegakaryocytic hypoplasia and thrombocytopenia with absent radii (TAR syndrome), produce a selective decrease in megakaryocyte production.

### Splenic Sequestration
Since one-third of the platelet mass is normally sequestered in the spleen, splenectomy will increase the platelet count by 30%. Postsplenectomy thrombocytosis is a benign self-limited condition that does not require specific therapy. In contrast, when the spleen enlarges, the fraction of sequestered platelets increases, lowering the platelet count. The most common causes of splenomegaly are portal hypertension secondary to liver disease and splenic infiltration with tumor cells in myeloproliferative or lymphoproliferative disorders (Chap. 54). Isolated splenomegaly is rare, and in most patients it is accompanied by other clinical manifestations of an underlying disease. Many patients with leukemia, lymphoma, or a myeloproliferative syndrome have both marrow infiltration and splenomegaly and develop thrombocytopenia from a combination of impaired marrow production and splenic sequestration of platelets.

### Accelerated Destruction
Abnormal vessels, fibrin thrombi, and intravascular coagulation may depress megakaryocyte production. Ingestion of large quantities of alcohol has a marrow-depressing effect leading to transient thrombocytopenia, particularly in binge drinkers. Thiazide diuretics, used to treat hypertension or congestive heart failure, impair megakaryocyte production and can produce mild thrombocytopenia (50,000 to 100,000/µL), which may persist for several months after the drug is discontinued.

Most drugs induce thrombocytopenia by eliciting an immune response in which the platelet is an innocent bystander. The platelet is destroyed by complement activation following the formation of drug-antibody complexes. Current laboratory tests can identify the causative agent in 10% of patients with clinical evidence of drug-induced thrombocytopenia. The best proof of a drug-induced etiology is a prompt rise in the platelet count when the suspected drug is discontinued. Patients with drug-induced platelet destruction may also have a secondary increase in megakaryocyte number without other marrow abnormalities.

Although most patients recover within 7 to 10 days and do not require therapy, occasional patients with platelet counts <10,000 to 20,000/µL have severe hemorrhage and may require temporary support with glucocorticoids, plasmapheresis, or platelet transfusions.

IDIOPATHIC THROMBOCYTOPENIC PURPURA  The immunologic thrombocytopenias can be classified on the basis of the pathologic mechanism, the inciting agent, or the duration of the illness. The explosive onset of severe thrombocytopenia following recovery from a viral exanthem or upper respiratory illness (acute ITP) is common in children and accounts for 90% of the pediatric cases of immunologic thrombocytopenia. Of these patients, 60% recover in 4 to 6 weeks and >90% recover within 3 to 6 months. Transient immunologic thrombocytopenia also complicates some cases of infectious mononucleosis, acute toxoplasmosis, or cytomegalovirus infection and can be part of the prodromal phase of viral hepatitis and initial infection with HIV. Acute ITP is rare in adults and accounts for <10% of postpubertal patients with immune thrombocytopenia. Acute ITP is caused by immune complexes containing viral antigens that bind to platelet Fc receptors or by antibodies produced against viral antigens that cross-react with these products. Several potent thrombin inhibitors with different structures from heparin can be used to treat patients with HIT (Chap. 103). Argatroban is the current drug of choice, but pentasaccharides and lepirudin can reduce the risk of thrombosis. Low-molecular-weight heparin products have reduced the incidence of HIT. They are effective antithrombotic agents (Chap. 103) and are less immunogenic. Unfortunately, 80 to 90% of the antibodies generated against conventional heparins cross-react with low-molecular-weight heparins, so only a minority of patients with preformed antibody can be treated with these products. Several potent thrombin inhibitors with different structures from heparin can be used to treat patients with HIT (Chap. 103). Argatroban is the current drug of choice, but pentasaccharides and lepirudin can reduce the risk of thrombosis.

A low platelet count may be the initial manifestation of systemic lupus erythematosus (SLE) or the first sign of a primary hematologic disorder. Thus, patients with chronic ITP should have a bone marrow examination and an antinuclear antibody determination. In addition, patients with hepatic or splenic enlargement, lymphadenopathy, or atypical lymphocytes should have serologic studies for hepatitis viruses, cytomegalovirus, Epstein-Barr virus, Toxoplasma, and HIV. HIV infection is a common cause of immunologic thrombocytopenia. Thrombocytopenia can be the initial symptom of HIV infection or a complication of fully developed clinical AIDS.

**TREATMENT**

Treatment of patients with ITP must take into account the age of the patient, the severity of the illness, and the anticipated natural history. Although adults have a higher incidence of intracranial bleeding than children, specific therapy may not be necessary unless the platelet count is <20,000/µL or there is extensive bleeding. Hemorrhage in patients with either acute or chronic ITP can usually be controlled with glucocorticoids but, in rare cases, may require temporary phagocytosis blockade with intravenous immunoglobulin (IVIg) or anti-RhD (WinRho). Although antibody premedications are effective, they are expensive and should be reserved for patients with severe thrombocytopenia and clinical bleeding who are refractory to other measures. Emergency splenectomy is usually reserved for patients with acute or chronic ITP who are desperately ill and have not responded to any medical measures. The treatment of symptomatic thrombocytopenia in patients with HIV infection is more complex because the administration of glucocorticoids or splenectomy may increase susceptibility to opportunistic infections. Splenectomy has been effective in the course of HIV before the onset of symptomatic AIDS. Treatment with zidovudine (AZT) and other antiviral agents that reduce viral load can improve the platelet count in patients with HIV-induced thrombocytopenia.

Symptomatic patients with chronic ITP are usually placed on prednisone, 60 mg/d for 4 to 6 weeks. The drug is then decreased slowly over another few weeks. About 50% of patients with chronic ITP will normalize their platelet count on high doses of prednisone. However, the majority will have a fall in platelet count following steroid withdrawal. Patients with chronic ITP who fail to maintain a normal platelet count after a course of prednisone are eligible for elective splenectomy. These glucocorticoid-responsive but glucocorticoid-dependent patients are very likely to respond to splenectomy, and 70% will have a normal platelet count within 1 week after surgery. Splenectomy can now often be performed by minimally invasive laparoscopic techniques that reduce morbidity and shorten hospital stay. Some patients who do not respond to glucocorticoids may still respond to splenectomy. Occasionally, patients may fail to respond to splenectomy because of the failure to remove an accessory spleen. In other patients, a small, inactive accessory spleen may grow or new splenic foci may develop from splenic cells shed at the time of surgery and cause the late onset of thrombocytopenia. In either case, the presence of splenic tissue can be diagnosed by examination of the blood smear for Howell-Jolly bodies that appear in the red cells of asplenic individuals. Persistent splenic tissue can be confirmed by a radionuclide scan.

Patients still thrombocytopenic after splenectomy or who relapse months to years after initial therapy have received a variety of immunosuppressive drugs including azathioprine, cyclophosphamide, vincristine, vinblastine, and cyclosporine. Danazol has also been used with some success. Although each of these drugs may be beneficial, they have serious side effects and should be used judiciously. IVIg and anti-RhD are only transiently effective and expensive. IVIg can cause meningsis and headache, and some lots have carried hepatitis C virus. Anti-RhD can cause hemolysis. These drugs should be used to raise the platelet count temporarily and to support patients before surgery or labor and delivery; they are not substitutes for splenectomy. If a patient is not bleeding and maintains a platelet count $>20,000/$
μL, consideration should be given to withholding therapy. Patients with severe chronic thrombocytopenia may live with their disease for two or three decades.

Rituximab, an anti-CD20 monoclonal antibody used to treat lymphoma, has also proven an effective approach to ITP and is probably preferable to long-term glucocorticoid therapy. Rituximab eliminates normal B cells, including those producing the antiplatelet antibody. This B cell depletion is transient (lasting 12 to 18 months, normally) and has surprisingly few side effects or toxicities.

FUNCTIONAL PLATELET DISORDERS As described in Chap. 53, normal hemostasis requires three critical platelet reactions—adhesion, aggregation, and granule release. Clinical bleeding can result from a failure of any of these important functions. Table 101-2 lists the major functional platelet disorders. Table 101-3 lists methods to assess platelet function.

von Will esbrand’s Disease vWD is the most common inherited bleeding disorder, occurring in 1 in 100 to 500 individuals. The von Willebrand factor (vWF) is a heterogeneous multimeric plasma glycoprotein with two major functions: (1) It facilitates platelet adhesion under conditions of high shear stress by linking platelet membrane receptors to vascular subendothelium; and (2) it serves as the plasma carrier for factor VIII, the antihemophilic factor, a critical blood coagulation protein. Discrete domains in each vWF subunit mediate each of these important functions. The normal plasma vWF level is 10 mg/L. The vWF activity is distributed among a series of plasma multimers with estimated molecular weights ranging from 400,000 to 20 million. A single large vWF precursor subunit is synthesized in endothelial cells and megakaryocytes, where it is cleaved and assembled into the di-sulfide-linked multimers present in plasma, platelets, and vascular subendothelium. A modest reduction in plasma vWF concentration or a selective loss in the high-molecular-weight multimers decreases platelet adhesion and causes clinical bleeding.

Although vWD is heterogeneous, certain clinical features are common to all the syndromes. With one exception (type III disease), all forms are inherited as autosomal dominant traits, and affected patients are heterozygous with one normal and one abnormal vWF allele. In mild cases, bleeding occurs only after surgery or trauma. More severely affected patients have spontaneous epistaxis or oral mucosal, gastrointestinal, or genitourinary bleeding. The laboratory findings are variable. The most diagnostic pattern is the combination of (1) a prolonged bleeding time, (2) a reduction in plasma vWF concentration, (3) a parallel reduction in biologic activity as measured with the ristocetin cofactor assay, and (4) reduced factor VIII activity. The variability in laboratory tests is related to both the heterogeneous nature of the defects in vWD and the fact that plasma levels are influenced by ABO blood group type, central nervous system disorders, systemic inflammation, and pregnancy. Since vWD is an autosomal dominant disorder, some vWF is produced by the remaining normal allele. Thus patients with mild defects may have laboratory values that fluctuate over time and may occasionally be within the normal range.

There are three major types of vWD. Their mode of inheritance and laboratory findings are shown in Fig. 101-2. Patients with type I disease, the most common abnormality, have a mild to moderate decrease in plasma vWF. In the milder cases, although hemostasis is impaired, the vWF level is just below normal (50% activity, or 5 mg/L). In type I disease, vWF antigen, factor VIII activity, and ristocetin cofactor activity are decreased with a normal spectrum of multimers detected by sodium dodecyl sulfate (SDS)–agarose gel electrophoresis. The variant forms of vWD (type II disease) are much less common and characterized by normal or near-normal levels of a dysfunctional protein. Patients with the type IIa variant of vWD have a deficiency in the high- and medium-molecular-weight forms of vWF multimer detected by SDS-agarose electrophoresis. This is due either to an inability to secrete the high-molecular-weight vWF multimers or to proteolysis of the multimers soon after they leave the endothelial cell and enter the circulation. Mutations in a localized region of the vWF A-2 domain have been identified in families with type IIa vWD (Fig. 101-3). The quantity of vWF antigen and the amount of associated factor VIII are usually normal. In the type IIb variant, high-molecular-weight multimers are also decreased; however, the decrease is due to the inappropriate binding of vWF to platelets. Intravascular platelet aggregates form that are rapidly cleared from the circulation, causing mild, variable thrombocytopenia. Mutations in a disulfide-bonded loop in the A-1 domain that binds to Gp Ib/IX are the cause of the type IIb defect (Fig. 101-3). A few patients have a platelet membrane disorder that mimics type Iib vWD—platelet-type vWD. It is due to mutations in the portion of Gp Ib/IX that interacts with vWF. Levels of total vWF antigen and factor VIII are normal. Approximately 1 in 1 million individuals have a severe form of vWD that is phenotypically recessive (type III disease). Type III patients are usually the offspring of two parents (usually asymptomatic) with mild type I disease. Type III patients may inherit a different abnormality from each parent (a doubly heterozygous or compound
heterozygous state) or be homozygous for a single defect. Type III patients have severe mucosal bleeding and no detectable vWF antigen or activity and, like patients with mild hemophilia, may have sufficiently low factor VIII that they have occasional hemarthroses. Major deletions in the vWF gene have been found in some type III families. Families with nonsense mutations and the combination of a deleted and nonsense mutant allele have also been described.

Type IIIa disease is due to a defect in the factor VIII binding site of vWF. Patients resemble those with mild hemophilia and have low levels of factor VIII. The presence of disease in both males and females in a hemophilia and have low levels of factor VIII. The bindingsite of vWF. Patients resemble those with mild hemophilia, may have sufficiently low factor VIII that they have occasional hemarthroses. Major deletions in the vWF gene have been found in some type III families. Families with nonsense mutations and the combination of a deleted and nonsense mutant allele have also been described.

There are two therapeutic options. Factor VIII concentrates retain high-molecular-weight vWF multimers (Humate-P, Alphanate), are highly purified and heat-treated to destroy HIV, and are appropriate treatments for all the inherited forms of vWD. During surgery or after major trauma, patients should receive factor VIII concentrates twice daily for 2 to 3 days to assure optimal hemostasis. Minor bleeding episodes such as protracted epistaxis or severe menorrhagia may respond to a single infusion. Recurrent menorrhagia, a major problem for women with severe vWD, can be treated effectively with oral contraceptive agents that suppress menses.

A second therapeutic option, which avoids the use of plasma, is the use of desmopressin, a vasopressin analogue that has minimal blood pressure–elevating and fluid-retaining properties and raises the plasma vWF level in both normal individuals and patients with mild vWD. Patients with type I disease are the best candidates for desmopressin therapy. However, they must be tested for an adequate response before anticipated surgery, and vWF levels must be monitored closely during therapy, since the patient may develop tachyphylaxis when therapy is continued for >8 h. Desmopressin should not be given to patients with variant forms of vWD without prior testing, since it may not improve multimer pattern or hemostasis in type IIa patients and may actually worsen the defect by depleting high-molecular-weight multimers, inducing intravascular platelet aggregation, and lowering the platelet count in type IIb patients. It is ineffective therapy for the severe (type III) form of vWD.
impaired hemostasis, leading to recurrent episodes of severe mucosal hemorrhage. Bernard-Soulier platelets react normally to all stimuli except ristocetin. In contrast, thrombasthenic platelets adhere normally and will agglutinate with ristocetin but will not aggregate with any of the agonists that require fibrinogen binding, such as adenosine diphosphate (ADP), thrombin, or epinephrine.

The only effective therapy for hemorrhagic episodes in these two disorders is transfusion with normal platelets. Alloimmunization will eventually limit the life span of infused platelets. In addition, a few patients have developed inhibitor antibodies with specificity for the missing protein. These antibodies bind to the protein that is expressed on the transfused normal platelets and impair their function.

**Platelet Release Defects**

The most common mild bleeding disorders arise from the ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit platelet production of thromboxane A₂, an important mediator of platelet secretion and aggregation (Figs. 53-3 and 53-4). These drugs inhibit cyclooxygenase (COX), which converts arachidonic acid to a labile endoperoxide intermediate that is critical for thromboxane formation. Aspirin is the most potent of these agents; it irreversibly acetylates the platelet enzyme so that a single dose impairs hemostasis for 5 to 7 days. The other agents are competitive and reversible inhibitors with more transient effects. Blocking thromboxane A₂ synthesis partially inhibits platelet release and aggregation with weak agonists, such as ADP and epinephrine, and produces a mild hemostatic defect. Cyclooxygenase exists in two isoforms, COX-1, which is constitutively expressed and active in the normal platelet, and COX-2, which is induced, especially in inflamed tissue. The selective COX-2 inhibitors, such as celecoxib, are increasingly being used to control arthritis pain and in other settings where NSAIDs are clinically useful. The COX-2 inhibitors are long-acting reversible inhibitors that have no adverse effects on platelet function. Their chronic use may be associated with high blood pressure and risk of thrombosis. The administration of high doses of certain antibiotics, particularly penicillin, can coat the platelet surface, block platelet release, and impair hemostasis.

Patients with release defects generally have minimal symptoms such as easy bruising, and bleeding is usually confined to the skin. Occasional patients will have prolonged oozing after surgery, particularly with procedures involving mucous membranes such as periodontal, oral, or reconstructive plastic surgery. The antiplatelet effect of drugs such as aspirin is more dramatic when they are administered to patients with underlying defects such as vWD or hemophilia. Patients with drug-induced COX deficiency often have a mildly prolonged bleeding time, and their platelets fail to aggregate when incubated with arachidonic acid, epinephrine, or low doses of ADP. Patients who have taken aspirin should be treated as if they have a mild hemostatic defect. Cyclooxygenase exists in two isoforms, COX-1, which is constitutively expressed and active in the normal platelet, and COX-2, which is induced, especially in inflamed tissue. The selective COX-2 inhibitors, such as celecoxib, are increasingly being used to control arthritis pain and in other settings where NSAIDs are clinically useful. The COX-2 inhibitors are long-acting reversible inhibitors that have no adverse effects on platelet function. Their chronic use may be associated with high blood pressure and risk of thrombosis. The administration of high doses of certain antibiotics, particularly penicillin, can coat the platelet surface, block platelet release, and impair hemostasis.

**Patients with Release Defects**

Occasional patients have responded to desmopressin. Impaired hemostasis. They can be treated with platelet transfusions.

**Platelet Release Defects**

Occasionally, patients with acute or chronic leukemia or one of the myeloproliferative disorders develop an acquired storage pool disorder due to dysplastic megakaryocyte development. In addition, patients with liver disease and some patients with SLE or other immune complex–mediated disorders may have circulating platelets that have degranulated prematurely. Platelet degranulation and a transient storage pool disorder may occur after prolonged cardiopulmonary bypass. Fortunately, most patients with storage pool defects have only mildly impaired hemostasis. They can be treated with platelet transfusions. Occasional patients have responded to desmopressin.

**Vessel Wall Disorders**

Bleeding from vascular disorders (nonthrombocytopenic purpura) is usually mild and confined to the skin and mucous membranes. The pathogenesis of bleeding is poorly defined in many of the syndromes, and classic tests of hemostasis, including the bleeding time and tests of platelet function, are usually normal. Vascular purpura arises from damage to capillary endothelium, abnormalities in the vascular subendothelial matrix or extravascular connective tissues that support blood vessels, or from the formation of abnormal blood vessels. Several idiopathic disorders involve the vessel wall and can cause more severe bleeding and organ dysfunction.

**Thrombotic Thrombocytopenic Purpura**

TTP is a fulminant, often lethal disorder that may be initiated by endothelial injury and subsequent release of vWF and other procoagulant materials from the endothelial cell. Causes include pregnancy, metastatic cancer, mitomycin C, high-dose chemotherapy, HIV infection, and certain drugs, such as the antiplatelet agent ticlopidine. Characteristic findings include the microvascular deposition of hyaline fibrin thrombi, thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, fluctuating levels of consciousness, and evanescent focal neurologic deficits. The presence of hyaline thrombi in arterioles, capillaries, and venules without any inflammatory changes in the vessel wall is diagnostic. The presence of a severe Coombs-negative hemolytic anemia with schistocytes or fragmented red blood cells in the peripheral blood smear, coupled with thrombocytopenia, and minimal activation of the coagulation and fibrinolytic systems help to confirm the clinical suspicion of TTP. This disorder should be distinguished from vasculitis and SLE, which can predispose patients to TTP. Platelet-associated IgG and complement levels are usually normal in TTP.

**Clinical Manifestations**

The classic pentad of TTP consists of hemolytic anemia with fragmentation of erythrocytes and signs of intravascular hemolysis, thrombocytopenia, diffuse and nonfocal neurologic findings, decreased renal function, and fever. These signs and symptoms occur variably, depending on the number and sites of the arteriolar lesions. The anemia may be very mild to very severe, and the thrombocytopenia often parallels it. The neurologic and renal symptoms are usually seen only when the platelet count is markedly diminished (<20 x 10⁹/µL). Fever is not reliably present. TTP may be acute in onset, but its course spans days to weeks in most patients and occasionally continues for months. Proteinuria and a moderate elevation of
blood urea nitrogen may be found on initial presentation; the latter continues to rise while urine output falls if the patient develops renal failure. Neurologic symptoms develop in >90% of patients whose disease terminates in death. Initially, changes in mental status such as confusion, delirium, or altered states of consciousness may occur. Focal findings include seizures, hemiparesis, aphasia, and visual field defects. These neurologic symptoms may fluctuate and terminate in coma. Involvement of myocardial blood vessels may be a cause of sudden death. The severity of the disorder can be estimated from the degree of anemia and thrombocytopenia and the serum lactic dehydrogenase level. Prothrombin time, partial thromboplastin time, fibrinogen concentration, and the level of fibrin split products are usually normal or only mildly abnormal. If the coagulation tests indicate a major consumption of clotting factors, the diagnosis of TTP is doubtful. A positive antinuclear antibody (ANA) determination is obtained in ~20% of patients.

Pathogenesis  TTP is due to a deficiency in the activity of a specific metalloproteinase called ADAMTS 13, a normal plasma constituent that cleaves the ultra-high-molecular-weight (UHMW) forms of vWF secreted by endothelial cells to yield the heterogeneous set of multimers normally present in plasma (Fig. 101-4). A small number of patients have recurrent episodes of a TTP-like illness (Upshaw-Schulman syndrome) and are deficient in ADAMTS 13; the syndrome is inherited as an autosomal recessive trait. The more common acquired form of TTP is due to an inhibitory antibody that blocks ADAMTS 13 activity. These findings have led to more reliable diagnostic tests based on ADAMTS 13 enzyme activity and may have implications beyond TTP. Studies are underway to see if asymptomatic carriers with 50% levels of ADAMTS 13 are at increased risk of thrombembolism.

**FIGURE 101-4** Pathogenesis of thrombotic thrombocytopenic purpura (TTP). Normally, the ultra-high-molecular-weight multimers of von Willebrand factor (vWF) produced by the endothelial cells are processed into smaller multimers by a plasma metalloproteinase called ADAMTS 13. In TTP, the activity of the protease is inhibited, and the ultra-high-molecular-weight multimers of vWF initiate platelet aggregation and thrombosis. (From Vesely et al., Copyright American Society of Hematology.)

**TREATMENT**

The treatment of acute TTP has focused on the use of exchange transfusion or intensive plasmapheresis coupled with infusion of fresh-frozen plasma. Therapy may remove abnormal forms of vWF, lower the concentration of ADAMTS 13 inhibitor, and replenish the deficient enzyme. Overall mortality has been markedly reduced, and the majority of patients with TTP recover from this formerly fatal disorder. Most patients surviving the acute illness recover completely, with no residual renal or neurologic disease. Occasional patients with a chronic, relapsing form of TTP require maintenance plasmapheresis and plasma infusion, and a few patients are controlled only with glucocorticoids. They presumably have persistence of the ADAMTS 13 inhibitor. In the future, TTP patients may be treated with some combination of enzyme replacement and immunosuppression to block inhibitor production.

**HEMOLYTIC-UREMIC SYNDROME**  HUS is a disease of infancy and early childhood that closely resembles TTP. Patients present with fever, thrombocytopenia, microangiopathic hemolytic anemia, hypertension, and varying degrees of acute renal failure. In many cases, onset is preceded by a minor febrile or viral illness, and an infectious or immune complex–mediated cause has been proposed. Epidemics related to infection with a specific strain of *Escherichia coli* (O157:H7) have been documented. The bacteria contain a *Shigella*-like toxin that damages endothelial cells. As in TTP, DIC is not found. In contrast to TTP, the disorder remains localized to the kidney, where hyaline thrombi are seen in the afferent arterioles and glomerular capillaries. Thrombi are not present in other vessels, and neurologic symptoms, other than those associated with uremia, are uncommon. No therapy is proven effective; however, with dialysis for acute renal failure, the initial mortality is only 5% in children but may be higher in adults. Between 10 and 50% of patients have some chronic renal impairment. ADAMTS 13 levels are normal, and no inhibitors of the enzyme are present in this disorder.

**HENOCH-SCHÖNLEIN PURPURA**  Henoch-Schönlein, or anaphylactoid, purpura is a distinct, self-limited type of vasculitis that occurs in children and young adults. Patients have an acute inflammatory reaction in capillaries, mesangial tissues, and small arterioles that leads to increased vascular permeability, exudation, and hemorrhage. Vessel lesions contain IgA and complement components. The syndrome may be preceded by an upper respiratory infection or streptococcal pharyngitis or be associated with food or drug allergies. Patients develop a purpuric or urticarial rash on the extensor surfaces of the arms and legs and on the buttocks as well as polyarthralgia or arthritis, colicky abdominal pain, and hematuria from focal glomerulonephritis. Despite the hemorrhagic features, all coagulation tests are normal. A small number of patients may develop fatal acute renal failure, and 5 to 10% develop chronic nephritis. Glucocorticoids provide symptomatic relief of the joint and abdominal pains but do not alter the course of the illness.

**METABOLIC AND INFLAMMATORY DISORDERS**  Acute febrile illnesses may cause capillary fragility and skin bleeding. Immune complexes containing viral antigens or the viruses themselves may damage endothelial cells. In addition, certain pathogens such as the rickettsiae that cause Rocky Mountain spotted fever replicate in endothelial cells and damage them. Thrombocytopenia is also a frequent finding in acute infectious disorders and may contribute to skin bleeding. In addition, whenever the platelet count is <10,000/μL, gaps develop between endothelial cells, which allow the diapedesis of red cells into the dermis, forming petechiae. Drugs such as the sulfonamides, penicillin, and allopurinol may cause vascular inflammation, resulting in maculopapular or urticarial rashes. Some of these mechanisms are additive, and drug reactions in thrombocytopenic individuals cause an intensely hemorrhagic rash.

Occasionally, patients with diffuse polycylic hyperglobulinemia will develop purpuric lesions on the lower limbs—a benign condition referred to as *hyperglobulinemic purpura*. Vascular purpura may occur in patients with various monoclonal gammapathies, including Waldenström’s macroglobulinemia, multiple myeloma, and cryoglobuli-
Cushing’s syndrome

Thus, collagen synthesis is impaired by scurvy. Patients with

The diagnosis is confirmed by the presence of hyperkeratosis of skin, and, occasionally, into the gastrointestinal and genitourinary tracts. Episodes of perifollicular skin bleeding as well as bleeding into muscles and, occasionally, into the gastrointestinal and genitourinary tracts. The diagnosis is confirmed by the presence of hyperkeratosis of skin, gum swelling, and low levels of the vitamin in leukocytes. Vitamin C is needed to synthesize hydroxyproline, an essential constituent of collagen. Thus, collagen synthesis is impaired by scurvy. Patients with Cushing’s syndrome, an excess production of glucocorticoids, or patients on large doses of glucocorticoids develop generalized protein wasting and may show skin bleeding or easy bruising due to atrophy of the supporting connective tissue around blood vessels. Aging causes a similar atrophy of perivascular connective tissue on the extensor surfaces of the hands and arms, leading to senile purpura—dark purple, irregularly shaped hemorrhagic areas due to abnormal skin mobility that tears small blood vessels.

Patients with inherited disorders of the connective tissue matrix such as Marfan’s syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum also have easy bruising. In addition to having fragile skin vessels and easy bruising, patients with Ehlers-Danlos syndrome may develop aneurysms in intraabdominal vessels and apoplectic rupture and hemorrhage due to defects in the vascular collagen network. Primary vascular abnormalities can also lead to bleeding. Patients with Osler-Rendu-Weber disease (hereditary hemorrhagic telangiectasia (HHT)), an inherited autosomal dominant disorder, have frequent episodes of nasal and gastrointestinal bleeding from abnormal telangiectatic capillaries. They may develop pulmonary arteriovenous fistulas. Two genetic defects have been identified in these patients, both involving proteins that bind to transforming growth factor β (TGF-β); HHT-1 has mutations in endoglin, and HHT-2 has mutations in ALK-1. Patients with angiodyplasia of the colon have increased incidence of gastrointestinal bleeding. In the Kasabach-Merritt syndrome, patients may have very extensive and progressively enlarging vascular malformation that may involve large portions of their extremities. Bleeding is secondary to DIC triggered by stagnant blood flow through the tortuous vessels.

DISORDERS OF COAGULATION AND THROMBOSIS

Robert I. Handin

Patients with congenital plasma coagulation defects characteristically bleed into muscles, joints, and body cavities hours or days after an injury. Most of the inherited plasma coagulation disorders are due to defects in single coagulation proteins, with the two X-linked disorders, factors VIII and IX deficiency, accounting for the majority. These patients may have severe bleeding and chronic disability and require specialized medical therapy. With rare exceptions, the known disorders prolong either the prothrombin time (PT), partial thromboplastin time (PTT), or both. If they are abnormal, quantitative assays of specific coagulation proteins are then carried out using the PT or PTT tests with plasma from congenitally deficient individuals as substrate. The corrective effect of varying concentrations of patient plasma is measured and expressed as a percentage of a normal pooled plasma standard. The interval range for most coagulation factors is 50 to 150% of this average value, and the minimal level of most individual factors needed for adequate hemostasis is 25%.

Acquired coagulation disorders are both more frequent and more complex, arising from deficiencies of multiple coagulation proteins and simultaneously affecting both primary and secondary hemostasis. The most common acquired hemorrhagic disorders are (1) disseminated intravascular coagulation (DIC), (2) the hemorrhagic diathesis of liver disease, and (3) vitamin K deficiency and complications of anticoagulant therapy. Although congenital and acquired bleeding disorders are relatively rare, venous and arterial thrombosis and embolism are common medical disorders that have been recognized for >100 years. Although risk factors such as atherosclerotic vascular disease, congestive heart failure, malignancy, and immobility predispose patients to thrombosis, specific coagulation defects have not yet been identified in most patients with thromboembolism. Several inherited coagulation abnormalities induce a hypercoagulable or prethrombotic state and predispose patients to thrombosis. These disorders affect young people, cause recurrent episodes of thromboembolism, and may involve multiple members of a single family. An understanding of the biochemical basis of thromboembolism is also important because anticoagulant and antithrombotic regimens are based on the premise that modifying critical coagulation pathways will reduce the incidence of thrombosis. For further discussion of the physiology of normal hemostasis and the cardinal manifestations of the hemorrhagic and thrombotic disorders, see Chap. 53.

FACTOR VIII DEFICIENCY—HEMOPHILIA A

Pathogenesis and Clinical Manifestations

The antihemophilic factor (AHF), or factor VIII coagulant protein, is a large (265-kDa), single-chain protein that regulates the activation of factor X by proteases generated in the intrinsic coagulation pathway (Figs. 53-6 and 53-7). It is synthesized in liver and circulates complexed to the von Willebrand factor (vWF) protein. Factor VIII molecule is present in low concentration (10 µg/L) and is susceptible to proteolysis. The gene for factor VIII is on the X chromosome, and carrier detection and prenatal diagnosis are well established.

One in 10,000 males is born with deficiency or dysfunction of the factor VIII molecule. The resulting disorder, hemophilia A, is characterized by bleeding into soft tissues, muscles, and weight-bearing joints. Symptomatic patients usually have factor VIII levels <5%, with a close correlation between the clinical severity of hemophilia and plasma AHF level. Patients with <1% factor VIII activity have severe
Tenets regarding the treatment of bleeding in hemophilia patients include the following: (1) Symptoms often precede objective evidence of bleeding. (2) Signs of bleeding may not appear until several days after well-documented trauma. The patients can generally be relied upon to identify early symptoms, usually pain. Early treatment is more effective, less costly, and can be lifesaving. (3) Avoid the use of aspirin or aspirin-containing drugs, which impair platelet function and may cause severe hemorrhage. Cyclooxygenase inhibitors can be used, as they do not impair platelet function.

Plasma products enriched in factor VIII reduce the degree of orthopedic deformity and permit virtually any form of elective and emergency surgery. The widespread use of factor VIII concentrates has also produced serious complications, including viral hepatitis, chronic liver disease, and AIDS. Cryoprecipitate, which contains about half the factor VIII activity of fresh-frozen plasma in one-tenth the original volume, is simple to prepare and is produced in hospital or regional blood banks.

Three developments have increased the safety of factor VIII therapy and have changed medical practice. First, heating of lyophilized factor VIII concentrates under carefully controlled conditions can inactivate HIV without destroying factor VIII activity. Second, highly purified factor VIII can be produced by adsorbing and eluting factor VIII from monoclonal antibody columns. Third, recombinant factor VIII is now available. Patients with hemophilia should receive either monoclonal purified or recombinant factor VIII to minimize viral infections and exposure to irrelevant proteins. 

Complications Most hemophilia patients have had multiple episodes of hepatitis, and a majority have elevated hepatocellular enzyme levels and abnormalities on liver biopsy. Donated blood is now being screened for various types of hepatitis, so the risk of this disease is diminishing. Between 10 and 20% of patients also have hepatospleno-megaly, and a small number develop chronic active or persistent hepatitis or cirrhosis. A few patients with hemophilia and end-stage liver disease have received liver transplants with cure of both diseases. Along with homosexuals and intravenous drug abusers, long-time he-

Hemophilia occurs hours or days after injury, can involve any organ, and, if untreated, may continue for days or weeks. This can result in large collections of partially clotted blood putting pressure on adjacent normal tissues and can cause necrosis of muscle (compartment syndromes), venous congestion (pseudophlebitis), or ischemic damage to nerves. Patients with hemophilia often develop femoral neuropathy due to pressure from an unsuspected retroperitoneal hematoma. They can also develop large calcified masses of blood and inflammatory tissue that are mistaken for cancers (pseudotumor syndrome).

Patients with severe hemophilia are usually diagnosed shortly after birth because of an extensive cephalohematoma or profuse bleeding at circumcision. However, young children with moderate disease may not bleed until they begin to walk or crawl, and individuals with mild hemophilia may not be diagnosed until they are adolescents or young adults. Typically, a hemophilia patient presents with pain followed by swelling in a weight-bearing joint, such as the hip, knee, or ankle. The presence of blood in the joint (hemarthrosis) causes synovial inflammation, and repetitive bleeding erodes articular cartilage and causes osteoarthritis, articular fibrosis, joint ankylosis, and eventually muscle atrophy. Bleeding may occur into any joint, but after a joint has been bled, it may become a site for subsequent bleeding episodes.

Hematuria, without any genitourinary pathology, is also common. It is usually self-limited and may not require specific therapy. The most feared complications of hemophilia are oropharyngeal and central nervous system bleeding. Patients with oropharyngeal bleeding may require emergency intubation to maintain an airway. Central nervous system bleeding can occur without antecedent trauma or without evidence of a specific lesion.

Patients suspected of having hemophilia should have a platelet count, bleeding time, PT, and PTT determination. Typically, the patient will have a prolonged PTT with all other tests normal. Because of the clinical similarity of factor VIII deficiency and factor IX deficiency, any male with an appropriate bleeding history and a prolonged PTT should have specific assays for factor VIII and factor IX.

Before surgery, every hemophilia patient should be screened for the presence of an inhibitor to factor VIII. Patients with hemophilia who do not have an inhibitor should receive factor VIII infusions just before surgery and will require daily monitoring so that the factor VIII level is maintained >50% for 10 to 14 days after surgery. When patients undergo joint replacement or other major orthopedic surgery, therapy should be continued for 3 weeks to permit wound healing and the institution of physical therapy.

Hemophilia patients also require treatment before dental procedures. Filling of a carious tooth can be managed by a single infusion of factor VIII concentrate coupled with the administration of 4 to 6 g of e-aminocaproic acid (EACA) four times daily for 3 to 4 days after the dental procedure. EACA is a potent antifibrinolytic agent that inhibits plasminogen activators present in oral secretions and stabilizes clot formation in oral tissue. Alternatives include tranexamic acid, a longer-acting antifibrinolytic. EACA is also effective when used as a mouthwash. For major oral and periodontal surgery and extractions of permanent teeth, patients should probably be hospitalized briefly and also treated with factor VIII concentrates. Therapy should begin just before surgery and continue for at least 2 to 3 days.

Many centers have organized home-care programs so that patients can administer their own factor VIII infusions with the onset of symptoms. Occasional patients with very frequent bleeding receive regularly scheduled infusions. Despite the expense and inconvenience of prophylactic infusions, their use in early childhood has reduced or eliminated hemorrhages. Concern about transmission of AIDS has made some patients reluctant to treat themselves, despite the fact that current blood products carry a very low or no risk of transmitting HIV.

The prospects for correcting factor VIII deficiency by gene therapy are promising; some success has been achieved in dogs. Clinical studies in humans are underway. Concerns about the side effects of current viral vectors used to deliver the factor VIII cDNA are slowing clinical trials.

Each unit of factor VIII infused, defined as the amount present in 1 mL normal plasma, will raise the plasma level of the recipient by 2%/kg of body weight. Factor VIII has a half-life of 8 to 12 h, making it necessary to infuse it continuously or at least twice daily to sustain a chosen factor VIII level. In patients with mild hemophilia, an alternative treatment is desmopressin (DDAVP), which transiently increases the factor VIII level. Desmopressin will increase the factor level two- to threefold. Although generally safe, it occasionally causes hypotension or may precipitate thrombosis in elderly patients.

An uncomplicated episode of soft tissue bleeding or an early hemarthrosis can be treated with one infusion of sufficient factor VIII concentrate to raise the factor VIII level to 15 or 20%. A more extensive hemarthrosis or retroperitoneal bleeding requires twice-daily or continuous infusions in order to keep the factor VIII level at 25 to 50% for at least 72 h. Life-threatening bleeding into the central nervous system or major surgery may require therapy for 2 weeks with levels kept at a minimum of 50% normal. Patients also need skilled orthopedic care, with immobilization of inflamed joints to promote healing and to prevent contractures, and physical therapy to strengthen muscles and maintain joint mobility.

Patients with severe hemophilia are usually diagnosed shortly after birth because of an extensive cephalohematoma or profuse bleeding at circumcision. However, young children with moderate disease may not bleed until they begin to walk or crawl, and individuals with mild hemophilia may not be diagnosed until they are adolescents or young adults. Typically, a hemophilia patient presents with pain followed by swelling in a weight-bearing joint, such as the hip, knee, or ankle. The presence of blood in the joint (hemarthrosis) causes synovial inflammation, and repetitive bleeding erodes articular cartilage and causes osteoarthritis, articular fibrosis, joint ankylosis, and eventually muscle atrophy. Bleeding may occur into any joint, but after a joint has been bled, it may become a site for subsequent bleeding episodes.

Hematuria, without any genitourinary pathology, is also common. It is usually self-limited and may not require specific therapy. The most feared complications of hemophilia are oropharyngeal and central nervous system bleeding. Patients with oropharyngeal bleeding may require emergency intubation to maintain an airway. Central nervous system bleeding can occur without antecedent trauma or without evidence of a specific lesion.

Patients suspected of having hemophilia should have a platelet count, bleeding time, PT, and PTT determination. Typically, the patient will have a prolonged PTT with all other tests normal. Because of the clinical similarity of factor VIII deficiency and factor IX deficiency, any male with an appropriate bleeding history and a prolonged PTT should have specific assays for factor VIII and factor IX.
Hemophilia patients are at high risk for AIDS because they frequently receive blood products before the era of testing them for HIV; they can also present with the full range of AIDS-related syndromes, including diffuse lymphadenopathy and immune thrombocytopenia. Although up to 50% of current multiply transfused hemophiliacs are HIV-positive and many have clinical AIDS, the advances in factor VIII concentrate production should prevent future HIV infection.

Despite frequent bleeding, severe iron-deficiency anemia is uncommon because most of the bleeding is internal and iron is effectively recycled. Mild iron deficiency from chronic epistaxis or gastrointestinal bleeding occurs in some patients. In addition, some patients have developed a mild Coombs-positive hemolytic anemia due to small amounts of anti-A and anti-B antibody that are present in intermediate purity factor VIII concentrates.

Following multiple transfusions, 10 to 20% of patients with severe hemophilia develop inhibitors to factor VIII. Inhibitors are usually IgG antibodies that rapidly neutralize factor VIII activity. Two types of inhibitors are found with different biologic characteristics and different clinical presentations. Patients with type I inhibitors have a typical anamnestic response and raise their antibody titer following exposure to factor VIII. Patients with a type II inhibitor have a low antibody titer that is not stimulated by factor VIII infusion. Patients with the type I inhibitor should not receive factor VIII. Control of bleeding may require the infusion of either porcine factor VIII concentrates, which may not be affected by inhibitors, or prothrombin complex concentrates, which contain trace quantities of activated coagulation factors and can bypass the block in coagulation produced by the inhibitor. Patients with low-titer type II antibodies may respond to higher doses of factor VIII. Another alternative is the infusion of recombinant factor VIIa; it activates factor X directly and bypasses the inhibitor-induced block.

Protocols to induce tolerance to human factor VIII use massive doses of the factor coupled with immunosuppression. Tolerance induction is expensive and not always effective; it should be reserved for severely affected patients.

Genetic Counseling and Carrier Detection It is possible to trace the defective allele in some families by examining the inheritance of restriction fragment length polymorphisms (RFLP) linked to the factor VIII gene. In addition, in families in which a specific mutation has been defined in the factor VIII gene, it can be readily detected by gene amplification and allele-specific oligonucleotide hybridization. For example, 45% of patients with severe hemophilia A have a chromosomal inversion arising from homologous recombination between sequences in intron 22 and an upstream gene. The inversion is readily detected by polymerase chain reaction (PCR) or Southern blotting. Precise diagnosis is possible early in pregnancy from either chorionic villus biopsy or amniocentesis.

Female carriers of hemophilia, who are heterozygotes, usually produce sufficient factor VIII from the factor VIII allele on their normal X chromosome for normal hemostasis. However, occasional hemophiliac carriers will have factor VIII levels far below 50% due to random inactivation of normal X chromosomes in tissue producing factor VIII. These symptomatic carriers may bleed with major surgery or bleed occasionally with menses. Rarely, true female hemophiliacs arise from consanguinity within families with hemophilia or from a common Turner’s syndrome or XO mosaicism in a carrier female.

Factor IX Deficiency—Hemophilia B Factor IX is a single-chain, 55-kDa proenzyme that is converted to an active protease (IXa) by factor Xa or by the tissue factor–VIIa complex. Factor IXa then activates factor X in conjunction with activated factor VIII. Factor IX is one of six proteins synthesized in the liver that require vitamin K for biologic activity. Vitamin K is a cofactor for a unique posttranslational modification that inserts a second carboxyl group onto certain glutamic acid residues on factor IX (Chap. 53). This modification permits calcium binding and adsorption onto phospholipid surfaces. Factor IX gene is on the X chromosome.

Factor IX deficiency or dysfunction (hemophilia B, Christmas disease) occurs in 1 in 100,000 male births. Accurate laboratory diagnosis is critical, since it is indistinguishable clinically from factor VIII deficiency (hemophilia A) but requires different treatment. Either fresh-frozen plasma or a plasma fraction enriched in the prothrombin complex proteins is used. Monoclonally purified or recombinant factor IX preparations are now available. In addition to the expected complications of hepatitis, chronic liver disease, and AIDS, the therapy of factor IX deficiency has a special hazard. Trace quantities of activated coagulation factors in prothrombin complex concentrates may activate the coagulation system and cause thrombosis and embolism. This is particularly hazardous in common insulin or immobilized surgical patients and patients with liver disease. As a result, some centers have returned to fresh-frozen plasma for factor IX–deficient surgical patients, while others have recommended the addition of small doses of heparin to the concentrate to activate antithrombin III during the infusion and reduce hypercoagulability. The recombinant or monoclonally purified products are less likely to be thrombogenic.

Factor XI Deficiency Factor XI is a 160-kDa dimeric protein activated to an active protease (XIa) by factor Xla in conjunction with high-molecular-weight kininogen and kallikrein (Figs. 53-6 and 53-7). Factor XI deficiency is inherited as an autosomal recessive trait and is especially common in Ashkenazi Jews. In contrast to deficiency in factors VIII and IX, the correlation between factor level and propensity to bleed is not as precise, spontaneous bleeding is less, and hemarthroses are rare. Many patients with factor XI deficiency present with posttraumatic bleeding or with bleeding in the peripartum period, and occasional factor XI–deficient women have menorrhagia. Daily infusions of fresh-frozen plasma are sufficient, since the half-life of factor XI is approximately 24 h. The majority of defective factor XI alleles were accounted for by a limited number of mutations.

Other Factor Deficiencies Deficiencies in factors V, VII, X, and prothrombin (factor II) are exceedingly rare autosomal recessive disorders. Spontaneous or posttraumatic musculoskeletal bleeding or menorrhagia can occur with these deficiencies, but hemarthroses are uncommon. Fresh-frozen plasma is the appropriate therapy, although prothrombin concentrates may be employed for patients with severe prothrombin deficiency or decreases in factors VII and X as long as the risks of hepatitis and thrombosis are recognized.

Defects in the contact activation pathway involving Hageman factor (factor XII), high-molecular-weight kininogen, and prekallikrein cause laboratory abnormalities but no clinical bleeding. Despite dramatic prolongation of the PTT, often to greater than 100 s, deficient individuals have normal hemostasis and can undergo major surgery without plasma replacement therapy. Direct activation of factor IX by the tissue factor–VIIa complex may bypass this defective step in coagulation (Fig. 53-8). Patients with these disorders should neither be treated inappropriately with plasma nor denied indicated surgery on the basis of these laboratory abnormalities.

Afibrinogenemia and Dysfibrinogenemia Fibrinogen is a 340-kDa dimeric molecule made up of two sets of three covalently linked polypeptide chains. Thrombin sequentially cleaves fibrinopeptides A and B from the αA and βB chains of fibrinogen to produce fibrin monomer, which then polymerizes to form a fibrin clot. Although fibrinogen is needed for platelet aggregation and fibrin formation, severe fibrinogen deficiency does not usually cause serious bleeding except after surgery. Patients with afibrinogenemia, who have no detectable fibrinogen in plasma or platelets, may have infrequent, mild bleeding episodes. Genetic analyses do not show any gross deletion or structural changes in the genes encoding the α, β, and γ chains of fibrinogen despite the total absence of plasma fibrinogen.

Fibrinogen is an abundant plasma protein (2.5 g/L). Mutations have been identified that alter the release of fibrinopeptides from the αA and βB chains of fibrinogen, the rate of polymerization of fibrin monomers, and the sites for fibrin cross-linking. These dysfibrinogenemias

---

The text above is a continuation of the previous discussion on hemophilia, factor IX deficiency, and other factor deficiencies. It provides detailed information on the genetic and clinical aspects of these disorders, including the mechanisms of action of various treatments and the implications for patient care.
are almost always inherited as autosomal dominant traits, so patients have nearly equal concentrations of normal and mutant fibrinogen in their plasma. Patients with dysfibrinogenemia have a slightly prolonged PT and PTT, a prolonged thrombin time, and a disparity in their plasma. Patients with dysfibrinogenemia have a slightly prolonged PT and a normal PTT. Later, as the levels of the other factors fall, the PTT will also become prolonged. Parenteral administration of 10 mg vitamin K rapidly restores vitamin K levels in the liver and permits normal production of prothrombin complex proteins within 8 to 10 h. Severe hemorrhage can be treated with fresh-frozen plasma, which immediately corrects the hemostatic defect. If the cause of vitamin K deficiency cannot be eliminated, patients may need monthly injections. Purified prothrombin complex concentrates should be avoided because they contain trace quantities of activated forms of the prothrombin complex proteins and can cause thrombosis in patients with liver disease. They also carry an increased risk of hepatitis.

**DISSEMINATED INTRAVASCULAR COAGULATION** DIC can be either an explosive and life-threatening bleeding disorder or a relatively mild or subclinical disorder. Although a long list of diseases can be complicated by DIC, it is most frequently associated with obstetric catastrophes, metastatic malignancy, massive trauma, and bacterial sepsis (Table 102-1). Tentative triggering mechanisms have been identified. Tumors and traumatized or necrotic tissue release tissue factor into the circulation. Endotoxin from gram-negative bacteria activates several steps in the coagulation cascade. In addition to a direct effect on the activation of Hageman factor (factor XII), endotoxin induces the expression of tissue factor on the surface of monocytes and endothelial cells. These activated cell surfaces then accelerate coagulation reactions. These potent thrombogenic stimuli cause the deposition of small thrombi and emboli throughout the microvasculature. This early thrombotic phase of DIC is then followed by a phase of procoagulant consumption and secondary fibrinolysis. Continued fibrin formation and fibrinolysis lead to hemorrhage from the coagulation factor and platelet depletion and the antithemostatic effects of fibrin degradation products (Fig. 102-2).

The clinical presentation varies with the stage and severity of the

**TABLE 102-1** Etiologic Factors and Disorders Causing Disseminated Intravascular Coagulation

| Liberation of tissue factors | Obstetric syndromes—abruptio placentae, amniotic fluid embolism, retained dead fetus, second trimester abortion |
| Endothelial damage | Aortic aneurysm, Hemolytic uremic syndrome, Acute glomerulonephritis |
| Vascular malformation, decreased blood flow | Kasabach-Merritt syndrome |
| Infections | Bacterial: staphylococci, streptococci, pneumococci, meningococci, gram-negative bacilli, Viral: arboviruses, varicella, variola, rubella, Parasitic: malaria, kala-azar |
| | Ricketsial: Rocky Mountain spotted fever |
| | Mycotic: acute histoplasmosis |

DIC, although sometimes indolent, can cause life-threatening hemorrhage and may require emergency treatment including (1) an attempt to correct any reversible cause of DIC; (2) measures to control the major symptom, either bleeding or thrombosis; and (3) a prophylactic regimen to prevent recurrence in cases of chronic DIC. Treatment will vary with the clinical presentation. In patients with an obstetric complication such as abruptio placenta or acute bacterial sepsis, prompt delivery of the fetus and placenta or treatment with appropriate antibiotics will reverse the DIC syndrome. In patients with metastatic tumor causing DIC, control of the primary disease may not be possible, and long-term prophylaxis may be necessary.

Patients with bleeding as a major symptom should receive fresh-frozen plasma to replace depleted clotting factors and platelet concentrates to correct thrombocytopenia. Those with acrocyanosis and incipient gangrene or other thrombotic problems need immediate anticoagulation with intravenous heparin. The use of heparin in the treatment of bleeding is still controversial. Although it is a logical way to reduce thrombin generation and prevent further consumption of clotting proteins, it should be reserved for patients with thrombosis or who continue to bleed despite vigorous treatment with plasma and platelets.

Patients who initially have mild asymptomatic DIC may begin to bleed following surgery or chemotherapy. For example, mild DIC, without clinical bleeding, has been documented during saline- or prostaglandin-induced midtrimester abortions. Prophylactic treatment of patients with heparin may prevent progression of a mild DIC syndrome and has been used in the treatment of patients with acute promyelocytic leukemia and in some patients with a retained dead fetus who require surgical extraction. However, most patients with low-grade DIC can be managed with plasma and platelet replacement and do not require heparin. Chronic DIC does not respond to oral warfarin anticoagulants, but it can be controlled with long-term heparin infusion. Occasional patients with indolent tumors and severe DIC have been maintained on heparin administered by intermittent subcutaneous injection or continuous infusion with portable pumps.

Despite our detailed understanding of the pathophysiology of DIC and a vigorous approach to therapy, treatment does not usually change the natural history of the underlying disorder. Therapy will only stabilize the patient, prevent exsanguination or massive thrombosis, and permit institution of definitive therapy.

**COAGULATION DISORDERS IN LIVER DISEASE**

Liver dysfunction is frequently accompanied by a hemostatic defect. The major causes of hemorrhage in patients with liver disease are shown in Table 102-2. Bleeding is usually due to an anatomic lesion that is exacerbated by a hemostatic defect. Most patients bleed from complications of portal hypertension, esophageal varices, or gastritis and peptic ulcer disease. Portal hypertension also causes splenomegaly, with splenic sequestration of platelets and thrombocytopenia, which contributes to the hemostatic defect.

Patients with hepatocellular liver disease cannot store vitamin K optimally and may have some degree of vitamin K deficiency. Cholestasis, a frequent feature of liver disease, impairs vitamin K absorption and further decreases liver vitamin K stores. Abnormalities in the γ-carboxylation of prothrombin complex proteins independent of vitamin K and the production of abnormal proteins have also been described. Patients may also have decreased production of other coagulation proteins, including fibrinogen and factor V. The liver also produces inhibitors of coagulation such as antithrombin III and proteins C and S and is the clearance site for activated coagulation factors and fibrinolytic enzymes. Thus patients with liver disease are also “hypercoagulable” and predisposed to developing DIC or systemic fibrinolysis. Coagulation defects in advanced liver failure are often difficult to distinguish from those of DIC.

Each patient with hemorrhage and liver disease should have a PT, PTT, platelet count, and fibrinogen determination, although it is not always possible to determine the major hemostatic abnormality from a single set of laboratory values. It is helpful to have previous laboratory data available for patients with chronic liver disease who develop an acute complication. The degree of prolongation of the PT predicts the risk of bleeding. Most patients present with moderate prolongation of the PT and PTT, mild thrombocytopenia, and a normal fibrinogen level. However, they may also present with a more complex defect combining defective synthesis, abnormal clearance, and active consumption of coagulation proteins. Since vitamin K deficiency is so common, a single parenteral dose of vitamin K is given after initial

laboratory studies have been obtained, even though this may only partially correct the laboratory abnormalities. The presence of severe thrombocytopenia or a low fibrinogen level suggests the additional complication of DIC and may require further studies and therapy.

The safest replacement therapy for a patient with liver disease is fresh-frozen plasma, since it supplies all known coagulation factors. However, even this form of therapy has drawbacks, since large quantities of plasma may precipitate hepatic encephalopathy and cause fluid and sodium overload. Prothrombin complex concentrates should be avoided because they replace only the vitamin K–dependent factors, may be contaminated with hepatitis and AIDS virus, and contain trace quantities of activated coagulation proteins. Similarly, fibrinogen concentrates (or cryoprecipitate), rich in factor VIII and fibrinogen, should not be given without additional fresh-frozen plasma. Anticoagulation with heparin has been advocated to control DIC, but this is particularly hazardous and not recommended in cirrhosis because heparin is metabolized erratically and may lead to severe bleeding.

**FIBRINOLYTIC DEFECTS** Bleeding can also occur from defects in the fibrinolytic system. Patients with α2 plasmin inhibitor deficiency or plasminogen activator inhibitor (PAI) 1 have rapid fibrinolysis following fibrin deposition after trauma or surgery and may experience recurrent hemorrhage. Similarly, patients with cirrhosis have an impaired clearance of tissue plasminogen activator (tPA) and systemic fibrinolysis that may contribute to their hemorrhagic defect. Rarely, patients with tumors such as metastatic prostatic cancer may develop diffuse bleeding from primary fibrinolysis rather than DIC. Clues to the diagnosis include a disproportionately low fibrinogen level with a relatively normal PT and PTT and the presence of a normal or nearly normal platelet count. With rare exceptions, patients with primary fibrinolysis should have an elevated titer of FDP but a normal D dimer level. However, it is sometimes difficult or impossible to differentiate primary fibrinolysis from the secondary fibrinolysis in DIC. Patients with clearly established primary fibrinolysis should not receive heparin; they require plasma therapy and, occasionally, fibrinolytic inhibitors such as EACA. However, EACA should not be given to patients suspected of having DIC unless they are also receiving heparin, since EACA can cause massive, often fatal, thrombosis in a patient with DIC.

**CIRCULATING ANTICOAGULANTS** Circulating anticoagulants, or inhibitors, are usually IgG antibodies that interfere with coagulation reactions. Specific inhibitors inactivate individual coagulation proteins and may cause severe hemorrhage. They arise in 15 to 20% of patients with factor VIII or factor IX deficiency who have received plasma infusions. Specific inhibitors also occur in previously normal individuals. Although the most common target protein is factor VIII, inhibitors with specificity for each of the coagulation proteins occur. In addition to hemophiliacs, anti-factor VIII antibodies are seen in postpartum females, in patients on various drugs, as part of the spectrum of autoantibodies in systemic lupus erythematosus (SLE) patients, and in normal elderly individuals. Circulating anticoagulants also occur in patients with AIDS.

Non-specific (lupus-like) inhibitors prolong coagulation tests by binding to phospholipids. They are assayed by their anticoagulant effect [lupus anticoagulant (LA) activity] or their ability to bind to the complex phospholipid cardiolipin [anticardiolipin antibody (ACLA) activity]. While most often encountered in patients with SLE, these non-specific inhibitors may develop in patients with many other disorders and also in otherwise normal individuals.

The critical laboratory feature that identifies the presence of either type of inhibitor is the failure of normal plasma to correct a prolonged PT, PTT, or both. Plasma from patients with a specific inhibitor will progressively inactivate a coagulation protein and thus prolong whichever of these screening tests requires the participation of that clotting factor. This effect persists after dilution. Non-specific inhibitors immediately prolong the PT and PTT and, at low dilution, block multiple coagulation reactions. However, these effects can be overcome by altering the quantity or type of phospholipid or by diluting the plasma.

Hemorrhage in patients with specific inhibitors may require treatment with massive plasma or concentrate infusion, the use of activated prothrombin complex concentrates to bypass the antibodies against factors VIII or IX, and plasmapheresis or exchange transfusion to lower antibody titer. Chronic immunosuppressive regimens have been particularly useful in otherwise normal individuals with an acquired factor VIII antibody. Many patients lose their antibody and recover within 6 to 12 months, although the acute mortality rate from bleeding may approach 10%.

Patients with LA activity have normal hemostasis and will not bleed unless they have concomitant thrombocytopenia or prothrombin deficiency. Both thrombocytopenia and hypoprothrombinemia are secondary to autoantibodies that bind either to platelets or the prothrombin molecule. While these antibodies have no effect on function, they accelerate clearance of the coated platelets or the antibody-prothrombin complexes.

The presence of LA activity may predispose patients to venous and arterial thromboembolism and may cause midtrimester abortions. However, the risk of thrombosis is difficult to estimate, and the appropriate therapy for individual patients difficult to choose. Tests for either LA or ACLA activity are not well standardized, and results vary among and within patients. The best predictor is a consistent prolongation of more than one coagulation test coupled with a high titer of ACLA activity. Second, the risk of thrombosis is increased in patients who have SLE compared with those with idiopathic LA or ACLA activity. Prophylactic therapy is not clearly beneficial, and treatments aimed at reducing the titer of antibody are not superior to conventional antithrombotic therapy.

Therapy should be individualized. Patients with SLE and either LA or ACLA activity who have had a thrombotic episode are at high risk for a recurrence and should receive long-term anticoagulant therapy. Women who have had more than one midtrimester abortion, especially those with SLE, should have a trial of anticoagulant therapy. Patients with a single thrombotic episode (stroke or pulmonary embolus) and no other risk factor except LA or ACLA activity should be treated. No consensus has been reached about treatment after an initial minor event [deep venous thrombosis (DVT)]. Asymptomatic patients with only laboratory abnormalities should not be treated. Glucocorticoids should be administered only in conjunction with antithrombotic agents and are not of proven efficacy.

**INHERITED PROTHROMBOTIC DISORDERS** Coagulation is carefully regulated by a series of inhibitors that limit thrombin generation and fibrin formation and by the fibrinolytic system, which effectively removes fibrin thrombi (Figs. 53-6 and 53-7). Inherited defects in the natural coagulation inhibitors (i.e., antithrombin, proteins C and S), abnormalities in the fibrinolytic system, and certain dysfibrinogenemias predispose patients to thrombosis (Table 53-5). A single point mutation in the factor V gene (factor V Leiden), which converts arginine 506 to glutamine and makes the molecule resistant to degradation by activated protein C, may account for 25% of inherited prothrombotic states. Antithrombin, protein C, and protein S defects are all autosomal dominant traits, so heterozygous individuals, who have a 50% reduction in protein concentration or a mixture of mutant and normal molecules, will have an increased risk of thrombosis. The patients have similar clinical presentations with a strong family history of thrombosis, episodes of recurrent venous thromboembolism, and symptoms by their early twenties. Any patient with this distinctive history should be tested for specific abnormalities.

**ANTITHROMBIN DEFICIENCY** Antithrombin complexes with activated coagulation proteins and blocks their biologic activity (Fig. 53-6). The rate of this reaction is enhanced by heparin-like molecules within the vessel wall or on endothelial cells. Plasma antithrombin III content is 5 to 10 mg/L (50 to 150% of normal) and the values only slightly below normal increasing the risk of thrombosis. For optimal screening, the antithrombin III concentration is measured by immunoassay and the
plasma antithrombin and heparin cofactor activity assessed with functional assays. The most common defect (1 in 2000 individuals) is mild (heterozygous) antithrombin deficiency. Dysfunctional antithrombin molecules with mutations affecting either the serine protease or heparin-binding site or activation of inhibitor by heparin have also been described.

Patients with antithrombin deficiency who develop acute thrombosis or embolism can be treated with intravenous heparin, since there is usually sufficient normal antithrombin to act as a heparin cofactor. Following their first episode of thromboembolism, patients should be placed on oral anticoagulants for life to prevent recurrent thrombosis. Family studies should be conducted when an antithrombin-deficient individual is discovered, since up to half the members of a kindred may be affected. Asymptomatic individuals with antithrombin deficiency should receive prophylactic anticoagulation with heparin or plasma infusions to raise their antithrombin level before medical or surgical procedures that may increase their risk of thrombosis. Chronic oral anticoagulation is not recommended until individuals at risk have a thrombotic episode.

DEFIENCIES OF PROTEINS C AND S Protein C is a vitamin K–dependent hepatic protein that binds to the endothelial cell surface protein thrombomodulin and is converted to an active protease by thrombin (Fig. 53-6). Activated protein C, in conjunction with protein S, proteolyzes factors Va and VIIIa, which shuts off fibrin formation. Activated protein C may also stimulate fibrinolysis and accelerate clot lysis. Deficiencies of proteins C and S are usually autosomal dominant disorders, and deficiencies in the two proteins cause an identical syndrome of recurrent venous thrombosis and pulmonary embolism. Dysfunctional molecules have also been identified in some patients with thrombosis. Rare patients with homzygous protein C deficiency have fulminant neonatal intravascular coagulation and require prompt diagnosis and treatment. The correlation between levels of proteins C and S and the risk of thrombosis is not as precise as for antithrombin III deficiency. In fact, some asymptomatic individuals with protein C “deficiency” have been discovered. In some well-studied protein C–deficient kindreds, asymptomatic individuals may have protein C levels almost as low as or lower than relatives with recurrent thrombosis. It is possible that an undiscovered cofactor is present in symptomatic patients. Finally, since a fraction of the available protein S is bound to C4b-binding protein and is unavailable for coagulation reactions, both free and total protein S levels or C4b-binding protein levels should be assessed for maximum accuracy.

Heterozygous patients with protein C or S deficiencies who develop acute thrombosis should be heparinized and then placed on oral anticoagulants. There are, however, two potential problems with the use of warfarin anticoagulants in these patients. First, these vitamin K antagonists (Fig. 102-1), which lower the level of the procoagulant factors II, VII, IX, and X, may reduce the concentration of proteins C and S sufficiently to nullify the desired antithrombotic effect. In addition, patients who are protein C–deficient may develop warfarin-induced skin necrosis; this defect may predispose patients to a rare but serious complication. Patients with homzygous protein C deficiency require periodic plasma infusions rather than oral anticoagulants to prevent recurrent intravascular coagulation and thrombosis.

RESISTANCE TO ACTIVATED PROTEIN C AND THE FACTOR V LEIDEN MUTATION Some patients with familial or recurrent venous thromboembolism were found not to prolong their PTT when activated protein C was added to their plasma. These patients were found to have identical mutations in which arginine 506 in factor V is converted to glutamine. This amino acid substitution abolishes a protein C cleavage site in factor V and thus prolongs the thrombogenic effect of factor V activation. About 3% of the population worldwide is heterozygous for this mutation. The mutation is absent in certain populations, e.g., Asians, African Americans, and Native Americans. It may account for 25% of patients with recurrent DVT or pulmonary embolism.

Heterozygosity at this allele increases an individual’s lifetime risk of venous thromboembolism sevenfold. The risk rises steadily with age. A homozygote has a twentyfold increased risk of thrombosis. Heterozygosity coupled with ingestion of oral contraceptives or pregnancy increases the risk at least fifteenfold. Coinheritance of factor V Leiden and another low-penetration defect such as protein C or S deficiency is also additive. Many previous studies of risk factors predisposing patients to venous thromboembolism are being reevaluated to take into account this common mutation.

PROTHROMBIN GENE MUTATION A specific point mutation in the prothrombin gene [conversion of G to A at position 20210 (G20210A)] also predisposes to venous thrombosis and embolism. This mutation is in the 3′-untranslated region of the gene and results in a 30% increase in plasma prothrombin levels, either through more efficient translation or greater stability of the message. Heterozygotes account for ~18% of cases with family histories of venous thrombosis and 6% of patients with first episodes of DVT.

The inheritance of multiple mutations increases the risk of thrombosis. The relationship between known mutations and the type of thrombosis is shown in Table 102-3. The fraction of patients with DVT with known mutations is shown in Table 102-4.

* Anticardiolipin antibody—lupus anticoagulant.

Patients who develop venous thromboembolism without a clear predisposing factor, have a strong family history, present under age 30, or have more than one episode should have assays for antithrombin III, proteins C and S, and factor V Leiden. Patients who present with DVT or pulmonary embolism during pregnancy or while using oral contraceptives have a 30% chance of having factor V Leiden.

Treatment recommendations for patients with the inherited prethrombotic disorders are still evolving. All patients should receive standard initial therapy with heparin, either conventional or low dose (Chap. 103), followed by 3 months of oral warfarin. This regimen should allow for maximal healing and reendothelialization of the thrombosed vessels and minimize recurrence in the damaged vascular beds. It is not clear which patients should go on to receive long-term (perhaps lifelong) anticoagulation, a judgment that depends on assessing the risk/benefit ratio.

Patients with antithrombin III deficiency who become symptomatic have a high likelihood of recurrent events and should be placed on lifelong anticoagulation. Patients with protein C or S deficiency or heterozygous factor V Leiden and prothrombin G20210A patients have a lower likelihood of recurrent disease. Long-term anticoagula-

tion should be reserved until their second or subsequent episode of thromboembolism. Homozygous factor V Leiden patients should be placed on long-term anticoagulation after their initial episode, and all patients should receive replacement therapy or receive heparin prophylaxis during surgery or after trauma; women with these defects should avoid the use of oral contraceptives. The asymptomatic relatives of patients shown to have these disorders should be screened to determine if they have inherited the defective gene. If so, they should receive appropriate prophylaxis but not start anticoagulation until they are symptomatic. In the absence of a congenital defect predisposing a patient to thrombosis, recurring or migratory thrombophlebitis may indicate an underlying malignancy.

DYSFIBRINOGENEMIAS AND FIBRINOLYTIC DEFECTS Recurrent venous thrombosis and embolism may be due to familial defects in fibrinogen or plasminogen or decreased synthesis or release of tPA. While most dysfibrinogenemias cause bleeding, several variants have excessively rapid release of fibrinopeptides and recurrent thromboembolism. Patients with this disorder and those with an abnormal plasminogen that resists activation by streptokinase and urokinase have been treated successfully with heparin and oral anticoagulants. Defects in tPA content or release have not been completely characterized. One group of patients with recurrent venous thrombosis and embolism failed to increase venous blood fibrinolytic activity when challenged with local ischemia or physical exercise. The other group had impaired fibrinolytic activity in extracts prepared from biopsied veins. Young patients with acute myocardial infarction may have impaired fibrinolysis due to increased plasma levels of PAI, a serine protease inhibitor that binds to tPA and is derived from endothelial cells.

Many common illnesses are associated with an increased risk of thrombosis (Table 53-5). These patients are said to have a “hypercoagulable” or “prethrombotic” state. This increased risk is seen in patients with chronic congestive heart failure and metastatic cancer and in patients undergoing major surgery. The generation of tissue factor activity in damaged or ischemic tissue or metastatic tumor, coupled with venous stasis and endothelial injury, induces the formation of venous and, more rarely, arterial thrombi. Several hematologic disorders, paroxysmal nocturnal hemoglobinuria, essential thrombocytopenia, and polycythemia vera predispose patients to venous and arterial thrombosis through diverse mechanisms related to increased blood viscosity and abnormal blood cells. Diseases that affect the endothelial cell, such as Behçet’s syndrome, Kawasaki’s disease, and homocystinuria, or the administration of drugs such as oral contraceptives, which lower antithrombin III levels, or L-asparaginase, which inhibits production of multiple coagulation factors, may also predispose patients to thrombosis. Infusion of granulocyte-macrophage colony-stimulating factor (GM-CSF) has been associated with thrombosis. Tamoxifen, an estrogen receptor antagonist, can cause venous thrombosis. The mechanism is unclear.

Plasma homocysteine levels influence the risk of both venous and arterial thromboembolism. Individuals with the congenital homocystinuria syndrome have, in addition to their Marfanoid habitus, an increased incidence of strokes and coronary artery disease. These patients have well-recognized enzyme defects (Chap. 343), excrete homocysteine in their urine, and have very high plasma levels of the amino acid. Some patients with early-onset cerebral vascular events have mild homocystinuria that can be brought out by a methionine loading test. Epidemiologic studies show a relationship between homocysteine levels that are nearer to the normal range and coronary artery disease. Vitamin B12 deficiency occurs in about 30% of people over age 70, produces elevated homocysteine levels, and may be a reversible cause of thrombotic disease.

**ANTIPLATELET, ANTICOAGULANT, AND FIBRINOLYTIC THERAPY**

Steven R. Deitcher

Arterial and venous thrombosis together with complicating embolic phenomena are major causes of mortality in the developed countries of the world. In the United States alone, myocardial infarction (MI) and thromboembolic stroke account for over 800,000 deaths annually, and from one-half to 2 million venous thromboembolic events (VTE) including deep venous thrombosis (DVT) and pulmonary embolism (PE) occur annually. A common feature of the management of all thromboembolic vascular diseases is the use of antithrombotic agents. Antithrombotic agents, including antiplatelet drugs, anticoagulants, and fibrinolytic agents, are used to prevent thrombotic events, prevent or mitigate the complications of thrombotic events, and restore vascular patency in order to prevent loss of tissue, limb, and organ function as well as life. The pathologic basis of thrombosis in different vascular beds dictates the choice of agents: drugs that inhibit platelet activation and aggregation play a primary role in arterial disease management; drugs that inhibit thrombin and fibrin generation play a primary role in venous disease.

**ANTIPLATELET DRUGS**

Antiplatelet treatment reduces overall mortality from vascular disease by 15% and nonfatal vascular events by 30%. Multiple targets exist for antiplatelet therapy (Fig. 103-1), including cyclooxygenase (COX), adenosine diphosphate (ADP) receptors, the platelet adhesion glycoprotein (Gp) Ib, and the platelet agonist thrombin. Prostaglandin E1 and stable analogues of prostacyclin inhibit platelet activation by increasing platelet cyclic AMP levels. Dipyridamole inhibits platelet activation by inhibiting phosphodiesterase to increase cyclic AMP. Because expression of functionally active GpIb/IIIa on platelet surfaces is the final common pathway of platelet activation regardless of initial stimulus, it is a logical therapeutic target.

**ASPIRIN** Aspirin (acetylsalicylic acid) irreversibly inactivates by acetylation the activity of platelet prostaglandin H synthase-1 and -2 (COX-1 and -2). COX inhibition leads to the prevention of thromboxane A2 synthesis and impairment of platelet secretion and aggregation. Non-enteric-coated aspirin is rapidly absorbed from the upper gastrointestinal tract; plasma salicylate concentrations peak within 1 h of ingestion. The effects of aspirin on platelet function occur within 1 h and last for the duration of the affected platelets’ life span (1 week). Toxicities including gastrointestinal discomfort, blood loss, and systemic bleeding are dose-related. Aspirin doses as low as 30 mg/day are antithrombotic. Aspirin has been convincingly shown to be effective in treatment of stable and unstable angina, acute MI, transient ischemic
attack and incomplete stroke, stroke following carotid artery surgery, and atrial fibrillation. The minimum effective aspirin dose for these indications is 75 to 325 mg/d. Aspirin reduces mortality after coronary artery bypass surgery. In patients with acute MI or stroke, aspirin prevents 35 to 40 cardiovascular events per 1000 patients treated (secondary prevention). For primary prevention in persons 50 to 60 years of age with at least one major risk factor for coronary artery disease, aspirin prevents 4 events per 1000 patients treated. Aspirin is advisable following peripheral arterial bypass surgery and carotid endarterectomy and in patients with intermittent claudication. Though beneficial when compared to placebo, aspirin cannot be recommended as first-line VTE prophylaxis in hip fracture patients because the benefit of aspirin is less than with anticoagulants.

**THIENOPYRIDINES** Ticlopidine and clopidogrel are structurally related compounds that selectively inhibit ADP-induced platelet aggregation and likely ADP-mediated amplification of the platelet response to other agonists. Though more effective than aspirin in reducing vascular events in many settings, enthusiasm for ticlopidine is dampened by its anticoagulant properties, including thrombotic thrombocytopenic purpura (TTP). Clopidogrel is rapidly absorbed, extensively metabolized, and inhibits ADP-induced platelet aggregation in a dose-dependent fashion with inhibition detectable 2 h after an oral dose of 400 mg. The plasma half-life of the main metabolite, SR 26334, is ~8 h. On repeated daily dosing of 50 to 100 mg, 25 to 30% inhibition of ADP-induced platelet aggregation is noted on the second day of therapy, with 50 to 60% steady-state inhibition noted after 4 to 7 days. Platelet function returns to normal about 7 days after the last dose of clopidogrel. The CAPRIE trial demonstrated a modest reduction in ischemic events in patients with recent stroke or MI and in those with symptomatic peripheral arterial disease randomly assigned to clopidogrel, 75 mg/d, compared to aspirin (5.32% vs. 5.83%). The majority of the difference in efficacy occurred in the patients who entered because of symptomatic peripheral arterial disease, with a 23.8% relative risk reduction. Another trial (PCI-CURE) demonstrated an advantage of pretreatment clopidogrel plus aspirin followed by long-term therapy over aspirin alone in patients with acute coronary syndromes. Clopidogrel rarely precipitates TTP.

**GpIIb/IIIa (collateral) ANTAGONISTS** GpIIb/IIIa is a member of the integrin family of receptors. These receptors recognize the amino acid sequence arginine-glycine-aspartate (Arg-Gly-Asp; RGD), which represents the cell attachment recognition sequence present in adhesive proteins such as fibrinogen. Three potent parenteral GpIIb/IIIa inhibitors (disintegrins) have been extensively studied, primarily in the settings of percutaneous coronary intervention (PCI), unstable angina, and non-Q-wave MI. Abciximab (c7E3 Fab) is a chimeric monoclonal Fab fragment of human and murine protein that binds to GpIIb/IIIa. Eptifibatide is a synthetic cyclic heptapeptide with a KGD sequence more specific for GpIIb/IIIa than RGD. Tirofiban is a synthetic peptidomimetic based on the RGD sequence. Oral, in contrast to intravenous, GpIIb/IIIa inhibitors have been generally disappointing.

**ANTICOAGULANT DRUGS**

Anticoagulant drugs are used to prevent and treat thrombosis in medical and surgical patients. Narrow-spectrum (single-protein target) anticoagulants (e.g., fondaparinux and ximelagatran) are being developed to supplant more broad-spectrum anticoagulants (e.g., heparin and warfarin). The molecular targets of selected agents are shown in Fig. 103-2. Oral delivery and lack of obligatory therapeutic monitoring are desired anticoagulant characteristics.

**HEPARIN** Commercial unfractionated heparin (UFH), obtained from bovine lung or porcine intestinal mucosa, consists of a heterogeneous mixture of highly sulfated polysaccharides (glycosaminoglycans) with molecular masses ranging from 4 to 30 kDa, with a mean molecular mass of ~15 kDa (≈45 saccharide units). UFH molecules contain a randomly distributed unique pentasaccharide sequence that binds to antithrombin. Once bound to UFH, the natural anticoagulant effect of antithrombin is potentiated, resulting in accelerated binding and inactivation of serine proteases such as the common pathway coagulation factors, factor Xa and thrombin. Heparin is active when given intravenously or subcutaneously. Delivery systems utilizing synthetic amino acids such as sodium N-[(2-hydroxybenzoyl)amino] caprylate (SNAC) facilitate oral heparin gut absorption. The half-life of heparin increases with increasing dosage. A 100-U/kg intravenous dose is cleared with a half-life of ~1 h. Heparin is cleared by the reticuloendothelial system and metabolized by the liver, and metabolic products are excreted in the urine. “True” heparin resistance, manifesting as inadequate anticoagulant [activated partial thromboplastin time (aPTT) prolongation] and antithrombotic (anti-factor Xa activity) responses from what would otherwise be perceived as an adequate heparin dose, likely results from the nonspecific heparin binding to white blood cells, vascular endothelial cells, and acute-phase proteins. In “apparent” heparin resistance, usually as a result of elevated factor VIII levels, the aPTT may be normal or near normal while the anti-factor Xa activity assay reveals a therapeutic heparin activity level. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay may result in a pronounced bleeding

---

**FIGURE 103-1** Antiplatelet drugs and targets for platelet function inhibition. The thienopyridines, ticlopidine and clopidogrel, inhibit the ADP-receptor of platelets. Aspirin targets platelet cyclooxygenase (COX). The disintegrins bind to and inhibit the final common pathway of platelet activation, namely the glycoprotein (Gp) IIb/IIIa complex. (TXA2, thromboxane A2.)

**FIGURE 103-2** Anticoagulant drugs and molecular targets of anticoagulation. Unfractionated heparin (UFH) targets factor Xa and thrombin. Fondaparinux (full-length heparin) and idraparinux are fragment-based heparins that are selective for factor Xa. Lepirudin, argatroban, and bivalirudin are direct thrombin inhibitors. APTT, activated partial thromboplastin time; aPTT, activated partial thromboplastin time; COX, cyclooxygenase; FVIIIa, factor VIIIa; FXIa, factor XIa; TXA2, thromboxane A2.
risk. These variables warrant close laboratory monitoring of heparin therapy.

**LOW-MOLECULAR-WEIGHT HEPARINS (LMWHs)** LMWHs are derived from the enzymatic or chemical cleavage of UFH into a mixture of glycosaminoglycans with a mean molecular mass of ~5 kDa (=15 saccharide units). LMWHs bind antithrombin via the same pentasaccharide sequence as UFH. Due to the predominance of molecules <18 saccharide units in length, LMWHs have limited antithrombin activity compared to anti-factor Xa activity, and LMWH therapy is unable to be monitored by aPTT. Whereas UFH has an anti-factor Xa:antithrombin activity ratio of 1:1, LMWHs have reported ratios of 1.9:1 to 4:1:1. LMWHs differ in their degree of tissue factor pathway inhibitor release, degree of sulfation, and degree of stimulated von Willebrand factor (vWF) release. Superior bioavailability, limited nonspecific binding, and non-dose-dependent half-lives facilitate once- or twice-daily subcutaneous dosing based solely on weight and without laboratory monitoring. LMWH is cleared by renal mechanisms; therefore, multiday use in patients with severe renal insufficiency (creatinine clearance <30 mL/min) should be avoided. Reversible elevations of liver transaminases may occur during the administration of LMWH and UFH. LMWHs are associated with less heparin-induced thrombocytopenia (HIT) (Chap. 101) and osteopenia than UFH but are only partially (≈60%) neutralized by protamine sulfate.

**HEPARINOIDs** The heparinoid dermatan sulfate acts as an anticoagulant by activating heparin cofactor II. Danaparoid is a glycosaminoglycan mixture derived from porcine intestinal mucosa composed of heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%). Danaparoid has an anti-factor Xa:antithrombin activity ratio of >22:1. Danaparoid’s potential for heparin cross-reactivity and longer half-life (24 h) make it less desirable than a direct thrombin inhibitor for the treatment of patients with HIT, the main indication for heparinoid use.

**PENTASACCHARIDES** Fondaparinux is a synthetic pentasaccharide that causes selective indirect inhibition of factor Xa. Fondaparinux is administered subcutaneously and does not require therapeutic monitoring. Fondaparinux elimination is prolonged in patients with renal impairment, in those >75 years, and in those weighing <50 kg. Fondaparinux is primarily used for thromboprophylaxis in patients with hip fracture undergoing surgery and in those undergoing elective knee and hip joint replacement. Fondaparinux does not bind platelet factor 4 and may result in less HIT than UFH and LMWH. A long-acting pentasaccharide, idraparinux, has a half-life of 130 h, which may facilitate once-weekly dosing for primary and/or secondary prevention of thromboembolic events.

**DIRECT THROMBIN INHIBITORS (DTI)** Despite elimination of all heparin exposure and platelet count recovery, patients with isolated, serologically confirmed HIT have up to a 50% risk of developing a confirmed thrombotic event during the 30-day period following HIT diagnosis. The persistent prothrombotic tendency associated with HIT, the presence of thrombus in HIT with thrombosis, and a patient’s original indication for heparin therapy all warrant use of an alternative anticoagulant agent such as DTI following heparin cessation.

**Lepirudin** Lepirudin is a recombinant hirudin that, unlike native hirudin in medicinal leech saliva, lacks sulfation on tyrosine 63 and has a leucine at position 1. Lepirudin is a potent, irreversible DTI that lacks any structural homology with heparin, does not cross-react with heparin, has a short half-life (1.5 h), inactivates clot-bound thrombin, and can be monitored by the aPTT assay or ecarin clotting time. The rate of death, amputation, and new thromboembolic events is reduced by >50% in HIT patients treated with lepirudin, compared with historic controls. Current lepirudin dosing recommendations for acute HIT management are 0.4 mg/kg as a bolus followed by 0.15 mg/kg per hour (up to 110 kg). The target aPTT is 1.5 to 2.5 times the median value for the normal range. The target plasma lepirudin concentration during heart bypass is 2.0 μg/mL. Outpatient subcutaneous lepirudin has been used to treat patients with HIT and patients refractory to other anticoagulant therapy. The major challenges of lepirudin treatment are the lack of an antidote, the extreme care needed when treating patients with even mild renal insufficiency, and immunogenicity. Marked bolus and infusion rate reductions are necessary in patients with a creatinine clearance of <60 mL/min. Lepirudin should be avoided completely or administered with extreme care in the settings of hemodialysis and acute renal failure. Approximately 40% of HIT patients treated with lepirudin develop IgG anti-hirudin antibodies that decrease renal elimination of the drug rather than exerting any in vivo neutralizing effect. This enhancement of anticoagulant effect often warrants a major reduction of the infusion rate.

**Argatroban** Argatroban is a synthetic, small-molecule, l-arginine derivative, rapid, and reversible DTI capable of inhibiting both free and fibrin-bound thrombin. Argatroban exerts its antithrombotic effects by inhibiting thrombin-mediated fibrin formation; coagulation factor V, VII, and XIII activation; and platelet activation. Argatroban does not cross-react with heparin. Argatroban is hepatically metabolized with biliary excretion and has a half-life of 40 min. Dose reduction is required in patients with significant hepatic disease. In HIT, the combined incidence of death, amputation, and new thromboembolic events is significantly lower in argatroban recipients compared with controls. The recommended starting intravenous infusion rate is 2 μg/kg per min with a target aPTT of 1.5 to 3 times the baseline value. Prothrombin time (PT) prolongation makes an accurate International Normalized Ratio (INR) determination during conversion to oral warfarin a challenge. Argatroban [350-μg/kg bolus followed by 25 μg/kg per min titrated to achieve an activated clotting time (ACT) of 300 to 450 s] provides adequate anticoagulation with minimal bleeding risk while enabling procedural success in HIT patients undergoing a PCI.

**Bivalirudin** Bivalirudin is a semisynthetic, bivalent DTI consisting of a dodecapeptide analogue of the carboxyterminus of hirudin. Bivalirudin has four glycine residues that connect the thrombin exosite 1 and thrombin active-site binding moieties. Bivalirudin has a very short half-life (25 min) and is a reversible DTI. Bivalirudin is primarily used during PCI, where it is at least as effective as heparin with an improved safety profile.

**Ximelagatran** Ximelagatran is an oral prodrug of the DTI melagatran. Ximelagatran is administered in a fixed-dose fashion, does not require therapeutic monitoring, and has no apparent major food or drug interactions. Ximelagatran is rapidly absorbed (peak levels in 15 to 30 min) and rapidly converted to melagatran (peak levels in 1 to 2 h). Melagatran is renally eliminated. Melagatran binds to the thrombin active site resulting in inhibition of thrombin-mediated activation of coagulation factors and platelets. It is active against free and clot-bound thrombin. Ximelagatran is promising as a treatment of acute VTE, chronic management of atrial fibrillation, and prevention of VTE in high-risk settings such as following surgery and HIT. Reversible liver function abnormalities have been reported.

**WARFARIN** Warfarin inhibits vitamin K epoxide reductase and vitamin K reductase, thus inhibiting γ-carboxylation of select glutamic acid residues in the N-terminus of prothrombin; factors VII, IX, and X; and protein C and protein S. Inhibition of γ-carboxylation leads to synthesis of hypofunctional coagulation proteins that are unable to bind to cellular surfaces to mediate coagulation reactions. Commercially available warfarin is a racemic mixture of levo- and dextrorotatory forms of the drug. The half-life of warfarin in plasma is ~36 h. Because factor X and prothrombin have half-lives ~2 days, reduction of all vitamin K–dependent coagulation proteins into the therapeutic range (~20% of normal) requires 4 to 5 days of therapy. Warfarin dosing is influenced by dietary stores of vitamin K, liver function, coexisting medical disorders, concurrent medications, and presence or absence of a common cytochrome P450 2C9 gene mutation. Warfarin metabolism is affected by other drugs metabolized by the cytochrome P450, by drugs that displace albumin-bound warfarin and impair gas-
trointestinal absorption, and by antibiotics that alter the natural flora of the colon (an endogenous source of vitamin K). The PT assay is useful to monitor warfarin therapy because this assay measures three vitamin K–dependent coagulation proteins—factors VII, X, and prothrombin. The PT is particularly sensitive to factor VII deficiency; with a half-life of 4 to 6 h, the factor VII level may drop rapidly after only 1 day of warfarin therapy and prolong the PT value. Large loading doses of warfarin result in a more rapid drop in factor VII levels, delay in attainment of a stable PT, a precipitous fall in protein C levels, and predisposition to warfarin-induced skin necrosis. The INR is a method that standardizes PT assays. Each new PT reagent (thromboplastin) is calibrated against the World Health Organization reference thromboplastin. A relative sensitivity of the unknown preparation compared with the reference called the International Sensitivity Index (ISI) is derived. By adjusting for the ISI of a particular thromboplastin, an INR, defined as the PT ratio (patient PT divided by the mean normal PT) that would have been obtained if the reference thromboplastin had been used, can be determined. The INR is calculated using the following formula: INR = (PT ratio)0.01. An INR of 2.0 to 3.0 is recommended for all indications except prosthetic mechanical heart valves and prophylaxis of recurrent MI, for which higher-intensity warfarin therapy (INR 2.5 to 3.5) is suggested, and primary prophylaxis where an INR <2.0 is usually desired. In part because many patients with lupus anticoagulants have elevated baseline PTs, the INR may not be an accurate means of monitoring warfarin therapy in this setting. Factors contributing to warfarin-associated bleeding include an INR > 3.0, structural gastrointestinal lesions, concomitant antplatelet therapy, hypertension, renal disease, and cerebrovascular disease. Visceral bleeding while on warfarin therapy often results in identification of structural lesions. In pregnant women, warfarin can cause an embryopathy consisting of nasal hypoplasia and epiphysial stippling. The risk may be greatest between weeks 6 and 12 of gestation and may reflect the effect of warfarin on a vitamin K–dependent bone matrix protein, osteocalcin. Most practitioners avoid warfarin during pregnancy. Warfarin-induced skin necrosis is a devastating complication of warfarin therapy, occurring within the first week of therapy and associated in some with protein C deficiency. The skin lesions often begin on fatty body parts (breasts, abdomen, thighs) as erythematous patches and progress to blebs followed by demarcated skin necrosis. Skin biopsy reveals generalized thrombosis of skin vessels. The “purple-toe syndrome” is an uncommon syndrome described in patients with underlying atherosclerotic vascular disease receiving warfarin. These patients present with atheroembolic symptoms including ischemic (purple) toes, livedo reticularis, gangrene, abdominal pain, or symptoms of renal infarction. Skin biopsy reveals cholesterol emboli in the purple-toe syndrome.

FIBRINOLYTIC DRUGS

Most thrombolytic agents are recombinant forms of physiologic plasminogen activators (PAs) that differ in plasma half-life, fibrin specificity, primary clinical usage, primary infusion strategy, and immunogenicity. Therapeutic PAs are fashioned after endogenous tissue-type plasminogen activator (t-PA) or urokinase that converts plasminogen into the active enzyme plasmin. Plasmin degrades fibrinogen and fibrin into fibrinogen degradation products. Major goals of new thrombolytic agent development include increasing fibrin specificity to theoretically reduce bleeding complications, prolonging initial plasma half-life to facilitate bolus administration, and reducing sensitivity to inactivation by plasminogen activator inhibitor (PAI) 1.

STREPTOKINASE

Streptokinase is obtained from cultures of β-hemolytic streptococci. By itself, streptokinase has no PA activity, but when complexed with plasminogen, it can convert other plasminogen molecules to plasmin. Streptokinase is not fibrin-specific; fibrinolytic state resulting from its therapeutic use is due to lysis of fibrinogen as well as fibrin. Platelet function may be perturbed because plasmin can proteolyze key platelet membrane receptors. The half-life of streptokinase is ~20 min. Because streptokinase is a bacterial protein, it is antigenic; allergic reactions occur in up to 6% of patients, and anaphylaxis occurs in ~0.1% of patients. Patients previously exposed to streptokinase or with previous streptococcal infections may acquire antistreptococcal antibody levels sufficient to neutralize its activity. Streptokinase has been primarily used to treat VTE and MI as well as to treat central venous line–associated thrombosis.

UROKINASE-TYPE PLASMINOGEN ACTIVATOR

Native urokinase is obtained from human fetal kidney cell cultures. Recombinant high-molecular-weight urokinase is produced using nonhuman, mammalian tissue cultures. Urokinase is not fibrin-selective and thus produces a lytic state. Its half-life is ~20 min, and it is used to treat DVT, PE, MI, peripheral arterial thrombosis, and occluded catheters.

TISSUE-TYPE PLASMINOGEN ACTIVATOR

Recombinant tissue-type plasminogen activator (rt-PA) produced by recombinant technology demonstrates high in vitro affinity for fibrin with which it forms a ternary complex with plasminogen. Despite reported fibrin-specificity, the lytic state is produced with dosages currently used. Bleeding complications with t-PA are similar to those of streptokinase or urokinase. The half-life of t-PA is ~5 min. t-PA is used to treat DVT, PE, acute MI, acute thrombotic stroke, and dysfunctional central venous lines.

TISSUE-TYPE PLASMINOGEN ACTIVATOR VARIANTS

Recombinant PA (r-PA; reteplase) is a nonglycosylated deletion mutant of wild-type human t-PA composed of only the kringle 2 and the protease domains of the parent molecule. Lack of the finger domain imparts lower fibrin-binding affinity. Lack of glycosylation, a finger domain, and epidermal growth factor domain imparts an extended half-life (15 min versus 5 min). TNK-t-PA differs from t-PA by three sets of mutations. The Asn177 → Gln and Thr103 → Asn mutations promote a lower plasma clearance rate and greater fibrin specificity. The Lys296-His297-Arg298 Ala-Ala-Ala mutation imparts an 80-fold increased resistance to PAI-1. The longer half-lives of r-PA and TNK-rt-PA compared with rt-PA facilitate bolus administration primarily for acute coronary thrombosis.

NEWER NON-t-PA FIBRINOLYTICS

Recombinant glycosylated pro-urokinase is a rapid acting and safe fibrin-specific PA. Staphylokinase produced by Staphylococcus aureus possesses substantial thrombolytic activity but may be immunogenic. Vampire bat (Desmodus rotundus) salivary PA, possessing 85% primary structure homology to human t-PA but lacking a kringle 2 domain, holds promise as a potent thrombolytic. Alfiniprase is a novel thrombolytic based on the snake venom–derived protein fibrolase. Alfiniprase is a direct fibrinolytic (not a PA) neutralized by α2-macroglobulin that holds promise as a rapid and safe catheter-delivered thrombolytic.

THROMBOLYTIC THERAPY–ASSOCIATED BLEEDING

Bleeding associated with all PAs stems from plasmin’s inability to differentiate between hemostatic and pathologic thrombi. Bleeding complications range from minor bleeding to life-threatening hemorrhage including intracranial hemorrhage. Older age, female sex, black ethnicity, systolic blood pressure ≥ 140 mmHg, diastolic blood pressure ≥ 100 mmHg, history of stroke, t-PA dose > 1.5 mg/kg, and lower body weight are all associated with increased intracranial hemorrhage risk. The ability of a thrombolytic agent (PA) to distinguish between plasminogen in the general circulation and plasminogen bound to fibrin surfaces dictates its fibrin specificity. Activation of fibrin-bound plasminogen results in the generation of fibrin-bound plasmin that is protected from inactivation by α2-antiplasmin. Bound plasmin generates soluble fibrin degradation products, whereas circulating plasmin degrades fibrinogen into fibrinogen degradation products. High fibrin specificity is thought to be associated with lower risk for hemorrhagic complications because of the belief that plasmin born on the fibrin surface of a thrombus will restrict its activity only to that surface. This view is not supported by available fibrinolysis-large-scale clinical trials. Unlike in acute MI where intravenous bolus PA dosing is necessary to facilitate rapid lysis of a relatively small thrombus, lysis of larger diameter and longer
peripheral thromboses is best achieved with catheter-directed infusions of PA over several hours to days. Drugs designed for bolus infusion to treat acute coronary thrombosis (e.g., r-PA and TNK-t-PA) may be associated with loss of fibrin specificity, accumulation of fragment X, and increased bleeding rates when given by extended continuous infusion.

**MANAGEMENT OF VENOUS THROMBOEMBOLIC DISEASE** (Fig. 103-3)

The major clinical consequences of extremity DVT include the post-thrombotic syndrome (swelling, stasis dermatitis, ulceration, and venous claudication all due to venous insufficiency), PE, and paradoxical embolus resulting in stroke. The major clinical consequences of PE include chronic dyspnea, pulmonary hypertension, pulmonary infarction, and death. Inadequately treated DVT involving the popliteal or more proximal leg veins is associated with a 20 to 50% risk of clinically relevant recurrence and is strongly associated with both symptomatic and fatal pulmonary embolism. Death from PE occurs most frequently within 2 days of presentation in untreated patients. All-cause mortality rates in treated patients with PE run as high as 11% at 2 weeks and 17% at 3 months.

**Calf Deep Venous Thrombosis** While calf DVT and proximal DVT may be considered separate diseases at their outset, 15 to 25% of calf DVTs propagate and convert into proximal DVT. Symptomatic and asymptomatic calf DVT appear to propagate with equal frequency. Such “proximal conversion” renders what was initially a calf DVT just as dangerous as any proximal DVT. Proximal conversion has been shown to occur within the initial 2 weeks after diagnosis in the majority of cases and warrants treatment accordingly. The most essential goal of calf DVT treatment should be to prevent early proximal conversion. Treatment approaches for isolated calf DVT range from identical therapy as is used for proximal DVT to a complete lack of any pharmacologic therapy. Appropriate management, which falls between these extremes, includes serial duplex ultrasound surveillance (twice-weekly for 2 to 3 weeks) with therapy begun only in the event of proximal conversion and abbreviated courses of standard anticoagulation. Serial surveillance seems especially prudent in situations such as recent gastrointestinal bleeding where the risk of anticoagulation likely exceeds the benefit. Situational calf DVT (DVT with a clear precipitant) can be safely treated with anticoagulation for only 6 weeks, assuming the precipitating illness or event has resolved. Inferior vena cava (IVC) filter placement is not recommended for calf DVT in most circumstances.

**Proximal Deep Venous Thrombosis** The goals of proximal DVT therapy include restoration of venous patency and prevention of embolization, thrombus extension, early and late recurrence, and postthrombotic syndrome. Studies done before the routine use of anticoagulant therapy demonstrated that 20% of patients with untreated DVT died of PE. Intravenous, aPTT-adjusted UFH and weight-based LMWH effectively prevent embolization, extension, and recurrence. LMWHs appear to be slightly but significantly better than standard heparin at restoring venous patency and may reduce the incidence of early postthrombotic syndrome. Placement of an IVC filter prevents PE in the short run but probably at the expense of a greater long-term DVT recurrence rate.

**Pulmonary Embolism** In general, acute PE should be treated in the same fashion as acute proximal DVT. It is advisable to start anticoagulation at the time of suspected PE even before diagnostic testing has been performed. LMWHs have been shown to be safe and effective in patients with acute PE treated in hospital. Outpatient treatment of PE is investigational. Placement of an IVC filter at the time of PE diagnosis is usually reserved for those with an absolute contraindication to anticoagulation. Filters may be reasonable in select patients with underlying cardiac or pulmonary disease perceived as being at high risk for death in the event of even a small PE. Placement of a filter because of a “free-floating” DVT is probably not indicated.

**Initial VTE Anticoagulation** Initial anticoagulation refers to the therapy begun at the time of VTE diagnosis and continued only until stable, usually oral, more long-term therapy has been achieved. Treatment with heparin or LMWH should be begun as soon as possible unless an absolute contraindication exists. A delay in achieving a therapeutic intensity of initial parenteral therapy may increase a patient’s long-term VTE recurrence rate. Weight-based initial dosing of heparin (80 U/kg bolus followed by 18 U/kg per hour) with subsequent dose adjustments based on any published standardized nomogram facilitates achieving a target aPTT. An aPTT that correlates with an anti-FXa activity level of 0.3 to 0.7 IU/mL is considered therapeutic. The aPTT should be checked every 4 to 6 h until the aPTT surpasses the minimum of the target range. Fixed-dose boluses and initial infusions are preferred by some and are not necessarily inferior to weight-based dosing. Active bleeding, HIT or a history of HIT, and known sensitivity to UFH or pork products are absolute contraindications to heparin therapy. Patients with acute DVT and active bleeding require placement of an IVC filter. In patients with filters placed because of bleeding, appropriate anticoagulation should be begun as soon as the bleeding source has been properly and completely treated. Because of the risk of re-bleeding, such a patient may benefit from inpatient anticoagulation initiation. Placement and subsequent removal of a temporary (or retrievable) IVC filter once the contraindication to anticoagulation has passed seems ideal. Patients who are excessively anticoagulated with heparin without serious bleeding can be treated simply by stopping the drug; the short half-life (1 to 2 h) of heparin ensures rapid return of the aPTT to the therapeutic range. In occasional patients with thrombosis, such as those with lupus anticoagulants, the aPTT assay may not be reliable in monitoring heparin therapy. For these patients, one can follow heparin levels determined using the anti-factor Xa method or give a LMWH, with the dosage determined solely by body weight. Excessively anticoagulated and actively bleeding patients should be considered for reversal of anticoagulation with protamine sulfate. Proamine is given by slow IV infusion, with 1 mg of protamine neutralizing ~100 U of heparin. Protamine infusion may be associated with anaphylaxis, and excess protamine may lead to a paradoxical bleeding disorder. Weight-based subcutaneous LMWH is an acceptable standard of care. Whether to use LMWH or UFH for acute anticoagulation should be determined for each patient taking into account the individual patient medical history, bleeding risk, ambu-
intravenous) can be started as soon as an aPTT continues for up to 6 months (Table 103-1). Warfarin therapy (oral or subcutaneous) may explain warfarin-induced skin necrosis and warfarin-induced limb gangrene in patients with HIT. This warfarin-induced paradoxical hypercoagulability of hypercoagulability caused by a rapid reduction in protein C functional activity. This warfarin-induced paradoxical hypercoagulability may explain warfarin-induced skin necrosis and warfarin-induced limb gangrene in patients with HIT.

**SUBACUTE VTE ANTICOAGULATION**

Subacute anticoagulation refers to treatment (usually oral warfarin) that follows acute-phase therapy and continues for up to 6 months (Table 103-1). Warfarin therapy (oral or intravenous) can be started as soon as an aPTT > 1.5 times control has been achieved with heparin or an initial weight-based dose of LMWH has been given. Bolus dosing of warfarin does not help achieve a stable target INR faster and may actually delay achievement of a stable INR and prolong hospitalization. Initial dosing with 2.5 to 7.5 mg/d (based on patient weight and nutritional status) seems prudent. Heparin and LMWH therapy must overlap oral warfarin therapy for a minimum of 4 days and ideally until a stable target range (2.0 to 3.0) INR has been achieved. Starting warfarin therapy early after heparin therapy (day 1 or 2) facilitates earlier hospital discharge and potential reduction in the incidence of HIT. Patients with massive DVT or PE may benefit from 7 to 10 days of initial heparin or LMWH therapy. Because of its teratogenic effects, warfarin therapy is contraindicated in pregnancy, so continued heparin or LMWH is prudent. Patients should be encouraged to consume a constant intake of dietary vitamin K and avoid large variations or fluctuations in their diet. Because of the number of pharmacologic interactions that exist between warfarin and other drugs, patients should be instructed to inform their physician of the addition or withdrawal of any medication, vitamin, and herbal preparation (Table 103-2). Recently completed studies (LITE, ONCENOX, and CLOT) provide strong evidence to support the use of LMWH as acute plus subacute VTE treatment. Once-daily tinzaparin (175 IU/kg) was as effective and safer than INR-adjusted oral warfarin in a mixed population of acute VTE patients. Once-daily tinzaparin, enoxaparin, and dalteparin were shown to be more effective than oral warfarin at preventing recurrent VTE in cancer patients with thrombosis. Patients with DVT secondary to a transient risk such as surgery, trauma, or pregnancy may be anticoagulated for a duration of 6 weeks to 3 months, as long as the risk factor has passed. Patients with a first idiopathic VTE should be anticoagulated for a minimum of 3 to 6 months.

**CHRONIC ANTICOAGULATION FOR VTE**

Patients with persistent risk factors for thrombosis such as an anti-phospholipid antibody, hyperhomocysteinemia, active malignancy, or a deficiency of a natural anticoagulant (protein S, protein C, and antithrombin), homozygous factor V Leiden, and those with recurrent idiopathic VTE may benefit from long-term therapy (Table 103-1). The risk of VTE recurrence is very low as long as therapeutic anticoagulation is continued. It is the up to 3 to 4% annual risk of major hemorrhage secondary to warfarin (INR 2.0 to 3.0) that prevents physicians from prescribing long-term anticoagulation with abandon. The long-term risks and inconvenience of chronic (>6 months) therapeutic-intensity warfarin anticoagulation have led to the study of alternative approaches to chronic-phase anticoagulation following VTE. Extended secondary prevention with the oral DTI ximelagatran (24 mg bid) for 18 months after 6 months of standard anti-coagulation in patients with VTE (THRIVE) revealed recurrence rates of 2.0% and 11.6% (p < .0001) in the ximelagatran and placebo groups, respectively. Reported major and minor bleeding rates on therapy were not different between groups. Another successful approach

a Malignancy, anti-phospholipid antibodies, homozygous factor V Leiden, natural anticoagulant deficiency, etc. 

Note: DVT, deep venous thrombosis.
to chronic-phase anticoagulation involves long-term, low-intensity oral warfarin therapy with infrequent (every 8 weeks) INR monitoring (PREVENT). In this landmark study, patients with idiopathic VTE who had received standard acute- and subacute-phase anticoagulant therapy were randomly assigned to placebo or low-intensity warfarin (target INR 1.5 to 2.0). Recurrent VTE rates were 7.2 per 100 person-years and 2.6 per 100 person-years in the placebo and warfarin groups, respectively. This 64% risk reduction was accomplished in both those with and without inherited thrombophilia without any increase in major hemorrhage rates. Such safe and effective regimens have the potential to redefine the standard of care for VTE.

**THROMBOLYSIS FOR VTE** Benefits of DVT thrombolysis include the ability to subsequently diagnose and treat underlying venous stenosis, venous compression (as in May-Thurner syndrome) or venous webs. Thrombolysis results in improved venous patency and symptom resolution and in a decrease in postthrombotic syndrome symptoms, and it may improve health-related quality of life. Because of the bleeding risk, thrombolysis is best reserved to treat iliofemoral DVT in the young and those with extensive thrombosis resulting in venous limb gangrene (*phlegmasia cerulea dolens*). Intravenous thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients. When compared to anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function. However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise. It remains unclear whether patients with PE and evidence of right ventricular dysfunction and/or elevated cardiac troponin levels are subgroups that benefit more from thrombolysis. Major hemorrhage rates have varied between 4 and 22% when thrombolytic agents are used in studies at the currently recommended doses.

**VENOUS THROMBOEMBOLIC DISEASE PREVENTION** If physicians focused more on VTE prophylaxis, much less time would need to be dedicated to emphasizing methods for VTE treatment. Fatal PE is the most common preventable cause of hospital death. A key to proper prophylaxis is the recognition of risk factors for thrombosis. Established clinical risk factors include: advanced age; prolonged immobility, stroke, or paralysis; prior VTE; active malignancy and its treatment; major surgery especially involving the abdomen, pelvis, and lower extremities; trauma, especially involving fracture of the pelvis, hip, or leg; obesity; varicose veins; depressed left ventricular ejection fraction; central venous access devices; inflammatory bowel disease; lobar pneumonia; nephrotic syndrome; pregnancy; estrogen use; and inherited and acquired hypercoagulable states. The number of risk factors, risk of DVT, risk of clinical PE, risk of fatal PE, and the required intensity of prophylactic therapy necessary to mitigate the risk all seem to increase in parallel. Medically ill patients (predominantly those immobilized with severe cardiopulmonary disease) have a 14.9% risk of developing DVT within 14 days of admission in the absence of active prophylaxis (MEDENOX). The DVT rate is reduced to 5.5% by the addition of a once-daily dose of LMWH (enoxaparin, 40 mg) without a significant increase in bleeding risk. Other studies have demonstrated equivalency between LMWH and heparin (5000 U tid) in medical patients with acute cardiac or pulmonary disease. Not all patients at risk will develop a thrombosis, and not all thromboses will result in symptoms, morbidity, or death. The benefit of pharmacologic thromboprophylaxis must always be weighed against the bleeding risk. Patients at high risk for bleeding should still receive prophylaxis in the form of intermittent pneumatic compression and/or thromboembolism-deterrence stockings.

**FURTHER READING**

CHANGING EPIDEMIOLOGY OF INFECTIOUS DISEASES  

With the advent of antimicrobial agents, some medical leaders believed that infectious diseases would soon be eliminated and become of historic interest only. Indeed, the hundreds of chemotherapeutic agents developed since World War II, most of which are potent and safe, include drugs effective not only against bacteria but also against viruses, fungi, and parasites. Nevertheless, we now realize that as we developed antimicrobial agents, microbes developed the ability to elude our best weapons and to counterattack with new survival strategies. Antibiotic resistance occurs at an alarming rate among all classes of mammalian pathogens. Pneumococci resistant to penicillin and enterococci resistant to vancomycin have become commonplace. Even Staphylococcus aureus that is resistant to vancomycin has appeared. Such pathogens present real clinical problems in managing infections that were easily treatable just a few years ago. Diseases once thought to have been nearly eradicated from the developed world—tuberculosis, cholera, and rickets—are now reemerging. For example—have rebounded with renewed ferocity. Newly discovered and emerging infectious agents appear to have been brought into contact with humans by changes in the environment and by movements of human and animal populations. An example of the propensity for pathogens to escape from their usual niche is the alarming 1999 outbreak in New York of an influenza strain that had never previously been isolated in the Americas. In 2003, severe acute respiratory syndrome (SARS) was first recognized. This emerging clinical entity is caused by a novel coronavirus that may have jumped from an animal niche to become a significant human pathogen. In early 2004, avian influenza spread rapidly through poultry farms in Asia and caused deaths in exposed humans, raising the specter of a new influenza pandemic.

Many infectious agents have been discovered only in recent decades (Fig. 104-1). Ebolavirus, human metapneumovirus, Anaplasma phagocytophila (the agent of human granulocytotropic ehrlichiosis), and retroviruses such as HIV humble us despite our deepening understanding of pathogenesis at the most basic molecular level. Even in developed countries, infectious diseases have made a resurgence. Between 1980 and 1996, mortality from infectious diseases in the United States increased by 64% to levels not seen since the 1940s.

The role of infectious agents in the etiology of diseases once believed to be noninfectious is being increasingly recognized. For example, it is now widely accepted that Helicobacter pylori is the causative agent of peptic ulcer disease and perhaps of gastric malignancy. Human papillomavirus is likely to be the most important cause of invasive cervical cancer. Human herpesvirus type 8 is believed to be the cause of most cases of Kaposi’s sarcoma. Epstein-Barr virus is a cause of certain lymphomas and may play a role in the genesis of Hodgkin’s disease. The possibility certainly exists that other diseases of unknown cause, such as rheumatoid arthritis, sarcoidosis, or inflammatory bowel disease, have infectious etiologies. There is even evidence that atherosclerosis may have an infectious component. In contrast, there are data to suggest that decreased exposures to pathogens in childhood may be contributing to an increase in the observed rate of allergic diseases.

Medical advances over infectious diseases have been hindered by changes in the patient population. Immunocompromised hosts now constitute a significant proportion of the seriously infected population. Physicians immunosuppress their patients to prevent the rejection of
transplants and to treat neoplastic and inflammatory diseases. Some infections, most notably that caused by HIV, immunocompromise the host in and of themselves. Lesser degrees of immunosuppression are associated with other infections, such as influenza and syphilis. Infectious agents that coexist peacefully with immunocompetent hosts wreak havoc in those who lack a complete immune system. AIDS has brought to prominence once-obscure organisms such as Pneumocystis, Cryptosporidium parvum, and Mycobacterium avium.

HOST FACTORS IN INFECTION For any infectious process to occur, the pathogen and the host must first encounter each other. Factors such as geography, environment, and behavior thus influence the likelihood of infection. Although the initial encounter between a susceptible host and a virulent organism frequently results in disease, some organisms can be harbored in the host for years before disease becomes clinically evident. For a complete view, individual patients must be considered in the context of the population to which they belong. Infectious diseases do not often occur in isolation; rather, they spread through a group exposed from a point source (e.g., a contaminated water supply) or from individual to individual (e.g., via respiratory droplets). Thus, the clinician must be alert to infections prevalent in the community as a whole. A detailed history, including information on travel, behavioral factors, exposures to animals or potentially contaminated environments, and living and occupational conditions, must be elicited. For example, the likelihood of infection by Plasmodium falciparum can be significantly affected by altitude, climate, terrain, season, and even time of day. Antibiotic-resistant strains are localized to specific geographic regions, and a seemingly minor alteration in a travel itinerary can dramatically influence the likelihood of acquiring chloroquine-resistant malaria. If such important details in the history are overlooked, inappropriate treatment may result in the death of the patient. Likewise, the chance of acquiring a sexually transmitted disease can be greatly affected by a relatively minor variation in sexual practices, such as the method used for birth control. Knowledge of the relationship between specific risk factors and disease allows the physician to influence a patient’s health even before the development of infection by modification of these risk factors and—when a vaccine is available—by immunization.

Many specific host factors influence the likelihood of acquiring an infectious disease. Age, immunization history, prior illnesses, level of nutrition, pregnancy, coexisting illness, and perhaps emotional state all have some impact on the risk of infection after exposure to a potential pathogen. The importance of individual host defense mechanisms, either specific or nonspecific, becomes apparent in their absence, and our understanding of these immune mechanisms is enhanced by studies of clinical syndromes developing in immunodeficient patients (Table 104-1). For example, the higher attack rate of meningococcal disease in people with deficiencies in specific complement proteins of the so-called membrane attack complex (see “Adaptive Immunity,” below) than in the general population underscores the importance of an intact complement system in the prevention of meningococcal infection.

Medical care itself increases the patient’s risk of acquiring an infection in several ways: (1) through contact with pathogens during hospitalization, (2) through breaching of the skin (with intravenous devices or surgical incisions) or mucosal surfaces (with endotracheal tubes or bladder catheters), (3) through introduction of foreign bodies, (4) through alteration of the natural flora with antibiotics, and (5) through treatment with immunosuppressive drugs.

Infection involves complicated interactions of parasite and host and inevitably affects both. In most cases, a pathogenic process consisting of several steps is required for the development of infections. Since the competent host has a complex series of barricades in place to prevent infection, a successful parasite must use specific strategies at each of these steps. The specific strategies used by bacteria, viruses, and parasites (Chap. 105) have some remarkable conceptual similarities, but the strategic details are unique not only for each class of organism but also for individual species within a class.

THE IMMUNE RESPONSE Innate Immunity As they have co-evolved with microbes, higher organisms have developed mechanisms for recognizing and responding to microorganisms. Many of these mechanisms, referred to together as innate immunity, are evolutionarily ancient, having been conserved from insects to humans (Fig. 104-2). In general, innate immune mechanisms exploit molecular patterns found specifically in pathogenic microorganisms. These “pathogen signatures” are recognized by host molecules that either directly interfere with the pathogen or initiate a response that does so. Innate immunity serves to protect the host without prior exposure to an infectious agent—i.e., before specific or adaptive immunity has had a chance to develop. Innate immunity also functions as a warning system that activates components of adaptive immunity early in the course of infection.

Examples of innate immune effectors include defensins, simple peptides found on the skin and mucosal surfaces with activity against bacteria, fungi, and viruses. Macrophages that engulf and kill microbes (and other cells with similar function) are found even in invertebrates, such as Drosophila. The complement system (described below and discussed in more detail in Chap. 295) can respond to microbes without prior exposure.

The response to lipopolysaccharide (LPS), a molecule found uniquely in gram-negative bacteria, is instructive in understanding innate immunity. Even minuscule amounts of LPS are detected by LPS-binding protein, CD14, and Toll-like receptor 4 (Fig. 104-2). The interaction of LPS with these components of the innate immune system prompts macrophages, via the transcriptional activator NFκB, to produce cytokines that lead to inflammation and enzymes that enhance the clearance of microbes. These initial responses serve not only to limit infection but also to initiate specific or adaptive immune responses.

Adaptive Immunity Once in the bloodstream or a normally sterile body site, the microorganism faces the host’s tightly integrated cellular and humoral immune systems. Cellular immunity (Chap. 295), comprising T lymphocytes, macrophages, and natural killer cells, primarily recognizes and combats pathogens that proliferate intracellularly. Cellular immune mechanisms are important in immunity to all classes of infectious agents, including most viruses and many bacteria (e.g., Mycoplasma, Chlamydia, Listeria, Salmonella, and Mycobacterium), parasites (e.g., Trypanosoma, Toxoplasma, and Leishmania), and fungi (e.g., Histoplasma, Cryptococcus, and Coccidioides). Usually, T lymphocytes are activated by macrophages and B lymphocytes, which present foreign antigens along with the host’s own major histocompatibility complex antigen to the T cell receptor. Activated T cells may then act in several ways to fight infection. Cytotoxic T cells may directly attack and lyse host cells that express foreign antigens. Helper T cells stimulate the proliferation of B cells and the production of immunoglobulins. B cells and T cells communicate with each other via a variety of signals; often, more than one signal is employed simultaneously. For example, costimulation through the CD40-CD40 ligand increases B cell responses, and costimulation via the B7-CD28 axis is required for activation of the CD4+ helper T cell. T cells elaborate cytokines (e.g., interferon) that directly inhibit the growth of pathogens or stimulate killing by host macrophages and cytotoxic cells. Cytokines also augment the host’s immunity by stimulating the inflammatory response (fever, the production of acute-phase serum components, and the proliferation of leukocytes). Cytokine stimulation does not always result in a favorable response in the host; septic shock (Chap. 254) and toxic shock syndrome (Chaps. 120 and 121) are among the conditions that are mediated by these inflammatory substances.

The reticuloendothelial system comprises monocyte-derived phagocytic cells that are located in the liver (Kupffer cells), lung (alveolar macrophages), spleen, kidney (mesangial cells), brain (microglia), and lymph nodes and that clear circulating microorganisms.

Although these tissue macrophages and polymorphonuclear leukocytes (PMNs) are capable of killing microorganisms without help, they function much more efficiently when pathogens are first opsonized (Greek, “to prepare for eating”) by components of the complement system such as C3b and/or by antibodies.

Extracellular pathogens, including most encapsulated bacteria (those surrounded by a complex polysaccharide coat), are attacked by the humoral immune system, which includes antibodies, the complement cascade, and phagocytic cells. Antibodies are complex glycoproteins (also called immunoglobulins) that are produced by mature B lymphocytes, circulate in body fluids, and are secreted on mucosal surfaces. Antibodies specifically recognize and bind to foreign antigens. One of the most impressive features of the immune system is the ability to generate an incredible diversity of antibodies capable of recognizing virtually every foreign antigen yet not reacting with self. In addition to being exquisitely specific for antigens, antibodies come in different structural and functional classes: IgG predominates in the circulation and persists for many years after exposure; IgM is the earliest specific antibody to appear in response to infection; secretary IgA is important in immunity at mucosal surfaces, while monomeric IgA appears in the serum; and IgE is important in allergic and parasitic diseases. Antibodies may directly impede the function of an invading organism, neutralize secreted toxins and enzymes, or facilitate the removal of the antigen (invading organism) by phagocytic cells. Immunoglobulins participate in cell-mediated immunity by promoting the antibody-dependent cellular cytotoxicity functions of certain T lymphocytes. Antibodies also promote the deposition of complement components on the surface of the invader.

The complement system (Chap. 295) consists of a group of serum proteins functioning as a cooperative, self-regulating cascade of enzymes that adhere to—and in some cases disrupt—the surface of invading organisms. Some of these surface-adherent proteins (e.g., C3b) can then act as opsonins for destruction of microbes by phagocytes. The latter, “terminal” components (C7, C8, and C9) can directly kill some bacterial invaders (notably, many of the neisseriae) by forming a membrane attack complex and disrupting the integrity of the bacterial membrane, thus causing bacteriolysis. Other complement components, such as C5a, act as chemotaxins for PMNs. Complement activation and deposition occur by either or both of two pathways: the classic pathway is activated primarily by immune complexes (i.e., antibody bound to antigen), and the alternative pathway is activated by microbial components, frequently in the absence of antibody. PMNs have receptors for both antibody and C3b, and antibody and complement function together to aid in the clearance of infectious agents.

PMNs, short-lived white blood cells that engulf and kill invading microbes, are first attracted to inflammatory sites by chemotaxins such as C5a, which is a product of complement activation at the site of infection. PMNs localize to the site of infection by adhering to cellular adhesion molecules expressed by endothelial cells. Endothelial cells express these selectins (CD62; ELAM-1), in response to inflammatory cytokines such as tumor necrosis factor (TNF) α and interleukin 1. The binding of these selectin molecules to specific receptors on PMNs results in the adherence of the PMNs to the endothelium. Cytokine-mediated upregulation and expression of intercellular adhesion molecule 1 (ICAM 1) on endothelial cells then take place, and this latter receptor binds to β integrins on PMNs, thereby facilitating diapedesis into the extravascular compartment. Once the PMNs are in the extravascular compartment, various molecules such as arachidonic acids further enhance the inflammatory process.

**Approach to the Patient**

The clinical manifestations of infectious diseases at presentation are myriad, varying from fulminant life-threatening processes to brief and self-limited conditions to indolent chronic maladies. The clinician must use all the skills of medicine to diagnose the infection and prescribe appropriate treatment. First, a careful history is essential and must include details on underlying chronic diseases; medications; occupation; travel; and risk factors for exposure to certain types of pathogens, such as those associated with sexual contacts, family illnesses, illicit drug use, particular animals, blood transfusions, ingestion of contaminated liquids or foods, or bites of insect vectors. Since infectious diseases may involve many organ systems, a careful review of systems may elicit important clues as to the disease process. The physical examination must be thorough, and attention must be paid to seemingly minor details: a soft heart murmur that might indicate bacterial endocarditis; an evanescent skin rash that suggests rheumatic fever; or a retinal lesion that suggests disseminated candidiasis or cytomegalovirus (CMV) infection.

**Laboratory Investigations**

Laboratory studies must be carefully considered and directed toward establishing an etiologic diagnosis in the shortest possible time, at the lowest possible cost, and with the least possible discomfort to the patient. Cultures must be performed in a manner that minimizes the likelihood of contamination with normal flora while maximizing the yield. A sputum sample is far more likely to be valuable when elicited with careful coaching by the clinician than when collected in a container simply left at the bedside with cursory instructions. Gram’s stains of specimens should be interpreted carefully and the quality of the specimen assessed. The findings on Gram’s staining should correspond to the results of culture; a discrepancy may suggest diagnostic possibilities such as infection due to fastidious or anaerobic bacteria.

The microbiology laboratory must be an ally in the diagnostic endeavor. Astute laboratory personnel will suggest optimal culture and transport conditions or alternative tests to facilitate diagnosis. If informed about specific potential pathogens, an alert laboratory staff will allow sufficient time for these organisms to become evident in culture, even when present in small numbers or when slow-growing. The parasitology technician who is attuned to the specific diagnostic considerations relevant to a particular case may be able to detect the rare, otherwise-elusive egg or cyst in a stool specimen. In cases where a
Optimal therapy for infectious diseases requires a broad knowledge of medicine and careful clinical judgment. Life-threatening infections such as bacterial meningitis or sepsis, viral encephalitis, or falciparum malaria must be treated immediately, often before a specific causative organism is identified. Antimicrobial agents must be chosen empirically and only be active against the range of potential infectious agents consistent with the clinical scenario. In contrast, good clinical judgment sometimes dictates withholding of antimicrobials in a self-limited process or until a specific diagnosis is made. The dictum *primum non nocere* should be adhered to, and it should be remembered that all antimicrobials carry a risk (and a cost) to the patient. Direct toxicity may be encountered—e.g., ototoxicity due to aminoglycosides, lipodystrophy due to antiretroviral agents, and hepatotoxicity due to antituberculous agents such as isoniazid and rifampin. Allergic reactions are common and can be serious. Since superinfection sometimes follows the eradication of the normal flora and colonization by a resistant organism, one invariable principle is that infectious disease therapy should be directed toward as narrow a spectrum of infectious agents as possible. Treatment specific for the pathogen should result in as little perturbation as possible of the host’s microflora. With few exceptions, abscesses require surgical or percutaneous drainage for cure. Foreign bodies, including medical devices, must generally be removed in order to eliminate an infection of the device or of the adjacent tissue. Other infections, such as necrotizing fasciitis, peritonitis due to a perforated organ, gas gangrene, and chronic osteomyelitis, require surgery as the primary means of cure; in these conditions, antibiotics play only an adjunctive role.

The role of immunomodulators in the management of infectious diseases has received increasing attention. Glucocorticoids have been shown to be of benefit in the treatment of *Haemophilus influenzae* meningitis in children and in therapy for *Pneumocystis* pneumonia in patients with AIDS. The use of these agents in other infectious processes remains less clear and in some cases (in cerebral malaria and septic shock, for example) is detrimental. Activated protein C is the first immunomodulatory agent widely available for the treatment of severe sepsis. Its usefulness demonstrates the interrelatedness of the clotting cascade and systemic immunity. Other agents that modulate the innate response include prostaglandin inhibitors, specific lymphotoxins, and TNF inhibitors. Specific antibody therapy plays a role in the treatment and prevention of many diseases. Specific immunoglobulins have long been known to prevent the development of symptomatic rabies and tetanus. More recently, CMV immune globulin has been recognized as important not only in preventing the transmission of the virus during organ transplantation but also in treating CMV pneumonia in bone marrow transplant recipients. There is a strong need for well-designed clinical trials to evaluate each new immunomodulatory modality.

**PERSPECTIVE** The genetic simplicity of many infectious agents allows them to undergo rapid evolution and to develop selective advantages that result in constant variation in the clinical manifestations of infection. Moreover, changes in the environment and the host can predispose new populations to a particular infection. The dramatic march of West Nile virus from a single focus in New York City in 1999 to locations across the North American continent by the summer of 2002 caused widespread alarm, illustrating the fear that new plagues induce in the human psyche. The intentional release of deadly spores of *Bacillus anthracis* awakened many from a sense of complacency regarding biological weapons.

“The terror of the unknown is seldom better displayed than by the response of a population to the appearance of an epidemic, particularly when the epidemic strikes without apparent cause.” Edward Kass made this statement in 1977 in reference to the newly discovered Legionnaire’s disease, but it could apply equally to SARS or to any other new and mysterious disease. The potential for infectious agents to emerge in novel and unexpected ways requires that physicians and public health officials be knowledgeable, vigilant, and open-minded in their approach to unexplained illness. The emergence of antimicrobial-resistant pathogens (e.g., enterococci that are resistant to all known antimicrobial agents and cause infections that are essentially untreatable) has led some to conclude that we are entering the “post-antibiotic era.” Others have held to the perception that infectious diseases no longer represent as serious a concern to world health as they once did. The progress that science, medicine, and society as a whole have made in combating these maladies is impressive, and it is ironic that, as we stand on the threshold of an understanding of the most basic biology of the microbe, infectious diseases are posing renewed problems. We are threatened by the appearance of new diseases such as AIDS, SARS, hepatitis C, and Ebola virus infection and by the reemergence of old foes such as tuberculosis, cholera, plague, and *Streptococcus pyogenes* infection. True students of infectious diseases were perhaps less surprised than anyone else by these developments. Those who know pathogens are aware of their incredible adaptability and diversity. As ingenious and successful as therapeutic approaches may be, our ability to develop methods to counter infectious agents so far has not matched the myriad strategies employed by the sea of microbes that surrounds us. Their sheer numbers and the rate at which they can evolve are daunting. Moreover, environmental changes, rapid global travel, population movements, and medicine itself—through its use of antibiotics and immunosuppressive agents—all increase the impact of infectious diseases. Although new vaccines, new antibiotics, improved global communication, and new modalities for treating and preventing infection will be developed, pathogenic microbes will continue to develop new strategies of their own, presenting us with an unending and dynamic challenge.

Over the past three decades, molecular studies of the pathogenesis of microorganisms have yielded an explosion of information about the various microbial and host molecules that contribute to the processes of infection and disease. These processes can be classified into several stages: microbial encounter with and entry into the host; microbial growth after entry; avoidance of innate host defenses; tissue invasion and tropism; tissue damage; and transmission to new hosts. Virulence is the measure of an organism’s capacity to cause disease and is a function of the pathogenic factors elaborated by microbes. These factors promote colonization (the simple presence of potentially pathogenic microbes in or on a host), infection (attachment and growth of pathogens and avoidance of host defenses), and disease (often, but not always, the result of activities of secreted toxins or toxic metabolites). In addition, the host’s inflammatory response to infection greatly contributes to disease and its attendant clinical signs and symptoms.

**MICROBIAL ENTRY AND ADHERENCE**

**ENTRY SITES** A microbial pathogen can potentially enter any part of a host organism. In general, the type of disease produced by a particular microbe is often a direct consequence of its route of entry into the body. The most common sites of entry are mucosal surfaces (the respiratory, alimentary, and urogenital tracts) and the skin. Ingestion, inhalation, and sexual contact are typical routes of microbial entry. Other portals of entry include sites of skin injury (cuts, bites, burns, trauma) along with injection via natural (i.e., vector-borne) or artificial (i.e., needle-stick injury) routes. A few pathogens, such as *Schistosoma* spp., can penetrate unbroken skin. The conjunctiva can serve as an entry point for pathogens of the eye.

Microbial entry usually relies on the presence of specific microbial factors needed for persistence and growth in a tissue. Fecal-oral spread via the alimentary tract requires a biology consistent with survival in the varied environments of the gastrointestinal tract (including the low pH of the stomach and the high bile content of the intestine) as well as in contaminated food or water outside the host. Organisms that gain entry via the respiratory tract survive well in small moist droplets produced during sneezing and coughing. Pathogens that enter by venereal routes often survive best on the warm moist environment of the urogenital mucosa and have restricted host ranges (e.g., *Neisseria gonorrhoeae*, *Treponema pallidum*, and HIV).

The biology of microbes entering through the skin is highly varied. Some of these organisms can survive in a broad range of environments, such as the salivary glands or alimentary tracts of arthropod vectors, the mouths of larger animals, soil, and water. A complex biology allows protozoan parasites such as *Plasmodium*, *Leishmania*, and *Trypanosoma* spp. to undergo morphogenic changes that permit transmission of the organism to mammalian hosts during insect feeding for blood meals. Plasmodia are injected as infective sporozoites from the salivary glands during mosquito feeding. *Leishmania* parasites are regenerated as promastigotes from the alimentary tract of sandflies and injected by bite into a susceptible host. Trypanosomes are first ingested from infected hosts by reduviid bugs; the pathogens then multiply in the gastrointestinal tract of the insects and are released in feces onto the host’s skin during subsequent feedings. Most microbes that land directly on intact skin are destined to die, as survival on the skin or in hair follicles requires resistance to fatty acids, low pH, and other antimicrobial factors on skin. Once it is damaged (and particularly if it becomes necrotic), the skin can be a major portal of entry and growth for pathogens or their toxic products. Tetanus and burn wound infections are clear examples. After animal bites, pathogens resident in the animal’s saliva gain access to the victim’s tissues through the skin. Rabies is the paradigm for this pathogenic process; rabies virus grows in striated muscle cells at the site of inoculation.

**MICROBIAL ADHERENCE** Once in or on a host, most microbes must anchor themselves to a tissue or tissue factor; the possible exceptions are organisms that directly enter the bloodstream and multiply there. Specific ligands or adhesins for host receptors constitute a major area of study in the field of microbial pathogenesis. Adhesins comprise a wide range of surface structures, not only anchoring the microbe to a tissue and promoting cellular entry where appropriate but also eliciting host responses critical to the pathogenic process (Table 105-1). Most microbes produce multiple adhesins specific for multiple host receptors. These adhesins are often redundant, are serologically variable, and act additively or synergistically with other microbial factors to promote microbial sticking to host tissues. In addition, some microbes adsorb host proteins onto their surface and utilize the natural host protein receptor for microbial binding and entry into target cells.
**Viral Adhesins** All viral pathogens must bind to host cells, enter them, and replicate within them. Viral coat proteins serve as the ligands for cellular entry, and more than one ligand-receptor interaction may be needed; for example, HIV utilizes its envelope glycoprotein (gp) 120 to enter host cells by binding to both CD4 and one of two receptors for chemokines (designated CCR5 and CXCR4). Similarly, the measles virus H glycoprotein binds to both CD46 and the membrane-organizing protein moesin on host cells. The gC protein on herpes simplex virus binds to heparin sulfate; this step is followed by attachment to mammalian cells mediated by the viral gD (and possibly gH) protein. CD46 has now been shown to be the cellular receptor for human herpesvirus type 6.

**Bacterial Adhesins** Among the microbial adhesins studied in greatest detail are bacterial pili and flagella (Fig. 105-1). Pili of *E. coli* and *Pseudomonas aeruginosa* are commonly used by gram-negative bacteria for attachment to host cells and tissues. In electron micrographs, these hairlike projections (up to several hundred per cell) may be confined to one end of the organism (polar pili) or distributed more evenly over the surface. An individual cell may have pili with a variety of functions. Most pili are made up of a major pilin protein subunit (molecular weight, 17,000 to 30,000) that polymerizes to form the pilus. Many strains of *Escherichia coli* express mannose-binding type 1 pili, whose binding to host tissues is inhibited by D-mannose. Other strains produce the Pap (pyelonephritis-associated) or P pilus adhesin that mediates binding to digalactose (gal-gal) residues on globosides of the human P blood groups. These pili have proteins located at the tips of the main pilus unit that are critical to the binding specificity of the whole pilus unit. Immunization with the mannose-binding FimH tip protein of type 1 pili prevents experimental *E. coli* bladder infections in mice and monkeys. *E. coli* cells causing diarrheal disease express pilius-like receptors for enterocytes on the small bowel, along with other receptors termed colonization factors.

**Fungal Adhesins** Several fungal adhesins have been described that mediate colonization of epithelial surfaces, particularly adherence to structures like fibronectin, laminin, and collagen. Fibronectin appears to be a commonly used receptor for various pathogens; a particular amino acid sequence in fibronectin, Arg-Gly-Asp or RGD, is critical for bacterial binding. The surface lipopolysaccharide (LPS) of *P. aeruginosa* mediates binding to the cystic fibrosis transmembrane conductance regulator (CFTR) on airway epithelial cells. Coagulase-negative staphylococci and *Staphylococcus aureus* readily colonize prosthetic devices and cathers commonly used in medical care; a surface polysaccharide composed of poly-N-acetyl glucosamine elaborated by these organisms promotes binding to the prosthetic material. High-powered imaging techniques such as atomic force microscopy have revealed that bacterial cells have a nonhomogeneous surface that is likely attributable to different concentrations of cell surface molecules, including microbial adhesins, at specific places on the cell surface (Fig. 105-1D).

**Eukaryotic Pathogen Adhesins** Eukaryotic parasites use complicated surface glycoproteins as adhesins, some of which are lectins (proteins that bind to carbohydrates) orpattern recognition receptors (PRR) such as Toll-like receptors (TLR). For example, members of the *Trypanosoma* and *Leishmania* genera have surface glycoproteins that mediate binding to integrins on host cells, facilitating invasion of host tissues. Some parasites use epithelial cells as a source of nutrients and energy; this process is mediated by adhesins that recognize host cell receptors. For example, the zymosan-binding protein (ZBP) of *Candida albicans* binds to CD11b/CD18 in neutrophils, promoting phagocytosis. In contrast, the lectin-like protein of *Yersinia* mediates adherence to host cells by binding to the carbohydrate ligands on the surface of the bacterial pathogen. These lectins are typically found on the surface of pathogenic microorganisms and are involved in the binding of the organism to host cells. The binding of these lectins to host cell carbohydrate receptors facilitates the internalization of the pathogen into the host cell and allows the pathogen to establish a foothold within the host body. This process is critical for the survival and dissemination of the pathogen, allowing it to evade the immune system and spread to other areas of the body. The understanding of the molecular mechanisms of adhesin binding is crucial for the development of effective vaccines and therapeutic strategies to combat infectious diseases.
bind to specific carbohydrates on host cells). For example, *Plasmodium vivax*, one of four *Plasmodium* species causing malaria, binds (via Duffy-binding protein) to the Duffy blood group carbohydrate antigen Fy on erythrocytes. *Entamoeba histolytica*, the third leading cause of death from parasitic diseases, expresses two proteins that bind to the disaccharide galactose/N-acetyl-galactosamine. Reports indicate that children with mucosal IgA antibody to one of these lectins are resistant to reinfection with virulent *E. histolytica*. A major surface glycoprotein (gp63) of *Leishmania* promastigotes is needed for these parasites to enter human macrophages—the principal target cell of infection. This glycoprotein promotes complement binding but inhibits complement lytic activity, allowing the parasite to use complement receptors for entry into macrophages; gp63 also binds to fibronectin receptors on macrophages. In addition, the pathogen can express a carbohydrate that mediates binding to host cells. Evidence suggests that, as part of hepatic granuloma formation, *Schistosoma mansoni* expresses a carbohydrate epitope related to the Lewis X blood group antigen that promotes adherence of helminthic eggs to vascular endothelial cells under inflammatory conditions.

**HOST RECEPTORS** Host receptors are found both on target cells (such as epithelial cells lining mucosal surfaces) and within the mucus layer covering these cells. Microbial pathogens bind to a wide range of host receptors to establish infection (Table 105-1). Selective loss of host receptors for a pathogen may confer natural resistance to an otherwise susceptible population. For example, 70% of individuals in West Africa lack Fy antigens and are resistant to *P. vivax* infection. *Salmonella typhi*, the etiologic agent of typhoid fever, uses CFTR to enter the gastrointestinal submucosa after being ingested. As homozymous mutations in CFTR are the cause of the life-shortening disease cystic fibrosis, heterozygote carriers (e.g., 4 to 5% of individuals of European ancestry) may have had a selective advantage due to decreased susceptibility to *S. typhi* infection.

Numerous virus–target cell interactions have been described, and it is now clear that different viruses can use similar host cell receptors for entry. The list of certain and likely host receptors for viral pathogens is long. Among the host membrane components that can serve as receptors for viruses are sialic acids, gangliosides, glycosaminoglycans, integrins and other members of the immunoglobulin superfamily, histocompatibility antigens, and regulators and receptors for complement components.

**MICROBIAL GROWTH AFTER ENTRY** Once established on a mucosal or skin site, pathogenic microbes must replicate before causing full-blown infection and disease. Within cells, viral particles release their nucleic acids, which may be directly translated into viral proteins (positive-strand RNA viruses), transcribed from a negative strand of RNA into a complementary mRNA (negative-strand RNA viruses), or transcribed into a complementary strand of DNA (retroviruses); for DNA viruses, mRNA may be transcribed directly from viral DNA, either in the cell nucleus or in the cytoplasm. To grow, bacteria must acquire specific nutrients or synthesize them from precursors in host tissues. Many infectious processes are usually confined to specific epithelial surfaces—influenza to the respiratory mucosa, gonorrhea to the urogenital epithelium, shigellosis to the gastrointestinal epithelium. While there are multiple reasons for this specificity, one important consideration is the ability of these pathogens to obtain from these specific environments the nutrients needed for growth and survival.

Temperature restrictions also play a role in limiting certain pathogens to specific tissues. Rhinoviruses, a cause of the common cold, grow best at 33°C and replicate in cooler nasal tissues but not in the lung. Leprosy lesions due to *Mycobacterium leprae* are found in and on relatively cool body sites. Fungal pathogens that infect the skin, hair follicles, and nails (dermatophyte infections) remain confined to the cooler, exterior, keratinous layer of the epithelium.

A topic of major interest is the ability of many bacterial, fungal, and protozoal species to grow in multicellular masses referred to as biofilms. These masses are biochemically and morphologically quite distinct from the free-living individual cells referred to as planktonic cells. Growth in biofilms leads to altered microbial metabolism, production of extracellular virulence factors, and decreased susceptibility to biocides, antimicrobial agents, and host defense molecules and cells. *P. aeruginosa* growing on the bronchial mucosa during chronic infection, staphylococci and other pathogens growing on implanted medical devices, and dental pathogens growing on tooth surfaces to form plaques represent several examples of microbial biofilm growth associated with human disease. Many other pathogens can form biofilms during in vitro growth, but the data are insufficient to determine whether this property is related to microbial virulence and induction of disease.

**AVOIDANCE OF INNATE HOST DEFENSES** As microbes have probably interacted with mucosal/epithelial surfaces since the emergence of multicellular organisms, it is not surprising that multicellular hosts have a variety of innate surface defense mechanisms that can sense when pathogens are present and contribute to their elimination. The skin is acidic and is bathed with fatty acids toxic to many microbes. Successful skin pathogens such as staphylococci must tolerate these adverse conditions. Mucosal surfaces are covered by a barrier composed of a thick mucus layer that entraps microbes and facilitates their transport out of the body by such processes as mucociliary clearance, coughing, and urination. Mucous secretions, saliva, and tears contain antibacterial factors such as lysozyme and antimicrobial peptides as well as antiviral factors such as interferons. Gastric acidity is inimical to the survival of many ingested pathogens, and many mucosal surfaces—particularly the nasopharynx, the vaginal tract, and the gastrointestinal tract—contain a resident flora of commensal microbes that interfere with the ability of pathogens to colonize and infect a host.

Pathogens that survive these factors must still contend with host endocytic, phagocytic, and inflammatory responses as well as with host genetic factors that determine the degree to which a pathogen can survive and grow. The growth of viral pathogens entering skin or mucosal epithelial cells can be limited by a variety of host genetic factors, including production of interferons, modulation of receptors for viral entry, and age- and hormone-related susceptibility factors; by nutritional status; and even by personal habits such as smoking and exercise.

**ENCOUNTERS WITH EPITHELIAL CELLS** Over the past decade, many bacterial pathogens have been shown to enter epithelial cells (Fig. 105-2); the bacteria often use specialized surface structures that bind to receptors, with consequent internalization. However, the exact role and the importance of this process in infection and disease are not well defined for most of these pathogens. Bacterial entry into host epithelial cells is seen as a means for dissemination to adjacent or deeper tissues or as a route to sanctuary to avoid ingestion and killing by professional phagocytes. Epithelial cell entry appears, for instance, to be a critical aspect of dysentery induction by *Shigella*.

Curiously, the less virulent strains of many bacterial pathogens are more adept at entering epithelial cells than are more virulent strains; examples include pathogens that lack the surface polysaccharide capsule needed to cause serious disease. Thus, *for Haemophilus influenzae*, *Streptococcus pneumoniae*, *Streptococcus agalactiae* (group B *Streptococcus*), and *Streptococcus pyogenes*, isogenic mutants or variants lacking capsules enter epithelial cells better than the wild-type, encapsulated parental forms that cause disseminated disease. These observations have led to the proposal that epithelial cell entry may be a manifestation of host defense, resulting in bacterial clearance by both shedding of epithelial cells containing internalized bacteria and initiation of a subclinical inflammatory response. However, a consequence of this process would be the opening of a hole in the epithelium, potentially allowing uningested organisms to enter the submucosa.
Entry of P. aeruginosa membrane conductance regulator (CFTR), the cell receptor for bacterial ingestion. Cystic fibrosis patients are extremely susceptible of the patient to chronic airway infection. P. aeruginosa failure of airway epithelial cell to ingest and promote the removal with clinical consequence of this disease is chronic airway-surface infection or nonfunctional in most severe cases of cystic fibrosis. The major clinical consequence of this disease is chronic airway-surface infection with P. aeruginosa in 80 to 90% of patients with cystic fibrosis. The failure of airway epithelial cells to ingest and promote the removal of P. aeruginosa has been proposed as a key component of the hyper-susceptibility of these patients to chronic airway infection.

This scenario has been documented in murine Salmonella typhimurium infections and in experimental bladder infections with uropathogenic E. coli. In the latter system, bacterial pili mediate cell attachment to integral membrane glycoproteins called uropelakins that coat the host cells, resulting in exfoliation of the cells with attached bacteria. Subsequently, infection is produced by residual bacterial cells that invade the denuded epithelium. Perhaps at low bacterial inocula epithelial cell ingestion and subclinical inflammation are efficient means to eliminate pathogens, while at higher inocula a proportion of surviving bacterial cells enter the host tissue through the damaged mucosal surface and multiply, producing disease. Alternatively, failure of the appropriate epithelial cell response to a pathogen may allow the organism to survive on a mucosal surface where, if it avoids other host defenses, it can grow and cause a local infection. Along these lines, as noted above, P. aeruginosa is taken into epithelial cells by CFTR, a protein missing or nonfunctional in most severe cases of cystic fibrosis. The major clinical consequence of this disease is chronic airway-surface infection with P. aeruginosa in 80 to 90% of patients with cystic fibrosis. The failure of airway epithelial cells to ingest and promote the removal of P. aeruginosa has been proposed as a key component of the hyper-susceptibility of these patients to chronic airway infection.

**ENCOUNTERS WITH PHAGOCYTES**

Phagocytosis of microbes is a major innate host defense that limits the growth and spread of pathogens. Phagocytes appear rapidly at sites of infection in conjunction with the initiation of inflammation. Ingestion of microbes by both tissue-fixed macrophages and migrating phagocytes probably accounts for the limited ability of most microbial agents to cause disease. A family of related molecules called collectins, soluble defense collagens, or pattern-recognition molecules are found in blood (mannose-binding lectins), in lung (surfactant proteins A and D), and most likely in other tissues as well and bind to carbohydrates on microbial surfaces to promote phagocyte clearance. Bacterial pathogens seem to be ingested principally by polymorphonuclear neutrophils (PMNs), while eosinophils are frequently found at sites of infection by protozoan or multicellular parasites. Successful pathogens, by definition, must avoid being cleared by professional phagocytes. One of several antiphagocytic strategies employed by bacteria and by the fungal pathogen Cryptococcus neoformans is to elaborate large-molecular-weight surface polysaccharide antigens, often in the form of a capsule that coats the cell surface. Most pathogenic bacteria produce such antiphagocytic capsules.

As activation of local phagocytes in tissues is a key step in initiating inflammation and migration of additional phagocytes into infected sites, much attention has been paid to microbial factors that initiate inflammation. Encounters with phagocytes are governed largely by the structure of the microbial constituents that elicit inflammation, and detailed knowledge of these structures for bacterial pathogens has contributed greatly to our understanding of molecular mechanisms of microbial pathogenesis (Fig. 105-3). One of the best-studied systems involves the interaction of LPS from gram-negative bacteria and the glycosylphosphatidylinositol (GPI)-anchored membrane protein CD14 found on the surface of professional phagocytes, including migrating and tissue-fixed macrophages and PMNs. A soluble form of CD14 is also found in plasma and on mucosal surfaces. A plasma protein, LPS-binding protein (LBP), transfers LPS to membrane-bound CD14 on myeloid cells and promotes binding of LPS to soluble CD14. Soluble CD14/LPS/LBP complexes bind to many cell types and may be internalized to initiate cellular responses to microbial pathogens. It has been shown that peptidoglycan and lipoteichoic acid from gram-positive bacteria and cell-surface products of mycobacteria and spirochetes can interact with CD14 (Fig. 105-3).

GPI-anchored receptors do not have intracellular signaling domains, and mammalian Toll-like receptors (TLRs) transduce signals for cellular activation due to LPS binding. TLRs initiate cellular activation through a series of signal-transducing molecules (Fig. 105-3) that lead to nuclear translocation of the transcription factor NF-κB, a master-switch for production of important inflammatory cytokines such as tumor necrosis factor α (TNF-α) and interleukin (IL) 1.

The initiation of inflammation can occur not only with LPS and peptidoglycan but also with viral particles and other microbial products such as polysaccharides, enzymes, and toxins. Bacterial flagella activate inflammation by binding to TLR5. Bacteria also produce a high proportion of DNA molecules with unmethylated CpG residues that activate inflammation through TLR9. TLR3 recognizes double-stranded RNA, a pattern-recognition molecule produced by many viruses during their replicative cycle. TLR1 and TLR6 associate with TLR2 to promote recognition of acylated microbial proteins and peptides.

The myeloid differentiation factor 88 (MyD88) molecule is a generalized adaptor protein that binds to the cytoplasmic domains of all known TLRs and also to receptors that are part of the IL-1 receptor (IL-1Rc) family. Numerous studies have shown that MyD88-mediated transduction of signals from TLRs and IL-1Rc is critical for innate resistance to infection. Mice lacking MyD88 are more susceptible than normal mice to infection with group B Streptococcus, Listeria monocytogenes, and Mycobacterium tuberculosis.

**Additional Interactions of Microbial Pathogens and Phagocytes**

Other ways that microbial pathogens avoid destruction by phagocytes include production of factors that are toxic to the phagocytes or that interfere with the chemotactic and ingestion function of phagocytes. Hemolysins,
leukocidins, and the like are microbial proteins that can kill phagocytes that are attempting to ingest organisms elaborating these substances. For example, staphylococcal hemolysins inhibit macrophage chemotaxis and kill these phagocytes. Streptolysin O made by S. pyogenes binds to cholesterol in phagocyte membranes and initiates a process of internal degranulation, with the release of normally granule-sequestered toxic components into the phagocyte’s cytoplasm. Entamoeba histolytica, an intestinal protozoan that causes amebic dysentery, can disrupt phagocyte membranes after direct contact via the release of protozoal phospholipase A and pore-forming peptides.

**Microbial Survival Inside Phagocytes**

Many important microbial pathogens use a variety of strategies to survive inside phagocytes (particularly macrophages) after ingestion. Inhibition of fusion of the phagocytic vacuole (the phagosome) containing the ingested microbe with the lysosomal granules containing antimicrobial substances (the lysosome) allows *M. tuberculosis*, *S. typhi*, and *Toxoplasma gondii* to survive inside macrophages. Some organisms, such as *L. monocytogenes*, escape into the phagocyte’s cytoplasm to grow and eventually spread to other cells. Resistance to killing within the macrophage and subsequent growth are critical to successful infection by herpes-type viruses, measles virus, poxviruses, *Salmonella*, *Yersinia*, *Legionella*, *Mycobacterium*, *Trypanosoma*, *Nocardia*, *Histoplasma*, *Toxoplasma*, and *Rickettsia*. *Salmonella* spp. use a master regulatory system, in which the *PhoP*/PhoQ* genes control other genes, to enter and survive within cells, with intracellular survival entailing structural changes in the cell envelope LPS.

**TISSUE INVASION AND TISSUE TROPISM**

**TISSUE INVASION**

Most viral pathogens cause disease by growth at skin or mucosal entry sites, but some pathogens spread from the initial site to deeper tissues. Virus can spread via the nerves (rabies virus) or plasma (picornaviruses) or within migratory blood cells (poliovirus, Epstein-Barr virus, and many others). Specific viral genes determine where and how individual viral strains can spread.

Bacteria may invade deeper layers of mucosal tissue via intracellular uptake by epithelial cells, traversal of epithelial cell junctions, or penetration through denuded epithelial surfaces. Among virulent *Shigella* strains and invasive *E. coli*, outer-membrane proteins are critical to epithelial cell invasion and bacterial multiplication. *Neisseria* and *Hansenophilus* spp. penetrate mucosal cells by poorly understood mechanisms before dissemination into the bloodstream. Staphylococci and streptococci elaborate a variety of extracellular enzymes, such as hyaluronidase, lipases, nucleases, and hemolysins, that are probably important in breaking down cellular and matrix structures and allowing the bacteria access to deeper tissues and blood. Organisms that colonize the gastrointestinal tract can often translocate through the mucosa into the blood and, under circumstances in which host defenses are inadequate, cause bacteremia. *Yersinia enterocolitica* can invade the mucosa through the activity of the invasin protein. Some bacteria (e.g., *Brucella*) can be carried from a mucosal site to a distant site by phagocytic cells (e.g., PMNs) that ingest but fail to kill the bacteria.

Fungal pathogens almost always take advantage of host immunocompromise to spread hematogenously to deeper tissues. The AIDS epidemic has resoundingly illustrated this principle: the immunodeficiency of many HIV-infected patients permits the development of life-threatening fungal infections of the lung, blood, and brain. Other than the capsule of *C. neoformans*, specific fungal antigens involved in tissue invasion are not well characterized. Both fungal pathogens and protozoal pathogens (e.g., *Plasmodium* spp. and *E. histolytica*) undergo morphologic changes to spread within a host. Malarial parasites grow in liver cells as merozoites and are released into the blood to invade erythrocytes and become trophozoites. *E. histolytica* is found as both a cyst and a trophozoite in the intestinal lumen, through which this pathogen enters the host, but only the trophozoite form can spread systemically to cause amebic liver abscesses. Other protozoal pathogens, such as *T. gondii*, *Giardia lamblia*, and *Cryptosporidium*, also undergo extensive morphologic changes after initial infection to spread to other tissues.

**TISSUE TROPISM**

The propensity of certain microbes to cause disease by infecting specific tissues has been known since the early days of bacteriology, yet the molecular basis for this propensity is understood somewhat better for viral pathogens than for other agents of infectious disease. Specific receptor-ligand interactions clearly underlie the ability of certain viruses to enter cells within tissues and disrupt normal tissue function, but the mere presence of a receptor for a virus on a target tissue is not sufficient for tissue tropism. Factors in the cell, route of viral entry, viral capacity to penetrate into cells, viral genetic elements that regulate gene expression, and pathways of viral spread in a tissue all affect tissue tropism. Some viral genes are best transcribed in specific target cells, such as hepatitis B genes in liver cells and Epstein-Barr virus genes in B lymphocytes. The route of inoculation of poliovirus determines its neuropotropism, although the molecular basis for this circumstance is not understood.
The lesser understanding of the tissue tropism of bacterial and parasitic infections is exemplified by Neisseria spp. There is no well-accepted explanation of why N. gonorrhoeae colonizes and infects the human genital tract while the closely related species N. meningitidis principally colonizes the human oropharynx. N. meningitidis expresses a capsular polysaccharide, while N. gonorrhoeae does not; however, there is no indication that this property plays a role in the different tissue tropisms displayed by these two bacterial species. N. gonorrhoeae can use cytidine monophosphate N-acetylneuraminic acid from host tissues to add N-acetylneuraminic acid (sialic acid) to its lipooligosaccharide (LOS) O side chain, and this alteration appears to make the organism resistant to host defenses. Lactate, present at high levels on genital mucosal surfaces, stimulates sialylation of gonococcal LOS. Bacteria with sialic acid sugars in their capsules, such as N. meningitidis, E. coli K1, and group B streptococci, have a propensity to cause meningitis, but this generalization has many exceptions. For example, all recognized serotypes of group B streptococci contain sialic acid in their capsules, but only one serotype (III) is responsible for most cases of group B streptococcal meningitis. Moreover, both H. influenzae and S. pneumoniae can readily cause meningitis, but these organisms do not have sialic acid in their capsules.

Tissue Damage and Disease

Disease is a complex phenomenon resulting from tissue invasion and destruction, toxin elaboration, and host response. Viruses cause much of their damage by exerting a cytopathic effect on host cells and inhibiting host defenses. The growth of bacterial, fungal, and protozoal parasites in tissue, which may or may not be accompanied by toxin elaboration, can also compromise tissue function and lead to disease. For some bacterial and possibly some fungal pathogens, toxin production is one of the best-characterized molecular mechanisms of pathogenesis, while host factors such as IL-1, TNF-α, kinins, inflammatory proteins, products of complement activation, and mediators derived from arachidonic acid metabolites (leukotrienes) and cellular degranulation (histamines) readily contribute to the severity of disease.

Viral Disease

Viral pathogens are well known to inhibit host immune responses by a variety of mechanisms. Immune responses can be affected by downregulating production of most major histocompatibility complex (MHC) molecules (adenovirus E3 protein), by diminishing cytotoxic T-cell recognition of virus-infected cells (Epstein-Barr virus EBNA1 antigen and cytomegalovirus IE protein), by producing virus-encoded complement receptor proteins that protect infected cells from complement-mediated lysis (herpesvirus and vaccinia virus), by making proteins that interfere with the action of interferon (influenza virus and poxvirus), and by elaborating superantigen-like proteins (mouse mammary tumor virus and related retroviruses, rabies nucleocapsid, and possibly the Nef protein of HIV). Superantigens activate large populations of T cells that express particular subsets of the T cell receptor β protein, causing massive cytokine release and subsequent host reactions. Another molecular mechanism of viral virulence involves the production of peptide growth factors for host cells, which disrupt normal cellular growth, proliferation, and differentiation. In addition, viral factors can bind to and interfere with the functions of host receptors for signaling molecules. Modulation of cytokine production during viral infection can stimulate viral growth inside cells with receptors for the cytokine, and virus-encoded cytokine homologues (e.g., the Epstein-Barr virus BCRF1 protein, which is highly homologous to the immunoinhibitory IL-10 molecule) can potentially prevent immune-mediated clearance of viral particles. Viruses can cause disease in neural cells by interfering with levels of neurotransmitters without necessarily destroying the cells, or they may induce either programmed cell death (apoptosis) to destroy tissues or inhibitors of apoptosis to allow for prolonged viral infection of cells. Overall, any disruption of normal cellular and tissue function due to viral infection can underlie the resultant clinical disease.

Bacterial Toxins

Among the first infectious diseases to be understood were those due to toxin-elaborating bacteria. Diphtheria, botulism, and tetanus toxins are responsible for the diseases associated with local infections due to Corynebacterium diphtheriae, Clostridium botulinum, and Clostridium tetani, respectively. Enterotoxins produced by E. coli, Salmonella, Shigella, Staphylococcus, and V. cholerae contribute to diarrheal disease caused by these organisms. Staphylococci, streptococci, P. aeruginosa, and Bordetella elaborate various toxins that cause or contribute to disease, including toxic shock syndrome toxin 1 (TSST-1), erythrogenic toxin; exotoxins A, S, and U; and pertussis toxin. A number of these toxins (e.g., chola toxin, diphtheria toxin, pertussis toxin, E. coli heat-labile toxin, and P. aeruginosa exotoxin) have adenine diphosphate (ADP)-ribose transferase activity, i.e., they catalyze the transfer of the ADP-ribose portion of nicotinamide adenine dinucleotide to target proteins and inactivate them. The staphylococcal enterotoxins, TSST-1, and the streptococcal pyogenic exotoxins behave as superantigens, stimulating certain T cells to proliferate without processing of the protein toxin by antigen-presenting cells. Part of this process involves stimulation of the antigen-presenting cells to produce IL-1 and TNF-α, which have been implicated in many of the clinical features of diseases like toxic shock syndrome and scarlet fever. A number of gram-negative pathogens (Salmonella, Yersinia, and P. aeruginosa) can inject toxins directly into host target cells by means of a complex set of proteins referred to as the type III secretion system. Loss or inactivation of this virulence system usually greatly reduces the capacity of a bacterial pathogen to cause disease.

Endotoxin

The lipid A portion of gram-negative LPS has potent biologic activities that cause many of the clinical manifestations of gram-negative bacterial sepsis, including fever, muscle proteolysis, uncontrolled intravascular coagulation, and shock. The effects of lipid A appear to be mediated by the production of potent cytokines due to LPS binding to CD14 and signal transduction via TLRs, particularly TLR4. Cytokines exhibit potent hypothermic activity through effects on the hypothalamus; they also increase vascular permeability, alter the activity of endothelial cells, and induce endothelial-cell procoagulant activity. Numerous therapeutic strategies aimed at neutralizing the effects of endotoxin are under investigation, but so far the results have been disappointing.

Invasion

Many diseases are caused primarily by pathogens growing in tissue sites that are normally sterile. Pneumococcal pneumonia is mostly attributable to the growth of S. pneumoniae in the lung and the attendant host inflammatory response, although specific factors that enhance this process (e.g., pneumolysin) may be responsible for some of the pathogenic potential of the pneumococcus. Disease that follows bacteremia and invasion of the meninges by meningitis-producing bacteria such as N. meningitidis, H. influenzae, E. coli K1, and group B streptococci appears to be due solely to the ability of these organisms to gain access to these tissues, multiply in them, and provoke cytokine production leading to tissue-damaging host inflammation.

Specific molecular mechanisms accounting for tissue invasion by fungal and protozoal pathogens are less well described. Except for studies pointing to factors like capsule and melanin production by C. neoformans and possibly levels of cell wall glucans in some pathogenic fungi, the molecular basis for fungal invasiveness is not well defined. Melanin has been shown to protect the fungal cell against death caused by phagocyte factors such as nitric oxide, superoxide, and hypochlorite. Morphogenic variation and production of proteases (e.g., the Candida asparyl proteinase) have been implicated in fungal invasion of host tissues.

If pathogens are effectively to invade host tissues (particularly the blood), they must avoid the major host defenses represented by complement and phagocytic cells. Bacteria most often avoid these defenses through their cell surface polysaccharides—either capsular polysaccharides or long O-side-chain antigens characteristic of the smooth LPS of gram-negative bacteria. These molecules can prevent the activation and/or deposition of complement opsonins or limit the access
of phagocytic cells with receptors for complement opsonins to these molecules when they are deposited on the bacterial surface below the capsular layer. Another potential mechanism of microbial virulence is the ability of some organisms to present the capsule as an apparent self antigen through molecular mimicry. For example, the polysialic acid capsule of group B N. meningitidis is chemically identical to an oligosaccharide found on human brain cells.

Immunochemical studies of capsular polysaccharides have led to an appreciation of the tremendous chemical diversity that can result from the linking of a few monosaccharides. For example, three hexoses can link up in more than 300 different, potentially serologically distinct ways, while three amino acids have only six possible peptide combinations. Capsular polysaccharides have been used as effective vaccines against meningococcal meningitis as well as against pneumococcal and H. influenzae infections and may prove to be of value as vaccines against any organisms that express a nontoxic, immunogenic capsular polysaccharide. In addition, most encapsulated pathogens become virtually avirulent when capsule production is interrupted by genetic manipulation; this observation emphasizes the importance of this structure in pathogenesis.

HOST RESPONSE. The inflammatory response of the host is critical for interruption and resolution of the infectious process but also is often responsible for the signs and symptoms of disease. Infection promotes a complex series of host responses involving the complement, kinin, and coagulation pathways. The production of cytokines such as IL-1, TNF-α, and other factors regulated in part by the NF-κB transcription factor leads to fever, muscle proteolysis, and other effects, as noted above. An inability to kill or contain the microbe usually results in further damage due to the progression of inflammation and infection. For example, in many chronic infections, degranulation of host inflammatory cells can lead to release of host proteases, elastases, histammines, and other toxic substances that can degrade host tissues. Chronic inflammation in any tissue can lead to the destruction of that tissue and to clinical disease associated with loss of organ function, such as sterility from pelvic inflammatory disease caused by chronic infection with N. gonorrhoeae.

The nature of the host response elicited by the pathogen often determines the pathology of a particular infection. Local inflammation produces local tissue damage, while systemic inflammation, such as that seen during sepsis, can result in the signs and symptoms of septic shock. The severity of septic shock is associated with the degree of production of host effectors. Disease due to intracellular parasitism results from the formation of granulomas, wherein the host attempts to wall off the parasite inside a fibrotic lesion surrounded by fused epithelial cells that make up so-called multinucleated giant cells. A number of pathogens, particularly anaerobic bacteria, staphylococci, and streptococci, provoke the formation of an abscess, probably because of the presence of zwitterionic surface polysaccharides such as the capsular polysaccharide of Bacteroides fragilis. The outcome of an infection depends on the balance between an effective host response that eliminates a pathogen and an excessive inflammatory response that is associated with an inability to eliminate a pathogen and with the resultant tissue damage that leads to disease.

TRANSMISSION TO NEW HOSTS

As part of the pathogenic process, most microbes are shed from the host, often in a form infectious for susceptible individuals. However, the rate of transmissibility may not necessarily be high, even if the disease is severe in the infected individual, as these traits are not linked. Most pathogens exit via the same route by which they entered: respiratory pathogens by aerosols from sneezing or coughing or through salivary spread, gastrointestinal pathogens by fecal-oral spread, sexually transmitted diseases by venereal spread, and vector-borne organisms by either direct contact with the vector through a blood meal or indirect contact with organisms shed into environmental sources such as water. Microbial factors that specifically promote transmission are not well characterized. Respiratory shedding is facilitated by overproduction of mucous secretions, with consequently enhanced sneezing and coughing. Diarrheal toxins such as cholera toxin, E. coli heat-labile toxins, and Shigella toxins probably facilitate fecal-oral spread of microbial cells in the high volumes of diarrheal fluid produced during infection. The ability to produce phenotypic variants that resist hostile environmental factors (e.g., the highly resistant cysts of E. histolytica shed in feces) represents another mechanism of pathogenesis relevant to transmission. Blood parasites such as Plasmodium spp. change phenotype after ingestion by a mosquito—a prerequisite for the continued transmission of this pathogen. Venereally transmitted pathogens may undergo phenotypic variation due to the production of specific factors to facilitate transmission, but shedding of these pathogens into the environment does not result in the formation of infectious foci.

In summary, the molecular mechanisms used by pathogens to colonize, invade, infect, and disrupt the host are numerous and diverse. Each phase of the infectious process involves a variety of microbial and host factors interacting in a manner that can result in disease. Recognition of the coordinated genetic regulation of virulence factor elaboration when organisms move from their natural environment into the mammalian host emphasizes the complex nature of the host-parasite interaction. Fortunately, the need for diverse factors in successful infection and disease implies that a variety of therapeutic strategies may be developed to interrupt this process and thereby prevent and treat microbial infections.

APPROACH TO THE ACUTELY ILL INFECTED FEBRILE PATIENT

Tamar F. Barlam, Dennis L. Kasper

The physician treating the acutely ill febrile patient must be able to recognize infections that require emergent attention. If such infections are not adequately evaluated and treated at initial presentation, the opportunity to alter an adverse outcome may be lost. In this chapter, the clinical presentations of and approach to patients with relatively common infectious disease emergencies are discussed. These infectious processes are discussed in detail in other chapters. Noninfectious causes of fever are not covered in this chapter; information on the approach to fever of unknown origin, including that eventually shown to be of noninfectious etiology, is presented in Chap. 18.
GENERAL CONSIDERATIONS

APPEARANCE  A physician must have a consistent approach to acutely ill patients. Even before the history is elicited and a physical examination performed, an immediate assessment of the patient’s general appearance yields valuable information. The perceptive physician’s subjective sense that a patient is septic or toxic often proves accurate. Visible agitation or anxiety in a febrile patient can be a harbinger of critical illness.

HISTORY  Presenting symptoms are frequently nonspecific. In addition to a general description of symptoms, it is important to obtain a sense of disease progression. Detailed questions should be asked about the onset and duration of symptoms and about changes in severity or rate of progression over time. Host factors and comorbid conditions may enhance the risk of infection with certain organisms or of a more fulminant course than is usually seen. Lack of splenic function, alcoholism with significant liver disease, intravenous drug use, HIV infection, diabetes, malignancy, and chemotherapy all predispose to specific infections and frequently to increased severity. The patient should be questioned about factors that might help identify a nidus for invasive infection, such as recent upper respiratory tract infections, influenza, or varicella; prior trauma; disruption of cutaneous barriers due to lacerations, burns, surgery, or decubiti; and the presence of foreign bodies, such as nasal packing after rhinoplasty, barrier contraceptives, tampons, arteriovenous fistulas, or prosthetic joints. Travel, contact with pets or other animals, or activities that might result in tick exposure can lead to diagnoses that would not otherwise be considered. Recent dietary intake, medication use, social or occupational contact with ill individuals, vaccination history, recent sexual contacts, and menstrual history may be relevant. A review of systems should focus on any neurologic signs or sensorium alterations, rashes or skin lesions, and focal pain or tenderness and should also include a general review of respiratory, gastrointestinal, or genitourinary symptoms. It is especially important to determine the duration and progression of these symptoms in order to gain an appreciation of the pace and urgency of the process.

PHYSICAL EXAMINATION  A complete physical examination should be performed, with special attention to some areas that are sometimes given short shrift in routine examinations. Assessment of the patient’s general appearance and vital signs, skin and soft tissue examination, and the neurologic evaluation are of particular importance.

The patient may appear either anxious and agitated or lethargic and apathetic. Fever is usually present, although elderly patients and compromised hosts (e.g., patients who are uremic or cirrhotic and those who are taking glucocorticoids or nonsteroidal anti-inflammatory agents) may be afebrile despite serious underlying infection. Measurement of blood pressure, heart rate, and respiratory rate helps determine the degree of hemodynamic and metabolic compromise. The patient’s airway must be evaluated to rule out the risk of obstruction from an invasive oropharyngeal infection.

The etiologic diagnosis may become evident in the context of a thorough skin examination (see also Chap. 17). Petechial rashes are typically seen with meningococcemia or Rocky Mountain spotted fever (RMSF); erythroderma is usual with toxic shock syndrome (TSS) and drug fever. The soft tissue and muscle examination is critical. Areas of erythema or duskniness, edema, and tenderness may indicate underlying necrotizing fasciitis, myositis, or myonecrosis. The neurologic examination must include a careful assessment of mental status for signs of early encephalopathy. Evidence of nuchal rigidity or focal neurologic findings should be sought. Focal findings, depressed mental status, or papilledema should be evaluated by brain imaging prior to lumbar puncture, which, in this setting, could initiate herniation.

DIAGNOSTIC WORKUP  After a quick clinical assessment, diagnostic material should be obtained rapidly and antibiotic and supportive treatment begun. Blood (for cultures; baseline complete blood count with differential; measurement of serum electrolytes, blood urea nitrogen, serum creatinine, and serum glucose; and liver function tests) can be obtained at the time an intravenous line is placed and before antibiotics are administered. For patients with possible acute endocarditis, three sets of blood cultures should be performed. Asplenic patients should have a blood smear examined to confirm the presence of Howell-Jolly bodies (indicating the absence of splenic function) and a buffy coat examined for bacteria; these patients can have >10^9 organisms per milliliter of blood (compared with 10^3/mL in patients with an intact spleen). Blood smears from patients at risk for severe parasitic disease, such as malaria or babesiosis, must be examined for the diagnosis and quantitation of parasitemia. Blood smears may also be diagnostic in chilblain.

Patients with possible meningitis should have cerebrospinal fluid (CSF) obtained before the initiation of antibiotic therapy. If focal neurologic signs, abnormal mental status, or papilledema mandates brain imaging before a lumbar puncture, antibiotics should be administered prior to imaging but after blood for cultures has been drawn. If CSF cultures are negative, laboratory examination of CSF by latex agglutination or immunoprecipitation can be attempted to make an etiologic diagnosis. However, blood cultures will provide the diagnosis in 50 to 70% of cases.

Focal abscesses necessitate immediate computed tomography or magnetic resonance imaging (MRI) as part of an evaluation for surgical intervention. Other diagnostic procedures, such as cultures of wounds or scraping of skin lesions, should not delay the initiation of treatment for more than minutes. Once emergent evaluation, diagnostic procedures, and (if appropriate) surgical consultation (see below) have been completed, other laboratory tests can be conducted. Appropriate radiography, computed axial tomography, MRI, urinalysis, erythrocyte sedimentation rate (ESR) determination, and transthoracic or transesophageal echocardiography may all prove important.

TREATMENT

In the acutely ill patient, empirical antibiotic therapy is critical and should be administered without undue delay. Table 106-1 lists first-line treatments for the infections considered in this chapter. (For a more detailed discussion of treatment, see specific chapters.) In addition to the initiation of parenteral antibiotic therapy, several of these infections require urgent surgical attention. General surgery for possible necrotizing fasciitis or myonecrosis, neurosurgical evaluation for subdural empyema or spinal epidural abscess, otolaryngologic surgery for possible mucormycosis, and cardiothoracic surgery for critically ill patients with acute endocarditis are as important as the rapid commencement of antibiotic therapy. For infections such as necrotizing fasciitis and clostridial myonecrosis, rapid surgical intervention supersedes other diagnostic or therapeutic maneuvers.

Adjunctive treatments, such as intravenous immunoglobulin administration for TSS, can be considered after initial stabilization. Some adjunctive treatments, such as dexamethasone for bacterial meningitis or protein C replacement for meningococcemia, must be considered in conjunction with the initiation of antibiotic treatment.

SPECIFIC PRESENTATIONS

For most infections, there is time for careful evaluation, diagnostic testing, and consultation with other physicians before therapy commences. However, the infections considered below according to common clinical presentation can have rapidly catastrophic outcomes, and their immediate recognition and treatment can be life-saving. Recommended empirical therapeutic regimens are presented in Table 106-1.

SEPSIS WITHOUT AN OBVIOUS FOCUS OF PRIMARY INFECTION  These patients initially have a brief prodrome of nonspecific symptoms and signs that progresses quickly to hemodynamic instability with hypotension, tachycardia, tachypnea, or respiratory distress. A patient may display altered mental status. Disseminated intravascular coagulation (DIC)

In HIV-infected intravenous drug users with suspected spinal epidural abscess, empirical therapy must cover gram-negative rods and methicillin-resistant Staphylococcus aureus. If resistant pneumococci are prevalent, add vancomycin (1 g q12h).

Sore throat. This disease is associated with wild rabbit, tick, and tabanid fly bites. Tularemia (Chap. 142) is seen throughout the United States, but occurs primarily in Arkansas, Oklahoma, and Missouri. This disease is associated with wild rabbit, tick, and tabanid fly bites. The uncommon typhoidal form can be associated with gram-negative septic shock and a mortality rate of >30%. In the United States, plague (Chap. 143) occurs primarily in New Mexico, Arizona, and Colorado after contact with ground squirrels, prairie dogs, or chipmunks. The septic form is particularly rare and is associated with shock, multiorgan failure, and a 30% mortality rate. These rare infections should be considered in the appropriate epidemiologic setting. Tularemia and plague, along with anthrax, are listed by the Centers for Disease Control and Prevention as important biological agents that might be intentionally used for bioterrorism (Table 106-2 and Chap. 205).

**SEPSES WITH SKIN MANIFESTATIONS** (See also Chap. 17) Maculopapular rashes may reflect early meningococcal or rickettsial disease but are usually associated with nonemergent infections. Exanthems are usually viral. It is noteworthy that primary HIV infection commonly presents with rash. Untreated, symptomatic HIV-seroconversion illness is associated with rapid progression to late-stage disease. The rash is typically maculopapular and involves the upper part of the body but can spread to the palms and soles. In addition, the patient is febrile and can have lymphadenopathy, severe headache, dysphagia, diarrhea, myalgias, and arthralgias. Recognition of this syndrome not only can prevent the spread of HIV to other individuals but also provides an opportunity for early treatment and improved prognosis.

**Petechiae** Petechial rashes caused by viruses are seldom associated with hypotension or a toxic appearance, although severe measles can be an exception. In other settings, petechial rashes require more urgent attention.

**MENINGOCOCCEMIA** (See also Chap. 127) Almost three-quarters of patients with bacteremic N. meningitidis infection have a rash. Meningococcemia most often affects young children (i.e., those 6 months to 5 years old, often in day care). However, sporadic cases and outbreaks occur in schools (grade school through college) and army barracks. Between 10 and 20% of all cases have a fulminant course, with shock, DIC, and multiorgan failure. Of these patients, 50 to 60% die, and survivors often require extensive debridement or amputation of gangrenous extremities. Patients may exhibit fever, headache, nausea, vomiting, myalgias, change in mental status, and meningismus. However, the rapidly progressive form of disease is not usually associated with meningitis. The rash is initially pink, blanching, and maculopapular, appearing on the trunk and extremities, but then becomes hemorrhagic, forming petechiae. Petechiae are first seen at the ankles, wrists, axillae, mucosal surfaces, and palpebral and bulbar conjunctiva, with subsequent spread to the lower extremities and trunk. A cluster of petechiae may be seen at pressure points—e.g., where a blood pressure cuff has been inflated. In rapidly progressive meningococcemia, the petechial rash quickly becomes purpuric (see Fig. 46-5) and patients develop DIC. Hypotension with petechiae for <12 h is associated with significant mortality. The mortality rate can exceed 90% among patients without meningitis who have rash, hypotension, and a normal or low white blood cell count and ESR. Cyanosis, coma, oliguria, metabolic acidosis, and elevated partial thromboplastin time are also associated with a fatal outcome. A better prognosis has been re-
The CSF glucose level is often normal; the protein concentration may be slightly elevated. Renal and hepatic injury and bleeding secondary to vascular damage are noted. Untreated infection has a mortality rate of 30%.

**Purpura Fulminans** (See also Chaps. 127 and 254) Purpura fulminans is the cutaneous manifestation of DIC and presents as large ecchymotic areas and hemorrhagic bullae. Progression of petechiae to purpura and ecchymoses is associated with congestive heart failure, septic shock, acute renal failure, acidosis, hypoxia, hypotension, and death. Purpura fulminans has been associated primarily with *N. meningitidis* but, in splenectomized patients, may be associated with *S. pneumoniae* and *H. influenzae*.

**Ecthyma Gangrenosum** Septic shock caused by *P. aeruginosa* and *A. hydrophila* can be associated with ecthyma gangrenosum (see Fig. 136-1): hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration. These gram-negative bacteremias are most common among patients with neutropenia, extensive burns, and hypogammaglobulinemia.

**Other Emergent Infections Associated with Rash** *Vibrio vulnificus* and other noncholera *Vibrio* bacteremic infections (Chap. 140) can cause focal skin lesions and overwhelming sepsis in the host with liver disease. After ingestion of contaminated shellfish, there is a sudden onset of
malaise, chills, fever, and hypotension. The patient develops bullous or hemorrhagic skin lesions, usually on the lower extremities, and 75% of patients have leg pain. The mortality rate can be as high as 50%. *Capnocytophaga canimorsus* can cause septic shock in asplenic patients. Infection with this fastidious gram-negative rod typically presents after a dog bite as fever, chills, myalgia, vomiting, diarrhea, dyspnea, confusion, and headache. Findings can include an exanthem or erythema multiforme (see Fig. 46-9), cyanotic mottling or peripheral cyanosis, petechiae, and ecchymosis. About 30% of patients with this fulminant form die of overwhelming sepsis and DIC, and survivors may require amputation because of gangrene.

**Erthrodema** TSS (Chaps. 120 and 121) is usually associated with erythrodema. The patient presents with fever, malaise, myalgias, nausea, vomiting, diarrhea, and confusion. There is a sunburn-type rash that may be subtle and patchy but is usually diffuse and is found on the face, trunk, and extremities. Erythrodema, which desquamates after 1 to 2 weeks, is more common in *Staphylococcus*-associated than in *Streptococcus*-associated TSS. Hypotension develops rapidly—often within hours—after the onset of symptoms. Multiorgan failure is seen. Commonly there is no indication of a primary focal infection, although possible cutaneous or mucosal portals of entry for the organism can be ascertained when a careful history is taken. Colonization rather than overt infection of the vagina or a postoperative wound, for example, is typical with staphylococcal TSS, and the mucosal areas appear hyperemic but not infected. Early renal failure may precede hypotension and distinguishes this syndrome from other septic shock syndromes. Clinical evaluation constitutes the diagnosis because TSS is defined by the clinical criteria of fever, rash, hypotension, and multiorgan involvement. The mortality rate is 5% for menstruation-associated TSS, 10 to 15% for nonmenstrual TSS, and 30 to 70% for streptococcal TSS.

**Sepsis with a Soft Tissue/Muscle Primary Focus** (See also Chap. 110) Necrotizing Fasciitis This infection may arise at a site of minimal trauma or postoperative incision and may also be associated with recent varicella, childhood, or muscle strain. The most common causes of necrotizing fasciitis are group A streptococci alone (Chap. 121) and a mixed facultative and anaerobic flora (Chap. 110). Diabetes mellitus, peripheral vascular disease, and intravenous drug use are associated risk factors. Use of nonsteroidal anti-inflammatory agents adversely affects granulocyte chemotaxis, phagocytosis, and bacterial killing, allowing progression of skin or soft tissue infections. The patient may have bacteremia and hypotension without other organ-system failure. Physical findings are minimal compared with the severity of pain and the degree of fever. The examination is often unremarkable except for soft tissue edema and erythema. The infected area is red, hot, shiny, swollen, and exquisitely tender. In untreated infection, the overlying skin develops blue-gray patches after 36 h, and cutaneous bullae and necrosis develop after 3 to 5 days. Necrotizing fasciitis due to a mixed flora, but not that due to group A streptococci, can be associated with gas production. Without treatment, pain decreases because of thrombosis of the small blood vessels and destruction of the peripheral nerves—an ominous sign. The mortality rate is >30% overall, >70% in association with TSS, and nearly 100% without surgical intervention. Life-threatening necrotizing fasciitis may also be due to *Clostridium perfringens* (Chap. 126); in this condition, the patient is extremely toxic and the mortality rate is high. Within 48 h, rapid tissue invasion and systemic toxicity associated with hemolysis and death ensue. The distinction between this entity and clostridial myonecrosis is made by muscle biopsy.

**Clostridial Myonecrosis** (See also Chap. 126) Myonecrosis is often associated with trauma or surgery but can be spontaneous. The incubation period is usually 12 to 24 h long, and massive necrotizing gangrene develops within hours of onset. Systemic toxicity, shock, and death can occur within 12 h. The patient’s pain and toxic appearance are out of proportion to physical findings. On examination, the patient is febrile, apathetic, tachycardic, and tachypneic and may express a feeling of impending doom. Hypotension and renal failure develop later, and hyperalertness is evident pretermittently. The skin over the affected area is bronze-brown, mottled, and edematous. Bullous lesions with serosanguineous drainage and a mousy or sweet odor can be present. Crepitus can occur secondary to gas production in muscle tissue. The mortality rate is >65% with spontaneous myonecrosis, which is often associated with *Clostridium septicum* and underlying malignancy. The mortality rates associated with trunc and limb infection are 63 and 12%, respectively, and any delay in surgical treatment increases the risk of death.

**Neurologic Infections with or without Septic Shock** Bacterial Meningitis (See also Chap. 360) Bacterial meningitis is one of the most common infectious emergencies involving the central nervous system. Although hosts with cell-mediated immune deficiency (including transplant recipients, diabetic patients, elderly patients, and cancer patients treated with certain chemotherapeutic agents) are at particular risk for *Listeria monocytogenes* meningitis, most cases in adults are due to *S. pneumoniae* (30 to 50%) and *N. meningitidis* (10 to 35%). An early presentation of headache, meningismus, and fever is classic but is seen in only one-half to two-thirds of patients. The elderly can present without fever or meningeal signs despite lethargy and confusion. Cerebral dysfunction is evidenced by confusion, delirium, and lethargy that can progress to coma. The presentation is fulminant, with sepsis and brain edema, in some cases; papilledema at presentation is unusual and suggests another diagnosis (e.g., an intracranial lesion). Focal signs, including cranial nerve palsies (IV, VI, VII), can be seen in 10 to 20% of cases; 50 to 60% of patients have bacteremia. A poor outcome is associated with coma at any time during the course, hypotension, meningitis due to *S. pneumoniae*, or a CSF glucose level of <0.6 mmol/L (<10 mg/dL). Mortality is associated with coma, respiratory distress, shock, a CSF protein level of >2.5 g/L, a peripheral white blood cell count of <5000/μL, and a serum sodium level of <135 mmol/L.

**Suppurative Intracranial Infections** (See also Chap. 360) Other rare intracranial lesions that present with sepsis and hemodynamic instability are subdural empyema, septic cavernous sinus thrombosis, and septic superior sagittal sinus thrombosis. Rapid recognition of the toxic patient with central neurologic signs is crucial to improvement of the dismal prognosis of these entities.

**Subdural Empyema** This infection arises from the paranasal sinuses in 60 to 70% of cases. Microaerophilic streptococci and staphylococci are the predominant etiologic organisms. The patient is toxic, with fever, headache, and nuchal rigidity. Of all patients, 75% have focal signs and 6 to 20% die. Despite improved survival rates, 15 to 44% of patients are left with permanent neurologic deficits.

**Septic Cavernous Sinus Thrombosis** This condition follows a facial or sphenoid sinus infection; 70% of cases are due to staphylococci and the remainder are due primarily to aerobic or anaerobic streptococci. A unilateral or retroorbital headache progresses to a toxic appearance and fever within days. Three-quarters of patients have unilateral periorbital edema that becomes bilateral and then progresses to ptosis, proptosis, ophthalmoplegia, and papilledema. The mortality rate is as high as 30%.

**Septic Thrombosis of the Superior Sagittal Sinus** This infection spreads from the ethmoid or maxillary sinuses. Its bacterial causes include *S. pneumoniae*, other streptococci, and staphylococci. The fulminant course is characterized by headache, nausea, vomiting, rapid progression to confusion and coma, nuchal rigidity, and brainstem signs. If the sinus is totally thrombosed, the mortality rate exceeds 80%.

**Brain Abscess** (See also Chap. 360) Brain abscess often occurs without systemic signs. Almost half of patients are afebrile, and presentations are usually and suggestive with a space-occupying lesion in the brain; 70% of patients have headache, 50% have focal neurologic signs, and 25% have papilledema. Abscesses can present as single or multiple lesions
resulting from contiguous foci or hematogenous infection, such as unrecognized endocarditis. The infection progresses over several days from cerebritis to an abscess with a mature capsule. More than half of infections are polymicrobial, with an etiology consisting of aerobic bacteria (primarily streptococcal species) and anaerobes. Abscesses arising hematogenously are especially apt to rupture into the ventricular space, causing a sudden and severe deterioration in clinical status and high mortality. Otherwise, mortality is low but morbidity is high (30 to 55%). Patients presenting with stroke and a parameningeal infectious focus, such as sinusitis or otitis, may have a brain abscess, and physicians must maintain a high level of suspicion. Prognosis worsens in patients with a fulminant course, delayed diagnosis, abscess rupture into the ventricles, multiple abscesses, or abnormal neurologic status at presentation.

**Cerebral Malaria** (See also Chap. 195) This entity should be urgently considered if patients who have recently traveled to areas endemic for malaria present with a febrile illness and lethargy or other neurologic signs. Fulminant malaria is caused by *Plasmodium falciparum* and is associated with temperatures of >40°C (>104°F), hypotension, jaundice, adult respiratory distress syndrome, and bleeding. By definition, any patient with a change in mental status or repeated seizure in the setting of fulminant malaria has cerebral malaria. In adults, this non-specific febrile illness progresses to coma over several days; occasionally, coma occurs within hours and death within 24 h. Nuchal rigidity and photophobia are rare. On physical examination, symmetric encephalopathy is typical, and upper motor neuron dysfunction with decorticate and decerebrate posturing can be seen in advanced disease. Unrecognized infection results in a 20 to 30% mortality rate.

**SPINAL EPIDURAL ABSCESSES** (See also Chap. 356) Patients with spinal epidural abscesses often present with back pain and develop neurologic deficits late in their course. At-risk patients include those with diabetes mellitus; intravenous drug use; chronic alcohol abuse; recent spinal trauma, surgery, or epidural anesthesia; and other comorbid conditions, such as HIV infection. The thoracic or lumbar spine is the most common location, and staphylococci are the most common etiologic agents; in HIV-infected intravenous drug users, therapy must cover gram-negative rods and methicillin-resistant *S. aureus*. If a patient gives a history of antecedent back pain and has new neurologic symptoms, this diagnosis must immediately be considered. Almost 60% of patients have fever and almost 90% have back pain. Paresthesia, bowel and bladder dysfunction, radicular pain, and weakness are frequent neurologic complaints, and examination of the patient may reveal abnormal reflexes and motor and sensory deficits. The ESR and leukocyte counts are usually elevated. Rapid recognition and treatment, including immediate drainage, can prevent or minimize permanent neurologic sequelae.

**FOCAL SYNDROMES WITH A FULMINANT COURSE** Infection at virtually any primary focus (e.g., osteomyelitis, pneumonia, pyelonephritis, or cholangitis) can result in bacteremia and sepsis. TSS has been associated with focal infections such as septic arthritis, peritonitis, sinusitis, and wound infection. Death occurs secondary to septic shock or toxin production with hemodynamic instability and multiorgan failure. Rapid clinical deterioration and death can be associated with destruction of the primary site of infection, as is seen in endocarditis and in necrotizing infections of the oropharynx (in which edema suddenly compromises the airway).

**Rhinoencephalitis** (See also Chap. 189) Patients with diabetes or malignancy are at risk for invasive rhinoencephalitis. Patients present with low-grade fever, dull sinus pain, diplopia, decreased mental status, decreased ocular motion, chemosis, proptosis, dusky or necrotic nasal turbinates, and necrotic hard-palate lesions that respect the midline. Without rapid recognition and intervention, the process continues an inexorable invasive course with high mortality.

**Acute Bacterial Endocarditis** (See also Chap. 109) This entity presents with a much more aggressive course than subacute endocarditis. Bacteria such as *S. aureus*, *S. pneumoniae*, *L. monocytogenes*, *Haemophilus* spp., and streptococci of groups A, B, and G attack native valves. Mortality rates range from 10 to 40%. The host may have comorbid conditions such as underlying malignancy, diabetes mellitus, intravenous drug use, or alcoholism. The patient presents with fever, fatigue, and malaise <2 weeks after onset of infection. On physical examination, a changing murmur and congestive heart failure may be noted. Hemorrhagic macules on palms or soles (Janeway lesions) sometimes develop. Petechiae, Roth’s spots, splinter hemorrhages, and splenomegaly are unusual. Rapid valvular destruction, particularly of the aortic valve, results in pulmonary edema and hypotension. Myocardial abscesses can form, eroding through the septum or into the conduction system and causing life-threatening arrhythmias or high-degree conduction block. Large friable vegetations can result in major arterial emboli, metastatic infection, or tissue infarction. Emboli can lead to stroke, change in mental status, visual disturbances, aphasia, ataxia, headache, meningsismus, brain abscess, cerebritis, spinal cord infarct with paraplegia, arthralgia, osteomyelitis, splenic abscess, septic arthritis, and hematura. Older patients with *S. aureus* endocarditis are especially likely to present with nonspecific symptoms—a circumstance that delays diagnosis and worsens prognosis. Rapid intervention is crucial for a successful outcome.

**Inhalational Anthrax** (See also Chap. 205) Inhalational anthrax, the most severe form of disease caused by *Bacillus anthracis*, had not been reported in the United States for more than 25 years until the recent use of this organism as an agent of bioterrorism (Table 106-2 and Chap. 205). Patients presented with malaise, fever, cough, nausea, drenching sweats, shortness of breath, and headache. Rhinorrhea was unusual. All patients had abnormal chest roentgenograms at presentation. Mediastinal widening, pulmonary infiltrates, and pleural effusions were the most common findings. All patients who developed fulminant disease before receiving antibiotics died. Hemorrhagic meningitis has been seen in up to 50% of patients in other large outbreaks. Without urgent intervention with antimicrobial agents and supportive care, inhalational anthrax progresses rapidly to hypotension, cyanosis, and death.

**CONCLUSION** Acutely ill febrile patients, with the syndromes discussed in this chapter, require close observation, aggressive supportive measures, and—in most cases—admission to intensive care units. The most important task of the physician is to distinguish these patients from other infected febrile patients who will not progress to fulminant disease. The alert physician must recognize the acute infectious emergency and then proceed with appropriate urgency.

**FURTHER READING**

Most humans live their lives ignoring the certainty of their own mortality. Perhaps this fact explains why the adage “an ounce of prevention is worth a pound of cure” has so little effect on their everyday behavior. Even when it comes to acting to protect their young, parents are capable of ignoring the potential for the death of their children in the developed world and of accepting the certainty of childhood deaths in the developing world. In both settings, parents all too often fail to seek out and demand the best preventive measures available. Unless mandated by the law in wealthy societies or provided by benevolent organizations or governments in poor nations, universal immunization has invariably remained an unattained goal.

Vaccination is ranked as one of the greatest public health achievements of the twentieth century and is the principal factor contributing to the reduction of morbidity and mortality among children around the world. The integration of immunization practices (a major component of primary disease prevention) into routine health care services has provided caregivers with control over a substantial proportion of the disease and mortality that plagued the United States during the first half of the twentieth century (Table 107-1). For society today, immunization is one of the few cost-saving interventions to prevent infectious disease. At present, >50 biologic products are licensed in the United States. A total of 21 antigens, many in the form of combined vaccines, are used for routine immunization during the first 18 months of life, including diphtheria/tetanus/acellular pertussis (DTaP) vaccine, trivalent inactivated poliovirus vaccine (IPV), measles/mumps/rubella (MMR) vaccine, Haemophilus influenzae type b (Hib) vaccine, hepatitis B (HepB) and hepatitis A (HepA) vaccines, and varicella vaccine. Recently, a heptavalent pneumococcal vaccine has been recommended for routine use in children, as has influenza vaccine (given annually). Five vaccines are designed for routine use in adults: tetanus/diphteria (Td) toxoids formulated for adult use; HepB vaccine; influenza virus vaccine; polyclonal pneumococcal polysaccharide vaccine; and varicella vaccine. Some preparations are designated as special-use vaccines for outbreak response, prophylaxis in travelers, or regional use (e.g., vaccines against Neisseria meningitidis, Japanese B encephalitis virus, yellow fever virus, and Salmonella typhi and HepA vaccine). Unfortunately, vaccines for eukaryotic pathogens (protozoa and helminths), which affect a large proportion of the world’s population, have been difficult to develop and remain only a hope for the future.

Healthy People 2010 Objectives for the Nation includes a set of immunization indicators. By 2010, 80% of children should have received DTaP, poliovirus, MMR, Hib, and HepB vaccines, while 90% of adults are expected to have received influenza and pneumococcal vaccines.

fectious agents (e.g., measles virus); and (2) the use of inactivated agents or their constituents or products obtained by genetic recombination (e.g., acellular pertussis vaccines). For many diseases (e.g., poliomyelitis), both approaches have been employed.

Live attenuated vaccines consisting of selected or genetically altered organisms that are avirulent or dramatically attenuated, yet remain immunogenic, generally produce long-lasting immunity. These agents are expected to cause a subclinical illness and immunologic response mimicking natural infection (except for the lack of clinically significant disease). They offer the advantage of replication in vivo, which increases the antigenic load presented to the host’s immune system; they may confer lifelong protection with one dose; they present all expressed antigens, thus overcoming immunogenetic restrictions in some hosts; they may reach the local sites most relevant to the induction of protective immunity; and they may produce important protective antigens in vivo that are not efficiently expressed in vitro.

Inactivated vaccines typically require multiple doses and periodic boosters thereafter for the maintenance of immunity. The exception to this rule is pure polysaccharide vaccine, whose effects cannot be boosted by additional exposures. Nonviable vaccines administered parenterally fail to elicit mucosal IgA-mediated immunity, as they lack a delivery system that can effectively transport them to local antigen-processing cells. However, killed vaccines can be extremely successful. For example, the nonviable HepA vaccine formulation appears to be close to 100% effective in inducing protective immunity. Currently available nonviable vaccines consist of inactivated whole organisms (e.g., plague vaccine); detoxified protein toxins (e.g., tetanus toxin); recombinant protein antigens (e.g., HepB vaccine); or carbohydrate antigens, either present as soluble purified capsular material (e.g., Streptococcus pneumoniae polysaccharides) or conjugated to a protein carrier (e.g., Hib polysaccharide conjugated to diphtheria or tetanus toxoids).

Despite their advantages, live vaccines are not always preferable. For example, live oral poliovirus vaccine (OPV) is contraindicated for use in children with immune deficiency diseases or their adult contacts. In addition, even though killed poliovirus vaccine does not completely immunize the gut or immunize contacts of vaccine recipients, the United States has now switched to a four-dose schedule of this vaccine because of the rare but real risk of vaccine-associated polio posed by live OPV.

**APPROACHES TO PASSIVE IMMUNIZATION** Passive immunization is generally used to provide temporary immunity in an unimmunized subject exposed to an infectious disease when active immunization either is unavailable (e.g., for respiratory syncytial virus) or has not been implemented before exposure (e.g., for rabies). Passive immunization is used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively]. Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., γ globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody to specific agents (e.g., hepatitis B virus (HBV) or varicella-zoster immune globulin); and (3) animal sera and antitoxins.

**ROUTE OF ADMINISTRATION** The route of administration in part determines the rapidity and nature of the immune responses to vaccines. Vaccines can be administered orally, intranasally, intradermally, subcutaneously, or intramuscularly. Parenterally administered vaccine may not induce mucosal secretory IgA, and mucosal immunization may not induce good systemic responses. Vaccines must be administered by the licensed route to ensure immunogenicity and safety. For example, administration of HepB vaccine into the gluteal rather than the deltoid muscle often fails to induce an adequate immune response, while subcutaneous rather than intramuscular administration of diphtheria/tetanus/pertussis vaccine (DTP) increases the risk of reactions.

**AGE** Because age influences the response to vaccines, schedules for immunization are based on age-dependent responses determined empirically from clinical trials. The presence of high levels of maternal antibody and/or the immaturity of the immune system in the early months of life impairs the initial immune response to some vaccines (e.g., measles or Hib polysaccharide) but not to others (e.g., HepB). In the elderly, vaccine responses may be diminished because of natural waning of the immune system. Hence, larger amounts of an antigen may be required to produce the desired response (e.g., in vaccination against influenza).

**ADJUVANT POTENTIATION** The immune response to some antigens is potentiated by the addition of adjuvants such as aluminum salts or, in the case of polysaccharides (e.g., the polyribosyl phosphate oligosaccharide of Hib), by conjugation to a carrier protein. Adjuvants—non-specific boosters of immune responses—are used with inactivated products such as diphtheria and tetanus toxoids, acellular pertussis vaccine, and HepB vaccine. The mechanism for adjuvant enhancement of immunogenicity is not well defined but relates in part to the rendering of soluble antigens into a particulate form; the mobilization of phagocytes to the site of antigen deposition; and the slowing down of the release of antigens, which prolongs stimulation of the immune response.

**THE IMMUNE RESPONSE** While many constituents of infectious microorganisms and their products, such as exotoxins, are or can be made to be immunogenic, only a limited number stimulate a protective immune response. The immune system is complex, and antigen composition and presentation are critical for stimulation of the desired immune responses.

**The Primary Response** In the primary response to a vaccine antigen, an apparent latent period of several days precedes the detection of humoral and cell-mediated immunity. Although the immune response begins with initial recognition of the antigen by the immune system, measurable circulating antibodies do not appear for 7 to 10 days. The immunoglobulin class of the response also changes over time. The primary response is characterized by early-appearing IgM antibodies. These generally exhibit only low affinity for the antigen, whereas later-appearing IgG antibodies display high affinity. For “thymus-dependent” antigens, CD4+ T-helper lymphocytes control the switch from IgM to IgG. Some individuals do not respond, even when presented repeatedly with a vaccine antigen, often because they lack the major histocompatibility complex determinants required to recognize the antigen. This situation is known as primary vaccine failure.

**The Secondary Response** Heightened humoral or cell-mediated responses are elicited by a second exposure to the same antigen and

**TABLE 107-2 Definitions of Immunizing Agents**

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Vaccine</td>
<td>A preparation of attenuated live or killed microorganisms of antigens presented to a potential host to induce immunity and prevent disease when active immunization is unavailable (e.g., respiratory syncytial virus) or has not been exposed to an infectious disease when active immunization is used. Passive immunization is generally used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively]. Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., γ globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody to specific agents (e.g., hepatitis B virus (HBV) or varicella-zoster immune globulin); and (3) animal sera and antitoxins.</td>
</tr>
<tr>
<td>Toxoid</td>
<td>A modified bacterial toxin that has been made nontoxic but retains the capacity to stimulate the formation of antitoxin. Passive immunization is generally used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively]. Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., γ globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody to specific agents (e.g., hepatitis B virus (HBV) or varicella-zoster immune globulin); and (3) animal sera and antitoxins.</td>
</tr>
<tr>
<td>Immune globulin</td>
<td>An antibody-containing protein fraction derived from human plasma and used primarily for maintenance of the immunity of persons with immunodeficiency disorders or for passive immunization when there is no opportunity for active immunization. Passive immunization is generally used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively]. Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., γ globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody to specific agents (e.g., hepatitis B virus (HBV) or varicella-zoster immune globulin); and (3) animal sera and antitoxins.</td>
</tr>
<tr>
<td>Antitoxin</td>
<td>An antibody derived from the serum of animals after stimulation with specific antigens and used to provide passive immunity to the toxin protein to which it is directed. Passive immunization is generally used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively]. Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., γ globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody to specific agents (e.g., hepatitis B virus (HBV) or varicella-zoster immune globulin); and (3) animal sera and antitoxins.</td>

</tbody>
</table>

* Both intramuscular and intravenous preparations are available.
occur rapidly, usually within 4 or 5 days. The secondary response depends on immunologic memory after the first exposure and is characterized by a marked proliferation of IgG antibody—producing B lymphocytes and/or effector T cells. Whereas polysaccharide vaccines, such as that for S. pneumoniae, evoke immune responses that are independent of T cells and are not enhanced by repeated administration, conjugation to proteins converts the polysaccharides to T cell–dependent antigens that induce immunologic memory and secondary responses to revaccination. Although levels of vaccine-induced antibodies may decline over time (secondary vaccine failure), revaccination or exposure to the organism generally elicits a rapid protective secondary response consisting of IgG antibodies with little or no detectable IgM. This anamnestic response indicates that immunity has persisted. Thus, lack of measurable antibody does not necessarily mean that the individual is unprotected. Furthermore, the mere presence of detectable antibodies after the administration of some vaccines and toxoids does not ensure clinical protection. A minimal circulating level of antibody is known to be required for protection from some diseases (e.g., 0.01 IU/mL for tetanus antitoxin).

Hypersensitivity Reactions Independent of antibody production, the stimulation of the immune system by vaccination may elicit unanticipated responses, especially hypersensitivity reactions. In the past, killed measles vaccine induced incomplete humoral immunity and cell-mediated hypersensitivity, resulting in the development of a syndrome of atypical measles in some children after subsequent exposure; thus, this type of vaccine is no longer in use.

Mucosal Immunity Some pathogens are confined to and replicate only at mucosal surfaces (e.g., Vibrio cholerae), while others are able to penetrate the mucosa and replicate (e.g., poliovirus, rubella virus, and influenza virus). At the mucosal site, these organisms induce secretory IgA. The induction of secretory IgA by vaccines may be an efficient way to block the essential first steps in pathogenesis, whether the organism is restricted to mucosal surfaces or invades the host across mucosal surfaces.

Measurement of the Immune Response Immune responses to vaccines are often gauged by the concentration of specific antibody in serum. While seroconversion serves as a dependable indicator of an immune response, it measures only one immunologic parameter and does not necessarily indicate protection. The development of circulating antibodies after immunization often correlates directly with clinical protection (e.g., against measles or rubella). Some responses may not in themselves confer immunity but may be sufficiently associated with protection that they remain useful proxy measures of protective immunity (e.g., vibriocidal serum antibodies in cholera).

HERD IMMUNITY Vaccination provides direct protection against infection of individuals, thereby decreasing the percentage of susceptible persons within a population. At a definable prevalence of immunity in the population (herd immunity), an organism can no longer circulate freely among the susceptibles. This indirect protection of unvaccinated (nonimmune) persons is called the herd immunity effect. The level of vaccination coverage needed to elicit a herd immunity effect is dependent on the mixing patterns of the population and the biology of the specific infectious agents. For example, measles and varicella viruses have high transmission rates and therefore require a higher level of vaccine coverage to elicit herd immunity than do organisms with lower transmission rates, such as S. pneumoniae. Wherever herd immunity for poliomyelitis and measles has been induced with vaccines, transmission of infection has ceased. It is not surprising that herd immunity may wane if immunization programs are interrupted (as was the case for diphtheria in the former Soviet Union) or if a sufficient percentage of individuals refuse to be immunized (as occurred for pertussis in the United Kingdom and Japan because concern about infrequence—albeit severe—vaccine reactions came to exceed the fear of the disease itself). In each setting, loss of herd immunity led to renewed circulation of the organism and subsequent large outbreaks.

TARGET POPULATIONS AND TIMING OF IMMUNIZATION Different age groups have different disease attack rates, and the effectiveness of vaccines depends on a variety of factors, including the individual’s responsiveness to vaccines, the demographic features of the populations at risk, and the duration and character of the immunologic response. In vaccination programs, which are as much community as individual endeavors, schedules for immunization are based on careful consideration of the variables affecting age-dependent responses and population interactions (e.g., school entry, college enrollment, military induction) as well as the feasibility of implementation.

For common and highly communicable childhood diseases like measles, the target population is the universe of susceptible individuals, and the time to immunize is as early in life as is feasible. Yet epidemiologic differences in measles transmission in different settings dictate different strategies for immunization. In the industrialized world, immunization with live-virus vaccine at 12 to 15 months of age has been the norm because the vaccine protects >95% of those immunized at this age and there is little measles morbidity or mortality among very young infants. In contrast, in the developing world, measles is a significant cause of death in young infants. Thus, it is desirable to immunize children earlier to narrow the window of vulnerability between the rapid decline of maternal antibody after 4 to 6 months and the development of vaccine-induced active immunity.

Hib causes meningitis, epiglottitis, and pneumonia in early childhood, with rates rising sharply after the disappearance of maternally derived antibody. The first Hib polysaccharide vaccines often failed when administered during infancy, mainly because of an age-related inability to respond to polysaccharide antigens. To overcome this problem, the protective polysaccharide was converted to a T cell–dependent antigen by conjugation to proteins to which infants could respond.

In contrast, rubella is primarily a threat to the fetus; young infants and children are not at risk of serious illness. An ideal strategy would be to immunize all women of reproductive age before pregnancy. Because it is difficult to systematically vaccinate adolescent and young-adult females and to assure the protection of as many women as possible, rubella is included in a combination vaccine (MMR vaccine) that is administered during infancy. Screening for rubella antibodies during pregnancy should be followed up with postpartum vaccination of seronegative individuals.

Some vaccines were originally formulated primarily for adults. For example, influenza virus and polyvalent pneumococcal polysaccharide vaccines are used to prevent pneumonia, hospitalizations, and deaths among the elderly. Unfortunately, these vaccines are underutilized, in part because physicians and otherwise-healthy individuals in the target group ignore the indications and in part because there is still a tendency to think about disease prevention with vaccines as a strategy for children. With the advent of pneumococcal conjugate vaccines and the cold-adapted influenza strain as well as of administration by nasal spray, infants can also be targeted to receive these vaccines.

THE DEVELOPMENT OF VACCINES

BIOLOGIC IMPEDIMENTS There are often major technical problems to overcome in vaccine development. Although just one major antigenic type of influenza virus is typically in circulation at any one time, the virus is characterized biologically by its antigenic drift. Thus, a new antigenic version capable of causing a global pandemic emerges regularly, and a new vaccine must be rapidly devised, produced, distributed, and administered. In contrast, many prevalent pneumococcal polysaccharide serotypes circulate at all times. Because immunity to the pneumococcus is serotype specific, an individual is susceptible to all serotypes against which he or she lacks antibody. Serotype-specific protection has made it more difficult to develop an effective pneumococcal vaccine than it was to develop a vaccine against H. influenzae, of which one capsular serotype (type b) is associated with nearly all cases of severe disease. To overcome this problem, pneumococcal
vaccine currently includes 23 polysaccharides that represent ~80% of the virulent serotypes commonly encountered in the United States. Unfortunately, some serotypes are poorly immunogenic, and immunized individuals remain susceptible to the serotypes not included in the vaccine.

**Strategy for Vaccine Development**

Vaccine development depends on the systematic application of a four-phase strategy: (1) studies in animals to identify protective antigens, (2) determination of how to present this antigen effectively to the immune system, (3) assessment of the safety and immunogenicity of the preparation in small and then in large human populations at various ages, and (4) evaluation of safety and efficacy in the target population. Each of these steps is simple in concept but difficult in execution; failure at any level stops the process. Progress in immunology has taught us much about the organization and function of the immune system (Chap. 295); it has also taught us that the immune system is complex and that details of antigen composition and presentation are critical for stimulating desired immune responses.

Ultimately, vaccines for humans must be tested in humans. After initial animal studies and small phase 1 and 2 human studies to assess immune responses, optimal dosage, and safety, clinical trials of vaccine efficacy are performed with informed volunteers who are challenged with a virulent strain. Larger clinical effectiveness trials in the community, typically involving 1000 to 10,000 vaccinees, may lead to application for licensure. Because of their limited size, however, these trials cannot be expected to detect rare adverse effects. Thus, licensing does not guarantee that a new vaccine is completely safe, and postlicensing monitoring is needed to ensure effectiveness and to document the occurrence of adverse events of low frequency. In 1999, the recently licensed herpes zoster vaccine was withdrawn because postmarketing surveillance suggested an association with a rare event in infants: intussusception of the bowel.

The development of vaccines goes beyond technology and proof of principle to issues such as development costs, manufacturers’ liability and indemnity, perceived public health needs, and the likelihood that a product will be used or sold. Given the complex science required, the costs of vaccine development are high and success is uncertain, adding risk to the development decision. It is unfortunate that the one sure implication of uncertainty in vaccine development is increased cost. In addition, a rational assignment of costs for development between the public and private sectors in the United States has never been achieved.

**Vaccine Formulations**

Studies of clinical immunology have shown that living and dead antigens do not induce the same immune responses and that the requirements for the development of protective immunity may differ with the organism. These insights, together with the refinement of epidemiologic concepts surrounding immunization, have changed the strategy of vaccine development. The goal is not only to select the correct antigens but also to ensure that the vaccines will result in the type of immune response needed for protection, whether T cell–mediated activation of macrophages or the generation of cytotoxic T cells, B cell–mediated secretory IgA, or a particular IgG subtype response to a specific polysaccharide epitope. To create a deliverable vaccine, constituents other than antigens are also required (Table 107-3). These constituents can affect the immunogenicity, efficacy, and safety of a vaccine and can render one formulation superior to another.

**Production of Vaccines**

As products to be given to healthy individuals to prevent disease, vaccines must not only be efficacious but also cause no harm. In the United States, quality assurance is the responsibility of vaccine manufacturers. Standards of manufacture of biologics (known as good manufacturing practices, or GMPs) are regulated and supervised by the U.S. Food and Drug Administration (FDA). Proof of the safety, efficacy, sterility, and purity of products is required before licensure, and sterility and purity are continually monitored for all lots of vaccine after licensure. Postmarketing studies of safety (phase 4 studies) are part of routine regulatory control. On rare occasions, either GMP or quality assurance breaks down; for example, the release of incompletely killed Salk polio vaccine in 1955 caused an outbreak of poliomyelitis in nearly 200 vaccine recipients and their contacts. Unregulated and/or uncontrolled manufacture of vaccines in developing countries has sometimes led to immunization with inactive products that fail to provide the expected protective immunity (e.g., tetanus toxoid produced in Bangladesh).

There is a serious new problem affecting the production of vaccines. For various reasons, including the high costs of vaccine development and the prospect of much higher profitability from investments in other products, the number of vaccine manufacturers in the United States has declined and the cost of some basic childhood vaccines has increased. These changes raise concerns about the future availability of these essential biologics for national use. Furthermore, pricing decisions made within the private-sector pharmaceutical industry can have a major impact on vaccine use. This situation has stimulated an initiative toward increased public involvement in supplying vaccine to individuals for whom price is an issue as well as in oversight of the vaccine supply and of price negotiations with industry.

**Administration of Vaccines**

Health care workers administering vaccines must take the precautions necessary to minimize the risk of spreading disease—for example, hand washing between immunizations. Different vaccines should not be mixed in the same syringe unless such a practice is specifically endorsed by licensure. Disposable needles and syringes must be safely discarded to prevent inadvertent needlestick injury or, in resource-poor settings, the reuse of these items.

The addition of new, individually injectable vaccines to the childhood immunization schedule has heightened parental concerns about multiple injections being administered at a single clinic visit. The development and use of combinations of vaccines are intended to mitigate these concerns. Even when multiple injections are required, providers must make every effort to administer all indicated vaccines at each visit.

Wherever effective primary health care systems ensure access to medical services for the majority and the population is educated about the need for and efficacy of vaccines, coverage rates for basic immunization are usually high, regardless of the route of vaccine administration or the number of doses necessary. However, without systematic attention to the completion of multiple-dose vaccine schedules, coverage rates for second, third, and booster doses may drop off significantly.

**Use of Vaccines**

Several professional groups develop recommendations for vaccine use in the United States: the Advisory Committee on Immunization Practices, the American Academy of Pediatrics (AAP), the American Academy of Family Practice, the American College of Obstetricians and Gynecologists, the American College of Physicians, and the Infectious Diseases Society of America. These recommendations are the

...
result of a collaborative process among the recommending groups, the pharmaceutical industry, and the FDA. Vaccines recommended in 2003 for routine administration to infants, children, and adults are shown in Table 107-4; vaccines recommended for special use are shown in Table 107-5; and schedules for immunization of children and adolescents and of adults are shown in Fig. 107-1 and Fig. 107-2, respectively. The recommendations on route, site, and dosages for vaccination have been derived from theoretical considerations, experimental trials, and clinical experience; deviation from these recommendations can result in inadequate protection. The administration of doses at intervals longer than those recommended does not diminish the ultimate protective response but merely delays it. In contrast, giving vaccines at shorter-than-recommended intervals may result in poor responses. When a scheduled dose is missed, it is not necessary to restart from the beginning or to add an extra dose (www.cdc.gov/nip/recs/child-catchup.pdf).

**Source:** Recommendations of the Advisory Committee on Immunization Practices, the American Academy of Pediatrics, and the American College of Physicians.

Vaccines recommended in 2003 for routine administration to infants, children, and adults are shown in Table 107-4; vaccines recommended for special use are shown in Table 107-5; and schedules for immunization of children and adolescents and of adults are shown in Fig. 107-1 and Fig. 107-2, respectively. The recommendations on route, site, and dosages for vaccination have been derived from theoretical considerations, experimental trials, and clinical experience; deviation from these recommendations can result in inadequate protection. The administration of doses at intervals longer than those recommended does not diminish the ultimate protective response but merely delays it. In contrast, giving vaccines at shorter-than-recommended intervals may result in poor responses. When a scheduled dose is missed, it is not necessary to restart from the beginning or to add an extra dose (www.cdc.gov/nip/recs/child-catchup.pdf).

**RECORDING AND REPORTING REQUIREMENTS** Certain aspects of vaccine use are regulated by the National Childhood Vaccine Injury Act (NCVIA) of 1986 (modified in 1995 and 2002). The act requires that all mandated childhood vaccinations be recorded by health care providers in the child’s permanent medical record, including date of administration, manufacturer and lot number, and name of the provider administering the vaccine. State-based immunization information systems and electronic registries have been developed to help public and private providers manage their immunization activities and particularly to address the problem of assessing immunization coverage when an individual’s records are divided among multiple medical facilities. By permitting active and targeted recall of children who are overdue for immunization and by providing data on immunization status at the time of an office visit, these systems improve vaccination rates and offer important public health benefits.

Parents must be informed about the benefits and risks of immunization and should maintain an up-to-date immunization record on their children. Educational materials providing the required information (Vaccine Information Statements) are available from the AAP or the Centers for Disease Control and Prevention (CDC; www.cdc.gov/nip/publications/vis/). The National Network for Immunization Information website (www.immunizationinfo.org) is an excellent source of authoritative information for parents.

**VACCINES FOR ROUTINE USE ■ Infants and Children** (See Fig. 107-1 and www.cdc.gov/nip/recs/child-catchup.pdf) It is current practice for all children in the United States to receive DTaP, poliovirus, MMR, Hib, HepB, varicella, and pneumococcal conjugate vaccines unless there are specific contraindications. The administration of HepA vaccine is currently recommended when there is a special risk of exposure to infection due to residence in communities with elevated rates of hepatitis A or travel to endemic countries. Influenza vaccine is recommended for children 6 to 24 months of age, especially those who have certain risk factors or who reside with persons with certain chronic disorders. In several European countries, meningococcal C conjugate vaccine is routinely recommended.

**Adults** (See Fig. 107-2) Immunization recommendations for adults (≥18 years old) fall into four categories: (1) routine vaccines for all adults; (2) vaccines for high-risk exposure groups (health care and other institutional workers, prisoners, students, military personnel, travelers to endemic areas, injection drug users, men who have sex with men); (3) vaccines for persons at high risk for severe outcomes of infection (pregnant women; the elderly; persons with chronic medical conditions, including diabetes, alcoholism, immunodeficiency, and renal, hepatic, respiratory, or cardiac disease); and (4) vaccines for household contacts of persons in group 3. A substantial proportion of adults in the United States no longer have protective levels of antibodies against tetanus or diphtheria. All adults who completed the pediatric series should be boosted with Td (adult formulation) every 10 years (once after age 50). If not previously immunized, however, adults require a primary immunizing course of Td. Young adults without laboratory evidence or a reliable history of past vaccination or disease should be immunized against measles, mumps, rubella, and varicella. A second dose of MMR vaccine is recommended for groups with a higher risk of exposure and for health care workers with certain other indications. Unless they have documented proof of immunity, rubella vaccine should be given to all nonpregnant women of childbearing age. Rubella-susceptible pregnant women should be vacci-

nated as early as possible in the postpartum period. Live-virus vaccines, such as MMR and varicella vaccines, are contraindicated in pregnant women and immunosuppressed individuals. Routine immunization against polio is not recommended for adults unless they are at particular risk of exposure because of travel to the remaining endemic areas. College students, particularly freshmen living at close quarters, are at increased risk of meningococcal meningitis and should be offered the meningococcal polysaccharide vaccine for serogroups A, C, Y, and W-135.

Current recommendations also include influenza vaccine for routine annual administration to individuals with chronic illness at any age, to persons living in the same household as chronically ill individuals, and to all adults >50 years of age. Polysaccharidic meningococcal polysaccharide vaccine is similarly recommended for adults ≥65 years of age and for all chronically ill persons. HepB vaccine is recommended for individuals at high risk from clinical, occupational, behavioral, and travel exposures, including patients undergoing hemodialysis, routine recipients of clotting factors, health care workers exposed to potentially infected blood or blood products, individuals living and working in institutions for the mentally handicapped, travelers to highly endemic countries, persons at elevated risk for sexually transmitted diseases, injection drug users, and household contacts of known carriers of hepatitis B surface antigen. HepA vaccine is recommended for these same groups and for persons with clotting disorders or chronic liver disease. There are a number of other special-use vaccines whose administration is related to travel and occupational exposures (e.g., Japanese B encephalitis, typhoid, yellow fever, rabies); specific recommendations for the use of these vaccines in the United States can be found at www.cdc.gov/nip.

**Adverse Events** Given the success of vaccination programs and the virtual disappearance of many vaccine-preventable diseases in the United States, concerns about vaccine safety have sometimes become inflated in conjunction with complacency about the consequences of infection. An adverse reaction or vaccine side effect is an untoward effect caused by a vaccine that is extraneous to its primary purpose (to produce immunity). In contrast, an adverse event can be either a true vaccine reaction or a coincidental event. A small number of highly publicized claims unsubstantiated by valid data have heightened the suspicion that some or all vaccines routinely cause unacceptable adverse events. Antivaccine advocacy groups actively encourage avoidance of immunization because of the unproven belief that vaccines can cause certain disorders (e.g., autism). Websites maintained by such groups commonly appear in the first 10 listings identified by search engines. This situation presents a challenge to physicians and public health officials who must educate parents about vaccine benefits and risks.

In fact, modern vaccines, while safe and effective, are associated with adverse events that range from infrequent and mild to rare and
life-threatening. The decision to recommend the use of a vaccine involves an assessment of the risks of disease and the benefits and risks of vaccination. Because these factors may change over time, continual assessment of the balance between societal benefits and individual risks is essential. Valid and invalid contraindications to childhood immunization and appropriate precautions in the use of specific vaccines can be found at www.cdc.gov/nip/recs/contraindications.pdf.

Ironically, ongoing efforts to enhance vaccine safety through quality improvement and changes in vaccine policy (e.g., the decision to eliminate the mercury-based preservative thimerosal from vaccines) have actually led to an even greater awareness of the possible adverse events associated with routine vaccine administration. It has been claimed that increased rates of diabetes mellitus in the general pediatric population are due to an increase in exposure to vaccine antigens in childhood, although rigorous studies have refuted this hypothesis. A putative link of measles immunization to autism has been the subject of intense international controversy. The Institute of Medicine issued four recent reports whose findings (1) fail to support hypotheses that vaccines are associated with multiple sclerosis, neurodevelopmental disorders, or immune dysfunction; (2) provide no evidence for a temporal association of these conditions with vaccination; and (3) elucidate no biologically plausible basis for the purported relationships.

Within 9 months of the introduction of routine administration of the rhesus reassortant rotavirus vaccine (Rotashield) in the United States, cases of intussusception were reported by the CDC to be temporally associated with administration of the initial dose. This report led first to the cessation of the vaccine’s use and subsequently to the withdrawal of the vaccine from the market and the discontinuation of its production. Although other analyses have failed to support the association, rotavirus vaccine has not been introduced into developing countries, where the risk of any real increase in intussusception would be dramatically outweighed by the benefit of decreased rotavirus mortality.

The ramifications of these events for future vaccine development and introduction have yet to be assessed. Vaccine components, including protective antigens, animal proteins introduced during vaccine production, and antibiotics or other preservatives or stabilizers, can certainly cause allergic reactions in some recipients. These reactions may be local or systemic and include urticaria and serious anaphylaxis. The most common extraneous allergen is egg protein introduced when vaccines such as those for measles, mumps, influenza, and yellow fever are prepared in embryonated eggs. Gelatin, which is used as a heat stabilizer, has been implicated in rare but severe allergic reactions. Local or systemic reactions (probably due to antigen-antibody complexes) can result from too-frequent administration of vaccines such as Td, diphtheria/tetanus vaccine, or rabies vaccine. Because live-virus vaccines can interfere with tuberculin test responses, necessary tuberculin testing should be done either on the day of immunization or at least 6 weeks later. When influenza vaccine is given to children <13 years old, only “split-virus” preparations should be used since whole-virus vaccines are associated with higher rates of adverse reactions in this age group.

The U.S. government conducts vaccine safety surveillance through a network of active and passive reporting. All detected adverse events whose occurrence is temporally related to vaccination must be reported to both the local health department and the vaccine manufacturer. For the purpose of postlicensure passive surveillance of vaccines, health care providers are required to report certain suspected adverse events following the administration of a mandated vaccine to the FDA’s Vaccine Adverse Events Reporting System. The NCVIA has established criteria for reimbursable vaccine-related adverse events (www.hrsa.gov/osp/vacp/table.htm). Although a temporal relationship does not establish cause and effect, this surveillance system remains the only mechanism for collecting the data needed for analysis, conclusions, and decision-making. The CDC has established an active-surveillance system for ongoing evaluation of vaccine safety in large populations of vaccinated individuals. The Vaccine Safety Datalink is a population-based network in which four large health maintenance organizations (HMOs) continuously monitor immunization records linked to the medical records of 600,000 children <7 years of age.

**USE OF VACCINES IN SPECIAL CIRCUMSTANCES**

**Influenza Pandemic Preparedness**  
Influenza pandemics occur at irregular intervals and are characterized by excess deaths, hospitalizations, public concern, and social and economic disruption. A National Preparedness Plan has been developed to assess the incidence of disease and the antigenic characteristics of the prevalent strain and to promote flexibility in vaccine manufacture and vaccination. This plan is based on enhancement of current capacities for virologic surveillance, disease surveillance, and emergency medical responses.

**Pregnancy**  
Because of the theoretical risk to the fetus and the real risk of litigation to the practitioner, routine immunization of pregnant women is best avoided. However, wherever hygienic conditions during delivery cannot be guaranteed, it is essential to ensure that pregnant women are immune to tetanus because the transfer of maternal anti-toxin is an important means of preventing neonatal tetanus. Pregnant women can safely receive tetanus as well as diphtheria toxoids. Live-virus vaccines, such as rubella, measles, mumps, and varicella, should be withheld during pregnancy. However, if the risk of exposure is great, polio and yellow fever vaccines may be safely administered. If indicated, some inactivated vaccines (e.g., HepB, influenza, and pneumococcal vaccines) may be given during the second and third trimesters of pregnancy (Fig. 107-3).

**Breast Feeding**  
Neither killed nor live vaccine affects the safety of breast feeding for either mother or infant. Breast-fed infants can be immunized on a normal schedule.

**Occupational Exposure**  
Immunization recommendations for most occupational groups remain to be developed. Specific practices are now mandated by the Occupational Safety and Health Administration for the immunization of health care workers against hepatitis B in the United States. Rubella is transmitted to and from health care workers in medical facilities, particularly in pediatric practice. Health care workers who might transmit rubella to pregnant patients should be immune to rubella; it is prudent to screen these employees for antibodies to rubella virus and to immunize susceptible individuals. Persons providing health care are also at greater risk from measles and varicella than the general public, and those who are likely to come into contact with measles- and varicella-infected patients should be im-
HIV Infection and Other Immunocompromised States

Limited studies in HIV-infected individuals have found no increase in the risk of adverse events from live or inactivated vaccines. However, immune responses may not be as vigorous in immunocompromised individuals as in those with a normal immune system. Persons known to be infected with HIV should be immunized with recommended vaccines in the same manner as individuals with a normal immune system and as early in the course of their disease as possible, before immune function becomes significantly impaired (Fig. 107-3). Live attenuated MMR vaccine can be administered to this group. When vaccination against polio is indicated, IPV should be administered to immunocompromised HIV-infected individuals and to their household contacts. Albeit prudent, it is not necessary in practice to test for HIV before making decisions about the immunization of asymptomatic individuals from known HIV risk groups.

Live attenuated vaccines are also contra-indicated in other immunocompromised patients, including those with congenital immunodeficiency syndromes and those receiving immunosuppressive therapy. Passive immunization with immunoglobulin preparations or antitoxins can be considered in individual cases, either as postexposure prophylaxis or as part of the treatment of established infection.

Postexposure Immunization

For certain infections, active or passive immunization soon after exposure prevents or attenuates disease expression. Recommended postexposure immunization regimens are compiled in Table 107-6. Measles immune globulin given within 6 days of exposure may prevent or modify infection, and measles vaccine given within the first few days after exposure may prevent symptomatic infection. Although clinical manifestations of rubella in pregnant women are minimized by postexposure passive immunization, this approach may not prevent maternal viremia, fetal infection, and congenital rubella syndrome. Therefore, the administration of immune globulin is recommended only for women developing rubella during pregnancy who will not consider abortion under any circumstances. Proper immunization for tetanus plays an important role in wound management. The need for active immunization—with or without passive immunization—depends on the condition of the wound and the patient’s immunization history (Table 107-7). Rarely have cases of tetanus occurred in persons with a documented primary series of tetanus toxoid. Tetanus immune globulin is useful in patients with tetanus. Survivors with no history of tetanus immunization should receive a primary series of toxoid since disease does not produce protective levels of antitoxin. Administration of rabies immune globulin plus rabies vaccine in the immediate postexposure period is highly effective in preventing disease. Similarly, for persons who have not been actively immunized, the use of hepatitis A immune globulin within 2 weeks of exposure to hepatitis A is likely to prevent clinical illness. Sound data indicate the efficacy of human hepatitis B immune globulin in preventing disease after exposure. While no high-titer preparation is available for postexposure protection against non-A, non-B hepatitis, standard human immune serum globulin is efficacious.

Simultaneous Administration of Multiple Vaccines

There are no contraindications to the simultaneous administration of several vaccines. The use of combination vaccines can potentially reduce the required number of injections from 9 to 3 during a child’s first 6 months of life and from 21 to 13 during the first 2 years. Simultaneous administration of the most widely used live and inactivated vaccines has not resulted in impaired antibody responses or in increased rates of adverse reactions. Moreover, this approach increases the probability that a child will ultimately be fully immunized. Simultaneous administration is useful in any age group when the potential exists for exposure to multiple infectious diseases during travel to endemic countries. Combination DTaP/Hib vaccines should not be used for primary immunization of infants because the result is a blunted, suboptimal response to Hib; however, the combination may be used for booster immunizations.

\[\text{FIGURE 107-3 Recommended immunizations for adults with medical conditions—United States, 2002–2003. A. Vaccine may be given if pregnancy is at second or third trimester during influenza season. B. Although chronic liver disease and alcoholism are not indicator conditions for influenza vaccination, give 1 dose annually if the patient is \geq 50 years old, has other indications for influenza vaccine, or requests vaccination. C. Asthma is an indicator condition for influenza vaccination but not for pneumococcal vaccination. D. Vaccinate all persons with chronic liver disease. E. Revaccinate once after \approx 5 years have elapsed since initial vaccination. F. Persons with impaired humoral (not cellular) immunity may be vaccinated [\text{MMWR} 1999; 48 (RR-06), 1–5]. G. Hemodialysis patients: Use special formulation of vaccine (40 \mu g/mL) or two 1.0-ml, 20-\mu g doses given at one site. Vaccinate early in the course of renal disease. Assess antibody titers to hepatitis B surface antigen annually; administer additional doses if titers decline to \lt 10 milliU/mL. H. Also administer pneumococcal vaccine. I. In persons undergoing elective splenectomy, vaccinate at least 2 weeks before surgery. J. Vaccinate as close to diagnosis as possible, when CD4+ cell counts are highest. K. Withhold MMR or other measles-containing vaccines from HIV-infected persons with evidence of severe immunosuppression [\text{MMWR} 1995; 45, 603–606; \text{MMWR} 1992; 41 (RR-17), 1–19]. (Approved by the Advisory Committee on Immunization Practices and accepted by the American College of Obstetricians and Gynecologists and the American Academy of Family Physicians.)}\]
When live-virus vaccines are not given together on the same day, an interval of at least 30 days should be allowed.

Because high doses of immune globulin may inhibit the efficacy of measles and rubella vaccines, an interval of at least 3 months is recommended between the administration of immune globulin and that of MMR vaccine or its components. Postpartum vaccination of rubella-susceptible women should not be delayed because of the administration of anti-Rho(D) immune globulin or any other blood product during the last trimester or at delivery. Should administration of an immune globulin preparation become necessary after vaccination, it should be postponed, if possible, for at least 14 days to allow time for vaccine-virus replication and development of immunity. In general, there is little interaction of immune globulin with inactivated vaccines, and postexposure passive prophylaxis can be given together with HepB vaccine or tetanus toxoid, resulting in both immediate and long-lasting protection.

Travel (See also Chap. 108) The International Sanitary Regulations allow countries to impose requirements for yellow fever and killed cholera vaccines, as a condition for admission, even though the latter is not an effective public health tool. Travelers should know whether these vaccines are required for entry into the countries on their itinerary to avoid being turned back or immunized on the spot, with the inherent danger of unsafe injections. Infants, children, and adults should have all routine immunizations updated before traveling, with particular attention to polio, measles, and DTaP vaccines. The use of HepA vaccine may be advisable for travelers to some locales. Special-use vaccines (Table 107-5), including rabies, meningococcal polysaccharide, typhoid, Japanese B encephalitis, and plague vaccines, should be considered for those individuals who expect to go beyond the usual tourist routes or to spend extended periods in rural areas in disease-endemic regions. Most U.S. cities have travel clinics that maintain up-to-date epidemiologic information and can provide the appropriate vaccines. The CDC also maintains a website for travelers (www.cdc.gov/travel).

**DELIVERY OF VACCINES** Over the past 25 years, considerable progress has been made to ensure that every child in the United States is fully immunized by the time of school entry. All 50 states now require immunization for school entry, and most have laws addressing attendance at preschools and day-care centers. Despite the dramatic impact of immunization and of other improvements in the health care provided to the American population on the incidence of vaccine-preventable illness (Table 107-1), many children are not fully immunized—both in poor communities (as a result of inadequate health services) and in affluent communities (where parental concern about potential adverse events may exceed concern about now-uncommon diseases). The failure to vaccinate preschool children was largely responsible for the resurgence of measles in the United States between 1989 and 1991, with >55,000 cases and >130 measles-related deaths. Outbreaks of pertussis, mumps, and congenital rubella syndrome have occurred wherever immunization rates among preschool children are low. While measles (36 cases in 2002) and rubella (14 cases in 2002) have reached historic lows, the risk of imported infection and spread to susceptibles persists.

**ACCESS TO IMMUNIZATION** Four major barriers to infant and childhood immunization have been identified within the health care system: (1) low public awareness and lack of public demand for immunization, (2) inadequate access to immunization services, (3) missed opportunities to administer vaccines, and (4) inadequate resources for public health and preventive programs. These problems are sources of public concern, and their solution must be a priority for national health policy in the United States. At the national level, outreach and educational campaigns promote parental awareness of the value of vaccination and encourage health care providers to use every opportunity to vaccinate the children in their care. At the state and local levels, community and business groups, religious and service groups, schools, and the media have joined together in community-based networks. Those who remain unvaccinated do so largely because health care practices and providers do not always perform optimally in delivering vaccines. The AFIX Program (Assessment of coverage, Feedback of diagnostic information, Incentives or recognition, and eXchange of information among providers) is one effort by the CDC to change the attitude of health care personnel who lack an appreciation of the value of immunization in their practices to one of awareness, concern, and knowledge. The CDC has also developed two approaches to immunization assessment: CASA (Clinic Assessment Software Application) and LQA (Lot Quality Assessment). CASA requires review of up to 200 immunization records to assess whether record keeping and documentation are adequate, whether children start their vaccine series on time, whether and when patients drop out of the system, whether recall is used effectively, and whether vaccines are given simultaneously. LQA requires the review of only 30 records and does not yield a precise immunization rate or a diagnosis of the problem. A National Immunization Week each April has been established to focus attention on the vacc-

### TABLE 107-6 Recommended Postexposure Immunization with Immunoglobulin Preparations in the United States

<table>
<thead>
<tr>
<th>Disease</th>
<th>Indicated</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Measles</td>
<td>Yes</td>
<td>Standard human immune globulin is recommended for exposed infants and adults with normal immunocompetence (but with a contraindication to measles vaccine) and for immunocompromised patients exposed to measles (regardless of immunization status). Patients should be actively immunized 3 to 6 months after immunoglobulin administration. Recommended dose: 0.25–0.50 mL/kg (40–80 mg of IgG/kg) IM; 80 mg of IgG/kg for immunocompromised contact; maximum, 15 mL.</td>
</tr>
<tr>
<td>Rubella</td>
<td>No</td>
<td>Efficacy is unreliable; therefore, standard human immune globulin is recommended for administration only to antibody-negative pregnant women in the first trimester who have a documented rubella exposure and will not consider terminating the pregnancy. Recommended dose is 0.55 mL/kg (90 mg of IgG/kg) IM.</td>
</tr>
<tr>
<td>Tetanus</td>
<td>Yes</td>
<td>Human tetanus immune globulin (TIG) has replaced equine tetanus antitoxin because of the risk of serum sickness with equine serum. Recommended dose for postexposure prophylaxis is 250–500 units of TIG (10–20 mg of IgG/kg) IM. Recommended dose for treatment of tetanus is 3000–6000 units of TIG IM.</td>
</tr>
<tr>
<td>Rabies</td>
<td>Yes</td>
<td>Human rabies immune globulin (RIG) is preferred over equine rabies antiserum because of the risk of serum sickness with equine serum. RIG or antiserum is recommended for nonimmunized individuals with animal bites in whom rabies cannot be ruled out and with other exposures to known rabid animals. Recommended dose of RIG is 20 IU/kg (22 mg of IgG/kg). Recommended dose of antiserum is 40 IU/kg. Rabies vaccine is given as well at 0, 3, 7, 14, and 28 days.</td>
</tr>
<tr>
<td>Hepatitis A</td>
<td>Yes</td>
<td>Standard immune globulin serum is given in a single dose of 0.02–0.04 mL/kg or (for continuous exposure) in a dose up to 0.06 mL/kg every 5 months. Postexposure treatment with hepatitis A immune globulin has not been studied.</td>

immunization needs of infants and children. To improve the quality and quantity of vaccination services, expanded immunization-clinic hours and computerization of immunization records have been implemented as well. State-mandated school-entry immunity requirements have also helped to raise population immunity.

Although special vaccination target groups (e.g., college students, military personnel, and health care workers) have been successfully immunized, there has been only modest progress toward immunization goals for older adults in the United States. As many as 60,000 adults die each year of vaccine-preventable diseases for which effective vaccines are not being optimally used. More than 30% of persons >65 years of age do not receive influenza vaccine each year, and even fewer have ever received pneumococcal vaccine. Health care providers more often miss vaccination opportunities with adults than with infants and children. From 60 to 90% of adults hospitalized for or dying of influenza-associated respiratory disease have received medical care during the previous year and could have been immunized at that time. Medicare reimbursement for excess hospitalization during influenza epidemics ranges from $750 million to $1 billion. Additional efforts are required to ensure that adults receive Td and HepB vaccines as well.

Recent childhood vaccine shortages in the United States have prompted federal authorities to recommend deferring some vaccinations and have caused states to reduce vaccination requirements. Efforts to resolve supply-and-demand issues have yielded plans to increase national stockpiles of vaccines.

</tbody>
</table>

**HANDLING OF VACCINES** Vaccines must be handled and stored with care. Vaccines should be kept at 2° to 8°C and, with the exception of varicella vaccine, should not be frozen. Varicella should be kept frozen at −15°C. Measles vaccine must be protected from light, which inactivates the virus.

**STANDARDS FOR IMMUNIZATION PRACTICE** National standards of immunization for adult and pediatric practice have been established to define common policies and practices for public health clinics and physicians’ private offices (Table 107-8). These standards highlight the need to distinguish between valid contraindications and conditions that are often considered to be but are not in fact contraindications (www.cdc.gov/nip/recs/contraindications.pdf). Among the valid contraindications applicable to all vaccines are a history of anaphylaxis or other serious allergic reactions to a vaccine or vaccine component and the presence of a moderate or severe illness, with or without fever. Infants who develop encephalopathy within 72 h of a dose of DTP or DTaP should not receive further doses; those who develop a “precaution” should not normally receive further doses. Because of theoretical risks to the fetus, pregnant women should not receive MMR or varicella vaccine. Diarrhea, minor respiratory illness (with or without fever), mild to moderate local reactions to a previous dose of vaccine, the concurrent or recent use of antimicrobial agents, mild to moderate malnutrition, and the convalescent phase of an acute illness are not valid contraindications to routine immunization. Failure to vaccinate children because of these conditions is increasingly viewed as a missed opportunity for immunization.

**THE NATIONAL VACCINE INJURY COMPENSATION PROGRAM** The use of mandated vaccines benefits society as a whole by reducing morbidity and the cost of care for preventable diseases and by reducing childhood mortality. Thus, in the United States, society has assumed the obligation to care for those injured by the administration of mandated vaccines. The NCVIA of 1986 (modified in 1995 and 2002) is the instrument in use to ensure both fairness to injured persons and protection for federal, state, and local immunization programs; private immunization providers; and vaccine manufacturers. The act was designed to implement two vital public policies: (1) to provide prompt and fair compensation to the families of children who have died or have been injured as a result of routine mandated immunization; and (2) to reduce the adverse impact of the tort system on vaccine supply, cost, and innovation/development. The success of immunization programs in the United States depends upon the continued viability of the National Vaccine Injury Compensation Program.
CONTROL OF VACCINE-PREVENTABLE DISEASE

A continuing task of public health practice is to maintain individual and herd immunity. The job is not over once a population is fully vaccinated; rather, it is imperative to immunize each subsequent generation as long as the threat of the reintroduction of the disease from anywhere in the world persists. Ongoing surveillance and prompt reporting of disease to local or state health departments are essential to this goal, ensuring a continuing awareness of the possibility of vaccine-preventable illness. Nearly all vaccine-preventable diseases are notifiable, and individual case data are routinely forwarded to the CDC. These data are used to detect outbreaks or other unusual events that require investigation and to evaluate prevention and control policies, practices, and strategies.

RESEARCH ON VACCINES AND IMMUNIZATION

The potential to eliminate selected diseases and to build sustainable immunization programs that reach every child is not being fulfilled with existing vaccines and delivery technology. New vaccines or new formulations that will not only improve protective responses but also simplify the immunization schedule are needed. The ideal would be vaccines that can be administered orally early in life, that provide lifelong protection against multiple infections, that can be given as one or only a few doses, and that are less reactive and more heat stable than current vaccines. Diseases for which safe and effective vaccines have not been achieved represent the more difficult immunologic challenges and mark the frontiers of vaccine development. To attain these ambitious goals may take decades. However, progress is already being made in combining current vaccines to facilitate complete immunization, and prototypes of new vaccines are being assessed in early clinical trials. The results will be applicable to immunization programs in both developed and developing countries.

REEMERGENCE OF CONTROLLED DISEASE AND EMERGENCE OF NEW DISEASE

The emergence of new pathogens is fostered by the genetic potential of microbes to evolve and exchange genetic material as well as by rapid changes in human demographics and behavior and in global ecology that create new or more favorable niches and hosts. Proof of the need for continuing vaccine research is provided by the emergence of new infectious diseases, including HIV infection, Lyme borreliosis, hantavirus pulmonary syndrome, hepatitis C, and—most recently—the severe acute respiratory syndrome (SARS) caused by a coronavirus; the sudden outbreak of epidemic cholera due to a previously unknown serotype (O139 Bengal); and the increase in global incidence and drug resistance of familiar diseases that were once considered under control (e.g., tuberculosis and malaria). In addition, some common illnesses without a previously known etiology, such as peptic ulcer disease and cervical and nasopharyngeal cancer, have now been epidemiologically linked to specific infectious agents and thus, by definition, are vaccine-preventable conditions.

NEW VACCINE APPROACHES

The first generation of vaccines included whole killed bacteria, partially purified microbial products that induced protective antibodies (e.g., tetanus and diphtheria toxoids), or live attenuated microorganisms. The second generation of vaccines has taken advantage of molecular genetics and protein chemistry; purified proteins or subunits of organisms have been isolated and manipulated, and genetically engineered and attenuated live native organisms have been generated, as have cloned antigens expressed by harmless vector organisms. One conceptual leap is the production of edible transgenic plants (e.g., potatoes, bananas) that express protective vaccine antigens (as a result of insertion of the relevant microbial genes) and that, when eaten, induce mucosal and systemic immune responses to homologous infectious challenges. While the practical use of this technique awaits further refinement, the concept that protective immunity can be induced in this manner has been proved in both animals and humans. Ease of production, stability, ease of administration without equipment, and low cost are the obvious advantages.

Another conceptual leap has led to a third generation of vaccines, in which nucleic acids (either DNA or RNA) are used to induce immunity. The principle is simple and offers many advantages (Table 107-9). First, a DNA plasmid containing the gene sequence for the immunogenic protein or fragment of interest is assembled and placed under the control of a strong promoter and an appropriate transcription termination sequence. A single immunization with the plasmid by a number of possible routes results in DNA uptake into cells, where the gene is expressed and processed normally. The resulting protein product of the vaccine DNA induces an immune response. It should be possible to manipulate the DNA construct, its mode of administration, or the coadministration of cytokine genes to drive a Th1, Th2, or cytotoxic T cell response that optimizes the protective immune response. Recently, a technique known as prime-boost has been used to convert antibody responses to an antigen into cell-mediated responses. In prime-boost, a priming dose—most often naked DNA encoding the antigen of interest—is followed at the optimal interval by the same DNA inserted into a viral vector (e.g., the modified vaccinia virus vector MVA). DNA vaccines may be particularly useful for the induction of tumor immunity, for the treatment of allergy by suppression of IgE production, or for gene therapy. Because RNA is less stable and does not persist or integrate into the chromosome or result in insertional mutagenesis, the value of RNA vaccines would be to diminish concerns about adverse events associated with the effects of DNA integration into the chromosome (Table 107-9). These virtues of RNA paradoxically represent the hurdles to overcome in producing stable, inexpensive, and effective RNA vaccines.

INTERNATIONAL CONSIDERATIONS

Since the establishment of the Expanded Programme on Immunization (EPI) by the World Health Organization (WHO) in 1981 and the involvement of UNICEF in the program’s implementation, levels of coverage for the recommended basic children’s vaccines (bacille Calmette-Guérin, poliomyelitis, DTP/DTaP, and measles) have risen from 5 to ~80% worldwide, although coverage does not necessarily translate into protective immunity. Each year, at least 2.7 million deaths from measles, neonatal tetanus, and pertussis and 200,000 cases of paralysis due to polio are prevented by immunization. Despite the successes of this program, many vaccine-preventable diseases remain prevalent in the developing world. Measles, for example, continues to kill an estimated 800,000 children each year, and diphtheria, whooping cough, polio, and neonatal tetanus still occur at unacceptably high rates. An estimated 20 to 35% of all deaths of children <5 years old are still associated with vaccine-preventable diseases.

In addition to the antigens included in the EPI for routine use in the developing world, others (hepatitis B, Hib, Japanese B encephalitis, yellow fever, meningococcus, mumps, and rubella) are used re-

...
According to the World Tourism Organization, the number of international tourist arrivals in 2001 amounted to 693 million—the highest figure ever documented. Not only are more people traveling; travelers are seeking more exotic and remote destinations. In 1999, more than 75 million people traveled from industrialized to developing countries; this figure represents a 50% increase from 1993. Studies show that between 50 and 75% of short-term travelers to the tropics or subtropics report some health impairment. Most of these health problems are minor, with only 5% requiring medical attention and fewer than 1% requiring hospitalization. Although infectious agents contribute substantially to morbidity among travelers, these pathogens account for only ~1% of deaths in this population. Cardiovascular disease and injuries are the most frequent causes of death among travelers from the United States, accounting for 49 and 22% of deaths, respectively. Age-specific rates of death due to cardiovascular disease are similar among travelers and nontravelers. In contrast, rates of death due to injury (the majority from motor vehicle, drowning, or aircraft accidents) are several times higher among travelers. Figure 108-1 summarizes the monthly incidence of health problems during travel in developing countries.

**HEALTH ADVICE FOR INTERNATIONAL TRAVEL**

J.S. Keystone, P.E. Kozarsky

### GENERAL ADVICE

Staying healthy during travel requires familiarity with the various health risks that may be encountered at a given destination. However, health maintenance recommendations are based not only on the traveler’s destination but also on risk assessment, which is determined by health status, specific itinerary, and lifestyle during travel. Detailed information regarding country-specific risks and recommendations may be obtained from the Centers for Disease Control and Prevention (CDC) publication *Health Information for International Travel* (www.cdc.gov/travel).

Fitness for travel is an issue of growing concern in view of the increased numbers of elderly and chronically ill individuals journeying to exotic destinations (see “Travel and Special Hosts,” below). Since most commercial aircraft are pressurized to 2500 m (8000 ft) above sea level (corresponding to a PaO of ~55 mmHg), individuals with serious cardiopulmonary problems should be evaluated before travel. In addition, those who have recently had surgery, a myocardial infarction, a cerebrovascular accident, or a deep-vein thrombosis (among other events) may be at high risk for adverse events in flight. A summary of current recommendations regarding fitness to fly has been

**IMMUNIZATIONS FOR TRAVEL** Immunizations for travel fall into three broad categories: routine (childhood/adult boosters that are necessary regardless of travel), required (immunizations that are mandated by international regulations for entry into certain areas or for border crossings), and recommended (immunizations that are desirable because they confer protection against a variety of illnesses for which travel increases the risk). Vaccines commonly given to travelers are listed in Table 108-1.

**Routine Immunizations**

- **Diphtheria, Tetanus, and Polio**

  Diphtheria continues to be a problem worldwide; large outbreaks have occurred over the past decade in the independent states formerly encompassed by the Soviet Union. Serosurveys show that tetanus antitoxin is lacking in many North Americans, especially in women over the age of 50. The risk of polio to the international traveler is extremely low, and wild poliovirus has been eradicated from the western hemisphere and Europe. However, studies in the United States have found varying levels of immunity in the general population, and data suggest that 12% of adult travelers from the United States are unprotected against at least one poliovirus serogroup. Foreign travel offers an ideal opportunity to have these immunizations updated.

**Measles**

Measles (rubeola) continues to be a major cause of morbidity and mortality in the developing world (Chap. 176). Several outbreaks of measles in the United States have been linked to imported cases. The group at highest risk consists of persons born after 1956 and vaccinated before 1980, in many of whom primary vaccination failed. Travelers in this group should be reimmunized.

**Influenza**

Influenza occurs year-round in the tropics and during the summer months in the southern hemisphere (coinciding with the winter months in the northern hemisphere). Vaccination should be considered for all travelers to these regions, particularly those who are elderly or chronically ill. The largest outbreak of travel-related influenza occurred in the summer of 1998 in Alaska and the Northwest Territories of Canada among cruise ship passengers and staff. Such outbreaks continue to occur; unfortunately, however, influenza vaccine is generally not available during the summer months in the United States (Chap. 171).

**Pneumococcal Infection**

Pneumococcal vaccine should be administered routinely to persons at high risk of serious infection, such as individuals with chronic heart, lung, or renal disease and those who have been splenectomized or have sickle cell disease.

**Required Immunizations**

- **Yellow Fever**

  Documentation of yellow fever vaccination may be required as a condition of entry into or passage through countries of sub-Saharan Africa and equatorial South America, where the disease is endemic or epidemic, or into countries that are at risk of having the infection introduced. This vaccine is given only by state-authorized yellow fever centers, and its administration must be documented on an official International Certificate of Vaccination. In Africa, the risk of yellow fever has been estimated to be as high as 1 case per 267 travelers per 2-week stay during epidemics and as low as 1 case per 2000 travelers per 2-week stay where the disease is endemic. The incidence of yellow fever among travelers is extremely low, probably because the vaccine is highly efficacious. However, recent data suggest that fewer than 50% of travelers entering areas endemic for yellow fever are immunized, and both American and European travelers have died of this very serious illness on their return home. It is also of concern that yellow fever—endemic areas may be expanding. Education about the importance of preventing this illness is crucial.

**Cholera**

According to the World Health Organization, cholera vaccination should no longer be required for en-
try into any country. The inactivated injectable vaccine is no longer available in the United States.

**Meningococcal Meningitis** Protection against meningitis (using the quadrivalent polysaccharide vaccine) is required for entry into Saudi Arabia during the Hajj.

**Recommended Immunizations**  
- **Hepatitis A and B**  
  Hepatitis A is the most frequent vaccine-preventable infection of travelers; Swiss data show that the incidence of symptomatic infection during a 1-month stay in a developing country ranges from 3 to 6 cases per 1000. The risk is six times greater for travelers who stray from the usual tourist routes. The results of a recent Canadian study showed that rates of hepatitis A among short-term vacationers to Mexico and the Caribbean were considerably lower (1 case per 10,000 to 20,000 travelers per month of stay). The mortality rate for hepatitis A increases with age, reaching almost 3% among symptomatic individuals over age 50. Of the four hepatitis A vaccines currently available in North America (two in the United States), all are interchangeable and have an efficacy rate of >95%. The monthly incidence of hepatitis B infection, both symptomatic and asymptomatic, is 80 to 240 cases per 100,000. For reasons that are not entirely clear, long-stay overseas workers are at considerable risk for hepatitis B infection. A combined hepatitis A and B vaccine is now available and has been approved for administration on a 3-week accelerated schedule in Canada and Europe.

**Typhoid Fever** The attack rate for typhoid fever is 1 case per 30,000 per month of travel to the developing world (Chap. 137). However, the attack rates in India, Senegal, and North Africa are tenfold higher; in these areas, rates are especially high among travelers to relatively remote destinations and among persons who are returning to their home-lands to stay with relatives or friends. Between 1994 and 1999 in the United States, 77% of imported cases involved the latter group. The two available vaccines—one oral and the other injectable—have an efficacy rate of ~70%.

**Meningococcal Meningitis** Although the risk of meningococcal disease among travelers has not been quantified, it is likely to be higher among travelers who live with poor indigenous populations in overcrowded conditions. Meningococcal polysaccharide vaccine is recommended for persons traveling to sub-Saharan Africa during the dry season or to areas of the world where there are epidemics. The vaccine, which protects against serogroups A, C, Y, and W-135, has an efficacy rate of >90%.

**Japanese Encephalitis** The risk of Japanese encephalitis, an infection transmitted by mosquitoes in rural Asia and Southeast Asia, is ~1 case per 5000 travelers per month of stay in an endemic area. Most symptomatic infections among U.S. residents have involved military personnel or their families. The vaccine efficacy rate is >90%; serious allergic reactions sometimes occur. The vaccine is recommended for persons staying >1 month in rural endemic areas.

**Cholera** The risk of cholera is extremely low, with ~1 case per 500,000 journeys to endemic areas. Cholera vaccine, no longer available in the United States, was rarely recommended but was considered for aid and health care workers in refugee camps or in disaster/war-torn areas. A more effective oral cholera vaccine is available in other countries.

**Rabies** Many cases of rabies have been reported in travelers, but there are no data on the risk of infection. Domestic animals, primarily dogs, are the major transmitters of rabies in developing countries (Chap. 179). Several studies have shown that the risk of rabies posed by a dog bite in an endemic area ranges from 1 to 3.6 cases per 1000 travelers per month of stay. Countries where canine rabies is highly endemic include Mexico, the Philippines, Sri Lanka, India, Thailand, and Vietnam. The three vaccines available in the United States provide >90% protection. Rabies vaccine is recommended for long-stay travelers, particularly children, and persons who may be occupationally exposed to rabies in endemic areas.

**Prevention of Malaria and Other Insect-Borne Diseases** It is estimated that more than 30,000 American and European travelers develop malaria each year (Chap. 195). The risk of malaria is highest in Oceania and sub-Saharan Africa (estimated at 1:5 and 1:50 per month of stay, respectively, among persons not using chemoprophylaxis) and during the past decade has increased by more than fivefold for travelers to Kenya. The risk is intermediate (1:250 to 1:1000 per month) for travelers to malarious areas on the Indian subcontinent and in Southeast Asia and is low (1:2500 to 1:10,000 per month) for travelers to South and Central America. Of the more than 1000 cases of malaria reported annually in the United States, 90% of those due to *Plasmodium falciparum* occur in travelers returning or immigrating from Africa and Oceania. With the worldwide increase in chloroquine- and multidrug-resistant falciparum malaria, decisions about chemoprophylaxis have become more difficult. In addition, the spread of malaria due to primaquine- and chloroquine-resistant strains of *Plasmodium vivax* has added to the complexity of treatment. The case-fatality rate of falciparum malaria in the United States is 4%; however, in only one-third of patients who die is the diagnosis of malaria considered before death.

Several recent studies indicate that fewer than 50% of travelers adhere to basic recommendations for malaria prevention. Keys to the prevention of malaria include both personal protection measures against mosquito bites, especially during dusk and dawn, and malaria chemoprophylaxis. The former measures include the use of DEET-containing insect repellents, permethrin-impregnated bed-nets and clothing, screened sleeping accommodations, and protective clothing. These practices also help prevent other insect-transmitted illnesses, such as dengue fever. Over the past decade, the incidence of dengue has increased, particularly in the Caribbean region, Latin America, and Southeast Asia. Dengue virus is transmitted by an urban-dwelling mosquito that bites at dawn and dusk.

The decision about whether to use malaria prophylaxis is based on the traveler’s destination; the particular medication is determined by the destination as well as the traveler’s preference and medical history. Table 108-2 lists the currently recommended drugs of choice for prophylaxis of malaria, by destination. Primaquine is an alternative medication used for prophylaxis by some physicians; although popular in parts of Europe, the chloroquine/proguanil combination is not recommended because of its low efficacy.

**Prevention of Gastrointestinal Illness** Diarrhea, the leading cause of illness in travelers (Chap. 113), is usually a short-lived, self-limited condition; however, 40% of affected individuals need to alter their scheduled activities, and another 20% are confined to bed. The most important determinant of risk is the destination. Incidence rates per 2-week stay have been reported to be as low as 8% in industrialized countries and as high as 55% in parts of Africa, Central and South America, and Southeast Asia. Infants and young adults are at particularly high risk. The incidence of diarrhea is proportional to the number of days spent in a country.
ber of dietary indiscretions. Studies of U.S. students in Mexico showed that eating meals in restaurants and cafeterias or consuming food from street vendors was associated with increased risk.

**Etiology** (See also Table 113-2) The most frequently identified pathogen causing traveler’s diarrhea is toxigenic *Escherichia coli*, although in some parts of the world (notably northern Africa and Southeast Asia) *Campylobacter* infections appear to predominate. Other common causative organisms include *Salmonella*, *Shigella*, rotavirus, and the Norwalk agent. Except for giardiasis, parasitic infections are uncommon causes of traveler’s diarrhea. A growing problem for travelers is the development of antibiotic resistance by many bacterial pathogens, including strains of *Campylobacter* resistant to quinolones and strains of *E. coli*, *Shigella*, and *Salmonella* resistant to trimethoprim-sulfamethoxazole.

**Precautions** Although the mainstay of prevention of traveler’s diarrhea involves food and water precautions, the literature has repeatedly documented dietary indiscretions in 98% of travelers within the first 48 h after arrival at their destination. The maxim “Boil it, cook it, peel it, or forget it!” is easy to remember but apparently difficult to follow. General food and water precautions include eating foods piping hot; avoiding foods that are raw, poorly cooked, or sold by street vendors; and drinking only boiled or commercially bottled beverages, particularly those that are carbonated. Heating kills diarrhea-causing organisms, whereas freezing does not; therefore, ice cubes made from unpurified water should be avoided.

**Self-Treatment** (See also Table 113-4) As traveler’s diarrhea often occurs despite rigorous food and water precautions, travelers should carry medications for self-treatment. For mild to moderate diarrhea, loperamide and fluid replacement may be sufficient. An antibiotic is useful in reducing the frequency of bowel movements and duration of illness in moderate to severe diarrhea. The standard regimen is a 3-day course of a quinolone taken twice daily (or, in the case of some newer formulations, once daily). However, studies have shown that a single double dose of a quinolone may be equally effective, particularly if infection with a multidrug-resistant organism is not suspected. For diarrhea acquired in areas such as Thailand, where >90% of *Campylobacter* infections are quinolone resistant, azithromycin may be a better alternative.

**Prophylaxis** Prophylaxis of traveler’s diarrhea with bismuth subsalicylate is widely used but only ~60% effective. For certain individuals (e.g., athletes, persons with a repeated history of traveler’s diarrhea, and persons with chronic diseases), a single daily dose of a quinolone during travel of <1 month’s duration is highly effective.

**Illness after Return** Although extremely common, acute traveler’s diarrhea is usually self-limited or amenable to antibiotic therapy. Persistent bowel problems after the traveler returns home have a less well-defined etiology and may require medical attention from a specialist. Infectious agents appear to be responsible for only a small proportion of cases with persistent bowel symptoms. Of the pathogens detected in these instances, *Giardia lamblia* (Chap. 199) is by far the most common; *Cyclospora cayetanensis*, *Cryptosporidium* species, and *Entamoeba histolytica* are rarely isolated. Studies suggest that enteric-adherent *E. coli* may be important. By far the most frequent causes of persistent diarrhea after travel are postinfectious sequelae, such as lactose intolerance or an irritable bowel syndrome. In the latter, intermittent diarrhea often alternates with constipation. When no infectious etiology can be identified, a trial of metronidazole therapy for presumed giardiasis, a strict lactose-free diet for 1 week, or a several-week trial of high-dose hydrophilic muciloid (plus lactulose for persons with constipation) relieves the symptoms of many patients.

**Prevention of Other Travel-Related Problems** Travelers are at high risk for sexually transmitted diseases. Surveys have shown that large numbers engage in casual sex, and there is a reluctance to use condoms consistently. An increasing number of travelers are being diagnosed with *schistosomiasis*. Travelers should be cautioned to avoid bathing, swimming, or wading in freshwater lakes, streams, or rivers in parts of tropical South America, the Caribbean, Africa, and Southeast Asia where this infection can be acquired. Prevention of travel-associated injury depends mostly on common-sense precautions. Riding on motorcycles and in overcrowded public vehicles is not recommended; in particular, individuals should not travel by road after dark in rural areas. In addition to its association with motor vehicle accidents, excessive alcohol use has been a significant factor in drownings, assaults, and injuries. Travelers are cautioned to avoid walking barefoot because of the risk of hookworm and *Strongyloides* infections (Chap. 201) and snakebites (Chap. 378).

**THE TRAVELER’S MEDICAL KIT** A traveler’s medical kit is strongly advisable, particularly for long-stay travelers. The contents may vary widely, depending on the itinerary, duration of stay, style of travel, and local medical facilities. While many medications are available abroad, often over the counter, directions for their use may be nonexistent or in a foreign language, or a product may be outdated or counterfeit. Therefore, if possible, a complete supply of medications should accompany the traveler. In the kit, the short-term traveler should consider carrying an analgesic, an anti-diarrheal agent, antihistamines, a laxative, oral rehydration salts, a sunscreen with a skin-protection factor of at least 30, a DEET-containing insect repellent for the skin, an insecticide for clothing (permethrin), and (if necessary) an antimarial drug. To these medications the long-stay traveler might add a broad-spectrum general-purpose antibiotic (levofloxacin or azithromycin), an antibacterial eye and skin ointment, and a topical antifungal cream. Regardless of the duration of travel, a first-aid kit containing such items as scissors, tweezers, and bandages should be considered.

**TRAVEL AND SPECIAL HOSTS**

**PREGNANCY AND TRAVEL** A woman’s medical history and itinerary, the quality of medical care at her destinations, and her degree of flexibility determine whether travel is wise during pregnancy. According to the American College of Obstetrics and Gynecology, the safest part of pregnancy in which to travel is between 18 and 24 weeks, when there is the least danger of spontaneous abortion or premature labor. Some obstetricians prefer that women stay within a few hundred miles of home after the 28th week of pregnancy in case problems arise; in general, however, healthy women may be advised that it is acceptable to travel.

Despite this general recommendation, there are some relative contraindications to international travel during pregnancy, including certain obstetric risk factors: a history of miscarriage, premature labor, incompetent cervix, or toxemia. General medical problems such as diabetes, heart failure, severe anemia, or a history of thromboembolic disease should also prompt the pregnant woman to postpone her travel. Finally, regions in which the pregnant woman and her fetus may be at excessive risk (e.g., those at high altitudes and those where live-virus vaccines are required or where multidrug-resistant malaria is endemic) are not ideal destinations during any trimester.

**Malaria** Malaria during pregnancy carries a significant risk of morbidity and death. Levels of parasitemia are highest and failure to clear the parasites after treatment is most frequent among *Plasmodium* species. Severe disease, with complications such as cerebral malaria, massive hemolysis, and renal failure, is especially likely in pregnancy. Fetal sequelae include spontaneous abortion, stillbirth, preterm delivery, and congenital infection.

**Traveler’s Diarrhea** Because dehydration due to traveler’s diarrhea can lead to inadequate placental blood flow, pregnant travelers must be extremely cautious regarding their food and beverage intake. The exclusive consumption of bottled (carbonated) or boiled drinks without ice, the eating of well-cooked meats and pasteurized dairy products, and the avoidance of pre-prepared salad items should help protect
against traveler’s diarrhea due to the usual causes as well as against infections such as toxoplasmosis, hepatitis E, and listeriosis, which can have serious sequela in pregnancy.

The mainstay of therapy for traveler’s diarrhea is rehydration. Loperamide may be used if necessary, but many of the usual antibiotics are contraindicated during pregnancy. Amoxicillin alone or with clavulanic acid may be used, but many strains of E. coli and other organisms implicated in traveler’s diarrhea are resistant. Azithromycin may be the best option.

Because of the major problems encountered when infants are given local foods and beverages, women are strongly encouraged to breastfeed when traveling with a neonate. A nursing mother with traveler’s diarrhea should not stop breast-feeding but should increase her fluid intake.

**Air Travel and High-Altitude Destinations**

Commercial air travel is not a risk to the healthy pregnant woman or to the fetus. Fetal oxygenation is not adversely affected by decreased cabin pressures because of the fetal hemoglobin dissociation curve; the higher radiation levels reported at altitudes of >10,500 m (>35,000 ft) should pose no problem to the healthy pregnant traveler. Since each airline has a policy regarding pregnancy and flying, it is best to check with the specific carrier when booking reservations. Domestic air travel is usually permitted until the 36th week, whereas international air travel is generally curtailed after the 32nd week.

There are no known risks for pregnant women who travel to high-altitude destinations and stay for short periods. However, there are likewise no data on the safety of pregnant women at altitudes of >4500 m (15,000 ft). Because of the harsh conditions usually associated with such trips, they are generally contraindicated for other reasons.

**The HIV-Infected Traveler**

The traveler infected with HIV is at special risk of serious infections due to a number of pathogens that may be more prevalent at travel destinations than at home. However, the degree of risk depends primarily on the state of the immune system at the time of travel. For persons whose CD4+ cell counts are normal or >500/µL, no data suggest a greater risk during travel than for persons without HIV infection. Individuals with AIDS (CD4+ cell counts of <200/µL) and others who are symptomatic need special counseling and should visit a travel medicine practitioner before departure, especially when traveling to the developing world.

Several countries now routinely deny entry to HIV-positive individuals, even though no data show that these restrictions decrease rates of transmission of the virus. In general, HIV testing is required of those individuals who wish to stay abroad >3 months or who intend to work or study abroad. Some countries will accept an HIV serologic test done within 6 months of departure, whereas others will not accept a blood test done at any time in the traveler’s home country. In addition, border officials often have the authority to make inquiries of individuals entering a country and to check the medications they are carrying. If a drug such as zidovudine is identified, the person may be barred from entering the country. Information on testing requirements for specific countries is available from consular offices but is subject to frequent change.

Health insurance policies should be checked to make sure they are valid for care in other countries. The HIV-positive traveler should strongly consider obtaining trip cancellation insurance and evacuation insurance in case of illness. It is ideal to have the name of a physician at the travel destination who is familiar with the treatment of patients with AIDS, as the clinical findings associated with infection may be atypical in a patient with AIDS, and several infections may exist simultaneously. The traveler should be encouraged to visit the physician promptly if problems arise.

**Immunizations**

All of the HIV-infected traveler’s routine immunizations should be up to date (Chap. 107). The response to immunization may be impaired at CD4+ cell counts of <200/µL (and in some cases at even higher counts). Thus HIV-infected persons should be vaccinated as early as possible to ensure adequate immune response to all vaccines. In patients receiving highly active antiretroviral therapy, at least 3 months must elapse before regenerated CD4+ cells can be considered fully functional; therefore, in these patients, vaccinations should be delayed, if possible, until the CD4+ cell count has been stable for this length of time. However, when the risk of illness is high or the sequelae of illness are serious, immunization is recommended. In certain circumstances, it may be prudent to check the adequacy of the serum antibody response before departure (e.g., yellow fever neutralization inhibition if exposure is unavoidable).

Because of the increased risk of infections due to *Streptococcus pneumoniae* and other bacterial pathogens that cause pneumonia following influenza, pneumococcal polysaccharide and influenza vaccines should be administered. The estimated rates of response to influenza vaccine are >80% among persons with asymptomatic HIV infection and <50% among those with AIDS.

In general, live attenuated vaccines are contraindicated for persons with immune dysfunction. Because measles (rubeola) can be a severe and lethal infection in HIV-positive patients, these patients should receive the measles vaccine (or the combination measles-mumps-rubella vaccine) unless they are severely immunocompromised (CD4+ cell count, <200/µL). Between 18 and 58% of symptomatic HIV-infected vaccinees develop adequate antibody titers, and between 50 and 100% of asymptomatic persons infected with HIV seroconvert. Immune globulin should be considered for measles-susceptible, severely immunosuppressed HIV-infected persons who are planning to travel to measles-endemic countries.

The decision of whether to administer any of the special vaccines to an HIV-infected traveler should be based on the individual’s risk. Inactivated vaccines can be administered without concern for safety but with concern about adequate protection. For example, data suggest that HIV-infected persons do not have as strong an antibody response to the meningococcal meningitis vaccine as uninfected persons. Moreover, few data are available on the efficacy of many of the other vaccines (e.g., those for hepatitis A and typhoid).

It is recommended that the live yellow fever vaccine not be given to HIV-infected travelers. Although the potential adverse affects of a live vaccine in an HIV-infected individual are always a consideration, there appear to have been no reported cases of illness in those who have inadvertently received this vaccine. Nonetheless, if the CD4+ cell count is <200/µL, an alternative itinerary that poses no risk of exposure to yellow fever is recommended. If the traveler is passing through or traveling to an area where the vaccine is required but the disease risk is low, a physician’s waiver should be issued. Bacille Calmette-Guérin vaccine should not be given because of reports of disseminated infection in HIV-infected persons.

A transient increase in viremia (lasting days to weeks) has been demonstrated in HIV-infected individuals following immunization with vaccines for such diseases as influenza, pneumococcal infection, and tetanus (Chap. 173). However, at this point, there is no evidence that this transient increase in HIV levels in the bloodstream is detrimental over time. Furthermore, it is likely that immune activation associated with infection with the live organisms in question would result in increases in viremia of greater magnitude and duration than those associated with vaccination. Therefore, the vaccination recommendations discussed above need not be modified at this time.

**Gastrointestinal Illness**

Decreased levels of gastric acid, abnormal gastrointestinal mucosal immunity, other complications of HIV infection, and medications taken by HIV-infected patients make traveler’s diarrhea especially problematic in these individuals. Traveler’s diarrhea is likely to occur more frequently, be more severe, and be more difficult to treat in association with HIV infection. *Salmonella*, *Shigella*, and *Campylobacter* infections are also more protracted and more often accompanied by bacterial bowel infections in HIV-infected patients.

*Cryptosporidium* (Chap. 199), a common cause of diarrhea in tropical countries, produces severe chronic diarrhea and cholecystitis with...
increased mortality among patients with AIDS. 

*Isospora belli* causes infections at high rates among AIDS patients in the developing world; this infection is associated with malabsorption, weight loss, and relapses after treatment. Persistent diarrhea due to microsporidiosis has been reported.

Because of these potential problems, the HIV-infected traveler must be careful to consume only appropriately prepared foods and beverages. In addition, this group of individuals may benefit from prophylaxis for traveler’s diarrhea, using bismuth subsalicylate or a daily antibiotic (ideally a quinolone derivative) for short-term travel to the developing world. If the traveler is already taking a sulfonamide prophylaxis for traveler’s diarrhea, using bismuth subsalicylate or a beverage. In addition, this group of individuals may benefit from self-treatment with a quinolone would be appropriate.

**Other Travel-Related Infections** Data are lacking on the severity of many vector-borne diseases in HIV-infected individuals. Malaria is especially severe in asplenic and certain immunocompromised hosts, including those with AIDS. *Babesia* infection is known to cause serious illness and to recur in HIV-infected patients; this tick-transmitted illness occurs in parts of the United States but is not known to be a widespread problem.

Visceral leishmaniasis (Chap. 196) has been reported in numerous HIV-infected travelers. The diagnosis may be difficult to make, given that splenomegaly and hypergulbinemia are often lacking and serologic results are frequently negative. This infection is difficult to treat, and its associated mortality is high. Even short-term travelers to southern Europe have developed the illness; thus the avoidance of sandy bites is critical.

Certain respiratory illnesses, such as histoplasmosis and coccidioidomycosis, cause greater morbidity and mortality among patients with AIDS than in the general population. Although tuberculosis is common among HIV-infected persons (especially in developing countries), the acquisition of this infection by the short-term traveler is not a major concern. The possibility of acquiring *Legionella* infections from spas should be considered, although no data confirm an increase in the severity of such infections in AIDS.

Finally, the HIV-infected traveler should always be cautious about safe sexual practices, which may help prevent both the transmission of HIV to others and the acquisition by the traveler of other sexually transmitted diseases that may be drug resistant or may result in serious sequelae (e.g., syphilis).

**Medications** Adverse events due to medications and drug interactions are common and raise complex issues for HIV-infected persons. Rates of cutaneous reaction (e.g., increased cutaneous sensitivity to sulfoo-namides) are unusually high among patients with AIDS. Physicians advising HIV-infected travelers need to consider the problems that may arise from the use of agents such as antimalarial drugs, medications for altitude acclimation, or antidiarrheal compounds. Since zidovudine is metabolized by hepatic glucuronidation, inhibitors of this process may elevate serum levels of the drug. Concomitant administration of mefloquine and ritonavir may result in decreased plasma levels of ritonavir. In contrast, no significant influence of concomitant mefloquine administration on plasma levels of indinavir or nelfinavir was detected in two HIV-infected travelers.

**CHRONIC ILLNESS, DISABILITY, AND TRAVEL** Chronic health problems should not prevent travel, but special measures can make the journey safer and more comfortable.

**Heart Disease** Cardiovascular events are the main cause of deaths among travelers and of in-flight emergencies on commercial aircraft. Persons with underlying heart disease should review their itineraries with a physician prior to departure; travel in harsh environments or to remote destinations is not wise. Extra supplies of all medications should be kept in carry-on luggage, along with a copy of a recent electrocardiogram and the name and telephone number of the traveler’s physician at home. Pacemakers are not affected by airport security devices, but electronic telephone checks of pacemaker function cannot be transmitted by international satellites. The traveler may benefit from supplemental oxygen, which should be ordered by a physician (since oxygen delivery systems are not standard) 48 to 72 h before flight time. Personal oxygen tanks are not permitted aboard aircraft. Travelers should request aisle seating and should walk, perform stretching and flexing exercises, and remain hydrated during the flight to prevent venous thrombosis and pulmonary embolism.

**Chronic Lung Disease** Chronic obstructive pulmonary disease is one of the most common diagnoses in patients who require emergency-room evaluation for symptoms occurring during airline flights. Patients with such disease experience dyspnea, edema, wheezing, cyanosis, and chest pain. The best predictor of the development of these symptoms is the sea level PaO2. A PaO2 of at least 72 mmHg corresponds to an in-flight arterial PaO2 of ~55 mmHg when the cabin is pressurized to 2500 m (8000 ft). Therefore, if the traveler’s baseline PaO2 is <72 mmHg, the provision of supplemental oxygen during the flight should be considered. Pulmonary function is also maximized by continuing bronchodilator treatment and the use of glucocorticoids as prescribed. Contraindications to flight include active bronchospasm, lower respiratory infection, lower-limb deep-vein phlebitis, pulmonary hypertension, and recent thoracic surgery (within the preceding 3 weeks) or pneumothorax. Consideration should be given to decreasing the amount of outdoor activity at the destination if there is excessive air pollution.

**Diabetes Mellitus** Alterations in glucose control and changes in insulin requirements are common problems among patients with diabetes who travel. Changes in time zone, in the amount and timing of food intake, and in physical activity demand more vigilant assessment of metabolic control. The traveler with diabetes should pack medication (including a bottle of regular insulin for emergencies), insulin syringes and needles, equipment and supplies for glucose monitoring, and snacks in carry-on luggage. Insulin is stable for ~3 months at room temperature but should be kept as cool as possible. The name and telephone number of the home physician and a card and necklace listing the patient’s medical problems and the type and dose of insulin used should accompany the traveler. When six or more time zones are crossed, insulin requirements may be temporarily altered, depending on food intake and physical activity. In traveling eastward (e.g., from the United States to Europe), the morning insulin dose on arrival may need to be decreased. The blood glucose can then be checked during the day to determine whether additional insulin is required. For flights westward, with lengthening of the day, an additional dose of regular insulin may be required. Comfortable footwear is essential for the traveler with diabetes.

**Other Special Groups** Other groups for whom special travel measures are encouraged include patients undergoing dialysis, those with transplants, and those with other disabilities. Up to 13% of travelers have some disability, but few advocacy groups and tour companies dedicate themselves to this growing population. The key to safe travel in each case is adequate research ahead of time. Patients undergoing chronic ambulatory peritoneal dialysis may ship their dialysis solutions to their destinations before traveling. They should carry essential medical records as well as antibiotics for self-treatment of presumed peritonitis. Hemodialysis patients need to reserve appointments at dialysis centers prior to their departure from home. Travel by transplant recipients to distant destinations should ideally be scheduled at least 1 year after surgery, as most rejection episodes occur early. Medication interactions are a source of serious concern for these travelers, and appropriate medical information should be carried, along with the home physician’s name and telephone number. Some travelers taking glucocorticoids carry stress doses in case they become ill. Immunization of those transplants may be contraindicated. Patients with marginal renal function may have inadequate metabolism of certain medications and should be closely monitored. Patients with diabetes and high blood glucose levels may require additional medication. Travelers should be aware of and prepared for the various resources available to them, such as the Centers for Disease Control and Prevention’s website for travelers with disabilities.
PROBLEMS AFTER RETURN

The most common medical problems encountered by travelers after their return home are diarrhea, fever, respiratory illnesses, and skin diseases. Frequently ignored problems are fatigue and emotional stress, especially in long-stay travelers. The approach to diagnosis requires some knowledge of geographic medicine, in particular the epidemiology and clinical presentation of infectious diseases. A geographic history should focus on the traveler’s exact itinerary, including dates of arrival and departure; exposure history (food indiscretions, drinking-water sources, freshwater contact, sexual activity, animal contact, insect bites); location and style of travel (urban vs. rural, first-class hotel accommodation vs. camping); immunization history; and use of antimalarial chemoprophylaxis.

DIARRHEA
See “Prevention of Gastrointestinal Illness,” above.

FEVER
Fever in a traveler who has returned from a malarious area should be considered a medical emergency because death from *P. falciparum* malaria can follow an illness of only several days’ duration. Although “fever from the tropics” does not always have a tropical cause, malaria should be the first diagnosis considered. The risk of *P. falciparum* malaria is highest among travelers returning from Africa or Oceania and among those who become symptomatic within the first 2 months after return. Other important causes of fever after travel include viral hepatitis (hepatitis A and E), typhoid fever, bacterial enteritis, arbovirus infections (e.g., dengue fever), rickettsial infections (including tick and scrub typhus and Q fever), and—in rare instances—leptospirosis, acute HIV infection, and amebic liver abscesses. In at least 25% of cases, no etiology can be found, and the illness resolves spontaneously. Clinicians should keep in mind that no present-day antimalarial agent prevents protection from malaria and that some immunizations (notably, that against typhoid fever) are only partially protective.

As noted above, the approach to the febrile returned traveler begins with a detailed medical and geographic history. Knowing exact dates of arrival and departure from tropical areas enables the physician to ascertain the shortest and longest possible incubation periods for illnesses in the differential diagnosis. For example, a traveler who develops fever <1 week after arrival in a malaria-free area cannot have malaria because the incubation period is too short, whereas a fever whose onset occurs >2 weeks after departure from an endemic area cannot be dengue fever because the incubation period is too long. In the physical examination, particular attention should be given to the skin so as not to miss a subtle rash or eschar.

When no specific diagnosis is forthcoming, the following investigations, where applicable, are suggested: complete blood count, liver function tests, thick/thin blood films for malaria (repeated twice if necessary), urinalysis, urine and blood cultures (repeated once), chest x-ray, and collection of an acute-phase serum sample to be held for subsequent examination along with a paired convalescent-phase serum sample.

SKIN DISEASES
Pyodermas, sunburn, insect bites, skin ulcers, and cutaneous larva migrans are the most common skin conditions encountered in travelers after their return home. In those with persistent skin ulcers, a diagnosis of cutaneous leishmaniasis, mycobacterial infection, or fungal infection should be considered. Careful, complete inspection of the skin is important in detecting the rickettsial eschar in a febrile patient or the central breathing hole in “a boil” due to myiasis.

EMERGING INFECTIOUS DISEASES
In recent years, travel and commerce have fostered the worldwide spread of HIV infection, led to the re-emergence of cholera as a global health threat, and created considerable fear about the possible spread of Ebola virus infection and severe acute respiratory syndrome (SARS). For travelers, there are more realistic concerns. One of the largest outbreaks of dengue fever ever documented is now raging in Latin America; schistosomiasis is being described in previously unaffected lakes in Africa; and antibiotic-resistant strains of sexually transmitted and enteric pathogens are emerging as an alarming rate in the developing world. In addition, concerns have been raised regarding the potential for bioterrorism involving not only standard strains of unusual agents but mutant strains as well. Time will tell whether travelers (as well as persons at home) will routinely be vaccinated against diseases such as anthrax and smallpox. As Nobel Laureate Dr. Joshua Lederberg pointed out, “The microbe that felled one child in a distant continent yesterday can reach yours today and seed a global pandemic tomorrow.” The vigilant clinician understands that the importance of a thorough travel history cannot be overemphasized.

Section 2 Clinical Syndromes: Community-Acquired Infections

109 INFECTIVE ENDOCARDITIS
Adolf W. Karchmer

The proliferation of microorganisms on the endothelium of the heart results in infective endocarditis. The prototypic lesion at the site of infection, the vegetation (Fig. 109-1), is a mass of platelets, fibrin, microcolonies of microorganisms, and scant inflammatory cells. Infection most commonly involves heart valves (either native or prosthetic) but may also occur on the low-pressure side of the ventricular septum at the site of a defect, on the mural endocardium where it is damaged by aberrant jets of blood or foreign bodies, or on intracardiac devices themselves. The analogous process involving arteriovenous shunts, arterioarterial shunts (patent ductus arteriosus), or a coarctation of the aorta is called infective endarteritis.

Endocarditis may be classified according to the temporal evolution
of disease, the site of infection, the cause of infection, or a predisposing risk factor such as injection drug use. While each classification criterion provides therapeutic and prognostic insight, none is sufficient alone. The classification of endocarditis as acute and subacute was initially used to describe the illness and the time elapsed until death; presently it is applied to the features and progression of infection until diagnosis. Acute endocarditis is a hectic, febrile illness, rapidly damages cardiac structures, hemogenously seeds extracardiac sites, and, if untreated, progresses to death within weeks. Subacute endocarditis follows an indolent course; causes structural cardiac damage only slowly, if at all; rarely causes metastatic infection; and is gradually progressive unless complicated by a major embolic event or ruptured mycotic aneurysm.

In developed countries, the incidence of endocarditis ranges from 1.5 to 6.2 cases per 100,000 population per year. In the late 1980s in a metropolitan area of the United States (Philadelphia), endocarditis occurred in 9.3 persons per 100,000 population per year. However, half of these cases arose as a consequence of injection drug use. The incidence of endocarditis is notably increased among the elderly. The cumulative rate of prosthetic valve endocarditis is 1.5 to 3.0% at 1 year after valve replacement and 3 to 6% at 5 years; the risk is greatest during the first 6 months after valve replacement.

* Includes viridans streptococci; *Streptococcus bovis*; other non–group A, groupable streptococci; and *Abiotrophia* spp. (nutritionally variant, pyridoxal-requiring streptococci).

† Includes *Haeomophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp., and *Kingella kingae*.

**Note:** Data are compiled from multiple studies.

**FIGURE 109-1** Vegetations (arrows) due to viridans streptococcal endocarditis involving the mitral valve.

**ETIOLOGY** Many species of bacteria and fungi have been reported to cause sporadic episodes of endocarditis; nevertheless, a small number of bacterial species cause the majority of cases (Table 109-1). The causative microorganisms vary somewhat among the major clinical types of endocarditis, in part because of the different portals of entry. The oral cavity, skin, and upper respiratory tract are the respective primary portals for the viridans streptococci, staphylococci, and HACEK organisms (*Haeomophilus*, *Actinobacillus*, *Cardiobacterium Eikenella*, and *Kingella*) causing community-acquired native valve endocarditis. *Streptococcus bovis* originates from the gastrointestinal tract, where it is associated with polyps and colonic tumors, and enters the bloodstream from the genitourinary tract. Nosocomial native valve endocarditis is largely the consequence of bacteremia arising from intravascular catheters and less commonly from nosocomial wound and urinary tract infection. Endocarditis complicates 6 to 25% of episodes of catheter-associated *Staphylococcus aureus* bacteremia; the higher rates are detected by careful transesophageal echocardiography (TEE) screening (see “Echocardiography,” below).

Prosthetic valve endocarditis arising within 2 months of valve surgery is generally the result of intraoperative contamination of the prosthesis or a bactereemic postoperative complication. The nosocomial nature of these infections is reflected in their primary microbial causes: coagulase-negative staphylococci, *S. aureus*, facultative gram-negative bacilli, diphtheroids, and fungi. The portals of entry and organisms causing cases beginning >12 months after surgery are similar to those in community-acquired native valve endocarditis. Epidemiologic evidence suggests that prosthetic valve endocarditis due to coagulase-negative staphylococci that presents between 2 and 12 months after surgery is often nosocomial in origin but with a delayed onset. At least 85% of coagulase-negative staphylococci that cause prosthetic valve endocarditis within 12 months of surgery are methicillin-resistant; the rate of methicillin resistance decreases to 25% among coagulase-negative staphylococci causing prosthetic endocarditis that presents >1 year after valve surgery.

Transvenous pacemaker lead— and/or implanted defibrillator—associated endocarditis is usually a nosocomial infection. The majority of episodes occur within weeks of implantation or generator change and are caused by *S. aureus* or coagulase-negative staphylococci.

Endocarditis occurring among injection drug users, especially when infection involves the tricuspid valve, is commonly caused by *S. aureus* strains, many of which are methicillin-resistant. Left-sided valve infections in addicts have a more varied etiology and involve abnormal valves, often ones damaged by prior episodes of endocarditis. A number of these cases are caused by *Pseudomonas aeruginosa*.
and Candida species, and sporadic cases are due to unusual organisms such as Bacillus, Lactobacillus, and Corinebacterium species. Polymicrobial endocarditis occurs more frequently in injection drug users than in patients who do not inject drugs. The presence of HIV in this population does not significantly impact the causes of endocarditis.

From 5 to 15% of patients with endocarditis have negative blood cultures; in one-third to one-half of these cases, cultures are negative because of prior antibiotic exposure. The remainder of these patients are infected by fastidious organisms, such as pyridoxal-requiring streptococci (now designated Abiotrophia species), the gram-negative cocccobacillary HACEK organisms, Bartonella henselae, or Bartonella quintana. Some fastidious organisms that cause endocarditis have characteristic epidemiologic settings (e.g., Coxella burnetii in Europe, Brucella species in the Middle East). Tropheryma whippelii causes an indolent, culture-negative, alebrile form of endocarditis.

**PATHOGENESIS** Unless it is injured, the normal endothelium is resistant to infection by most bacteria and to thrombus formation. Endothelial injury (e.g., at the site of impact of high-velocity jets or on the low-pressure side of a cardiac structural lesion) causes aberrant flow and allows either direct infection by virulent organisms or the development of an uninfected platelet-fibrin thrombus—a condition called nonbacterial thrombotic endocarditis (NBTE). The thrombus subsequently serves as a site of bacterial attachment during transient bacteremia. The cardiac lesions most commonly resulting in NBTE are mitral regurgitation, aortic stenosis, aortic regurgitation, ventricular septal defects, and complex congenital heart disease. These lesions result from rheumatic heart disease (particularly in the developing world, where rheumatic fever remains prevalent), mitral valve prolapse, degenerative heart disease, and congenital malformations. NBTE also arises as a result of a hypercoagulable state; this phenomenon gives rise to the clinical entity of marantic endocarditis (uninfected vegetations seen in patients with malignancy and chronic diseases) and to bland vegetations complicating systemic lupus erythematosus and the antiphospholipid antibody syndrome.

Organisms that cause endocarditis generally enter the bloodstream from mucosal surfaces, the skin, or sites of focal infection. Except for more virulent bacteria (e.g., S. aureus) that can adhere directly to intact endothelium or exposed subendothelial tissue, microorganisms in the blood adhere to thrombi. If resistant to the bactericidal activity of serum and the microbicidal peptides released by platelets, the organisms proliferate and induce a procoagulant state at the site by eliciting tissue factor from adherent monocytes or, in the case of S. aureus, from monocytes and from intact endothelium. Fibrin deposition, resulting from tissue factor initiation of the coagulation cascade, combines with platelet aggregation, stimulated by tissue factor and independently by proliferating microorganisms, to generate an infected vegetation. The organisms that commonly cause endocarditis bear surface components that facilitate adherence to injured endothelium and host proteins or, in the case of S. aureus, to intact endothelial cells or to thrombi. Fibronectin-binding proteins present on many gram-positive bacteria, clumping factor (a fibrinogen- and fibrin-binding surface protein) on S. aureus, and glucans on streptococci facilitate adherence. Fibronectin-binding proteins are required for S. aureus invasion of intact endothelium; thus these surface proteins may facilitate infection of previously normal valves. In the absence of host defenses, organisms enmeshed in the growing platelet-fibrin vegetation proliferate to form dense microcolonies. Organisms deep in vegetations are metabolically inactive (nongrowing) and relatively resistant to killing by antimicrobial agents. Proliferating surface organisms are shed into the bloodstream continuously, whereupon some are cleared by the reticuloendothelial system and others are redeposited on the vegetation and stimulate further vegetation growth.

The pathophysiologic consequences and clinical manifestations of endocarditis—other than constitutional symptoms, which are probably a result of cytokine production—arise from damage to intracardiac structures; embolization of vegetation fragments, leading to infection or infarction of remote tissues; hematogenous infection of sites during bacteremia; and tissue injury due to the deposition of circulating immune complexes or immune responses to deposited bacterial antigens.

**CLINICAL MANIFESTATIONS** The clinical syndrome of infective endocarditis is highly variable and spans a continuum between acute and subacute presentations. Native valve endocarditis (whether acquired in the community or nosocomially), prosthetic valve endocarditis, and endocarditis due to injection drug use share clinical and laboratory manifestations (Table 109-2). Although the relationship is not absolute, the causative microorganism is primarily responsible for the temporal course of endocarditis. β-Hemolytic streptococci, S. aureus, and pneumococci typically result in an acute course, although S. aureus occasionally causes subacute disease. Endocarditis caused by Staphylococcus lugdunensis (a coagulase-negative species) or by enterococci may present acutely. Subacute endocarditis is typically caused by viridans streptococci, enterococci, coagulase-negative staphylococci, and the HACEK group. Endocarditis caused by Bartonella species and the agent of Q fever, C. burnetii, is exceptionally indolent.

The clinical features of endocarditis are nonspecific. However, these symptoms in a febrile patient with valvular abnormalities or a behavior pattern (injection drug use) that predisposes to endocarditis suggest the diagnosis, as do bacteremia with organisms that frequently cause endocarditis, otherwise-unexplained arterial emboli, and progressive cardiac valvular incompetence. In patients with subacute presentations, fever is typically low-grade and rarely exceeds 39.4°C (103°F). In contrast, temperatures between 39.4 and 40°C (103 and 104°F) are often noted in acute endocarditis. Fever may be blunted or absent in patients who are elderly or severely debilitated or who have marked cardiac or renal failure.

**Cardiac Manifestations** Although heart murmurs are usually indicative of the predisposing cardiac pathology rather than of endocarditis, valvular damage and ruptured chordae may result in new regurgitant murmurs. In acute endocarditis involving a normal valve, murmurs are heard on presentation in only 30 to 45% of patients but ultimately are detected in 85%. Congestive heart failure develops in 30 to 40% of patients; it is usually a consequence of valvular dysfunction but occasionally is due to endocarditis-associated myocarditis or an intracardiac fistula. The temporal progression of heart failure is variable; failure due to aortic valve dysfunction progresses more rapidly than that due to mitral valve dysfunction. Extension of infection beyond valve leaflets into adjacent annular or myocardial tissue results in peri-valvular abscesses, which in turn may cause fistulae (from the root of

</table>
the aorta into cardiac chambers or between cardiac chambers) with new murmurs. Abscesses may burrow from the aortic valve annulus through the epicardium, causing pericarditis. Extension of infection into paravalvular tissue adjacent to either the right or the noncoronary cusp of the aortic valve may interrupt the conduction system in the upper interventricular septum, leading to varying degrees of heart block. Although paravalvular abscesses arising from the mitral valve may potentially interrupt conduction pathways near the atrioventricular node or in the proximal bundle of His, such interruption occurs infrequently. Embolization to a coronary artery may result in myocardial infarction; nevertheless, embolic transmural infarcts are rare.

Noncardiac Manifestations The classic nonsuppurative peripheral manifestations of subacute endocarditis are related to the duration of infection and, with early diagnosis and treatment, have become infrequent. In contrast, septic embolization mimicking some of these lesions (subungual hemorrhage, Osler’s nodes) is common in patients with acute S. aureus endocarditis (Fig. 109-2). Musculoskeletal symptoms, including nonspecific inflammatory arthritis and back pain, usually remit promptly with treatment but must be distinguished from focal metastatic infection. Hematogenously seeded focal infection may involve any organ but most often is clinically evident in the skin, spleen, kidneys, skeletal system, and meninges. Arterial emboli are clinically apparent in up to 50% of patients. Vegetations >10 mm in diameter (as measured by echocardiography) and those located on the mitral valve are more likely to embolize than are smaller or nonmitral vegetations. Embolic events—often with infarction—involve the extremities, spleen, kidneys (Fig. 109-3), bowel, or brain are often noted at presentation. With antibiotic treatment, the frequency of embolic events decreases from 13 per 1000 patient-days during the initial week to 1.2 per 1000 patient-days after the third week. Emboli occurring late during or after effective therapy do not in themselves constitute evidence of failed antimicrobial treatment. Neurologic symptoms, most often resulting from embolic strokes, occur in up to 40% of patients. Other neurologic complications include aseptic or purulent meningitis, intracranial hemorrhage due to hemorrhagic infarcts or ruptured mycotic aneurysms, seizures, and encephalopathy. (Mycotic aneurysms are focal dilations of arteries occurring at points in the artery wall that have been weakened by infection in the vasa vasorum or where septic emboli have lodged.) Microabscesses in brain and meninges occur commonly in S. aureus endocarditis; surgically drainable abscesses are infrequent.

Immune complex deposition on the glomerular basement membrane causes diffuse hypocellular interstitial glomerulonephritis and renal dysfunction, which typically improve with effective antimicrobial therapy. Embolic renal infarcts cause flank pain and hematuria but rarely cause renal dysfunction.

Manifestations of Specific Predisposing Conditions In almost 50% of patients who have endocarditis associated with injection drug use, infection is limited to the tricuspid valve. These patients present with fever, faint or no murmur, and (in 75% of cases) prominent pulmonary findings, including cough, pleuritic chest pain, nodular pulmonary infiltrates, and occasionally pyopneumothorax. Infection involving valves on the left side of the heart presents with the typical clinical features of endocarditis.

Nosocomial endocarditis (defined as that which results from hospital care within the prior month and most commonly presenting as intravascular catheter–associated bacteremia), if not associated with a retained intracardiac device, has typical manifestations. Endocarditis associated with flow-directed pulmonary artery catheters is often cryptic, with symptoms masked by comorbid critical illness, and is commonly diagnosed at autopsy. Transvenous pacemaker lead– and/or implanted defibrillator–associated endocarditis commonly follows initial implantation or a generator unit change; may be associated with obvious or cryptic generator pocket infection; and results in fever, minimal murmur, and pulmonary symptoms similar to those encountered in addicts with tricuspid endocarditis.

Prosthetic valve endocarditis presents with typical clinical features. Cases arising within 60 days of valve surgery (early onset) lack peripheral vascular manifestations and may be obscured by comorbidity associated with recent surgery. In both early-onset and more delayed presentations, paravalvular infection is common and often results in partial valve dehiscence, regurgitant murmurs, congestive heart failure, or disruption of the conduction system.

**DIAGNOSIS** The Duke Criteria The diagnosis of infective endocarditis is established with certainty only when vegetations obtained at cardiac surgery, at autopsy, or from an artery (an embolus) are examined histologically and microbiologically. Nevertheless, a highly sensitive and specific diagnostic schema—known as the Duke criteria—has been developed on the basis of clinical, laboratory, and echocardiographic findings (Table 109-3). Documentation of two major criteria, of one major and three minor criteria, or of five minor criteria allows a clinical diagnosis of definite endocarditis. The diagnosis of endocarditis is rejected if an alternative diagnosis is established, if symptoms resolve and do not recur with ≤4 days of antibiotic therapy, or if surgery or autopsy after ≤4 days of antimicrobial therapy yields no histologic evidence of endocarditis. Illnesses not classified as definite endocarditis or rejected are considered cases of possible infective endocarditis when either one major and one minor criteria or three minor criteria are identified. Requiring the identification of clinical features of en-
microscopic examination with special stains (i.e., the periodic acid–Schiff stain for T. whipplei) and by use of polymerase chain reaction to recover unique microbial DNA or 16S rRNA.

**Echocardiography** Cardiac imaging with echocardiography allows anatomic confirmation of infective endocarditis, sizing of vegetations, detection of intracardiac complications, and assessment of cardiac function. A two-dimensional study with color flow and continuous wave Doppler is optimal. Transthoracic echocardiography (TTE) is noninvasive and exceptionally specific; however, it cannot image vegetations <2 mm in diameter, and in 20% of patients it is technically inadequate because of emphysema or body habitus. Thus, TTE detects vegetations in only 65% of patients with definite clinical endocarditis (i.e., it has a sensitivity of 65%). Moreover, TTE is not adequate for evaluating prosthetic valves or detecting intracardiac complications. TEE is safe and significantly more sensitive than TTE. It detects vegetations in >90% of patients with definite endocarditis; nevertheless, false-negative studies are noted in 6 to 18% of endocarditis patients. TEE is the optimal method for the diagnosis of prosthetic endocarditis or the detection of myocardial abscess, valve perforation, or intracardiac fistula.

Experts favor echocardiographic evaluation of all patients with a clinical diagnosis of endocarditis; however, the test should not be used to screen patients with otherwise-explained positive blood cultures or patients with unexplained fever. In patients with a low pretest likelihood of endocarditis (<5%), a high-quality TTE that is negative is sufficient to exclude endocarditis. For patients whose habitus makes them difficult to study with TTE and for those who may have prosthetic valve endocarditis or who are at high risk of intracardiac complications, TEE is the preferred imaging modality. For patients with a pretest probability of endocarditis ranging from 5 to 50%, initial evaluation by TEE—in lieu of a sequential strategy of TTE, which, if negative, will be followed by TEE—is cost-effective. A negative TEE when endocarditis is likely does not exclude the diagnosis but rather warrants repetition of the study in 7 to 10 days with optimal multiplanar technique.

**Other Studies** Many laboratory studies that do not aid in diagnostic evaluation are nevertheless important in the management of patients with endocarditis; these studies include complete blood counts, creatinine measurement, chest radiography, and electrocardiography. The erythrocyte sedimentation rate, C-reactive protein level, circulating immune complex titer, and rheumatoid factor concentration are commonly increased in endocarditis (Table 109-2). Cardiac catheterization is useful primarily to assess coronary artery patency in older individuals who are to undergo surgery for endocarditis.

# TREATMENT

### ANTIMICROBIAL THERAPY

It is difficult to eradicate bacteria from the atherosclerotic vegetation in infective endocarditis because this site is rel-
Aminoglycosides should not be administered as single daily doses and should be introduced as part of the initial treatment. Target peak and trough serum concentrations of gentamicin 1 h after a 20- to 30-min infusion or IM injection are 3–5 μg/mL and ≤1 μg/mL, respectively; the target peak serum concentration of streptomycin (timing as with gentamicin) is 20–25 μg/mL.

Although given for several weeks longer, the regimens recommended for the treatment of endocarditis involving prosthetic valves (except for staphylococcal infections) are similar to those used to treat native valve infection (Table 109-4). Recommended doses and duration of therapy should be adhered to unless alterations are required by adverse events.

Organism-Specific Therapies Streptococci Although most strains of viridans streptococci and S. bovis that cause endocarditis are susceptible to penicillin [minimum inhibitory concentration (MIC) ≤0.1 μg/mL], recent reports indicate increasing penicillin resistance among viridans streptococci recovered from blood cultures. In the selection of optimal therapy, the penicillin MIC must be determined (Table 109-4). The 2-

</table>

<sup>1</sup> Doses are for adults with normal renal function. Doses of gentamicin, streptomycin, and vancomycin must be adjusted for reduced renal function. Ideal body weight is used to calculate doses per kilogram (men = 50 kg + 2.3 kg per inch over 5 feet; women = 45.5 kg + 2.3 kg per inch over 5 feet).

<sup>2</sup> MIC ≤ 0.1 μg/mL.

<sup>3</sup> Aminoglycosides should not be administered as single daily doses and should be introduced as part of the initial treatment. Target peak and trough serum concentrations of gentamicin 1 h after a 20- to 30-min infusion or IM injection are 3–5 μg/mL and ≤1 μg/mL, respectively; the target peak serum concentration of streptomycin (timing as with gentamicin) is 20–25 μg/mL.

<sup>4</sup> Desirable peak vancomycin level 1 h after completion of a 1-h infusion is 30–45 μg/mL.

<sup>5</sup> MIC > 0.1 μg/mL and <0.5 μg/mL.

<sup>6</sup> MIC ≥ 0.5 μg/mL and <8.0 μg/mL.

<sup>7</sup> Antimicrobial susceptibility must be evaluated; see text.

<sup>8</sup> Rifampin increases warfarin and dicumarol requirements for anticoagulation.
week penicillin/gentamicin regimen should not be used to treat complicated native valve infection or prosthetic valve endocarditis. Although small studies have suggested that a 2-week regimen of single daily doses of ceftriaxone (2 g IV) plus gentamicin (3 mg/kg) or netilmicin (4 mg/kg) is effective for penicillin-susceptible streptococcal endocarditis, the data are not sufficient to support routine use of this regimen. Penicillin/gentamicin is recommended for the treatment of endocarditis caused by group B streptococci.

**ENTEROCOCCI** Enterococci are resistant to oxacillin, nafcillin, and the cephalosporins and are inhibited only by penicillin, ampicillin, teicoplanin (not available in the United States), and vancomycin. To kill enterococci requires the synergistic interaction of a cell wall–active antibiotic (penicillin, ampicillin, vancomycin, or teicoplanin) that is effective at achievable serum concentrations and an aminoglycoside (gentamicin or streptomycin) to which the isolate does not exhibit high-level resistance. An isolate’s resistance to cell wall–active agents (gentamicin or streptomycin) to which the isolate does not exhibit antibiotic (penicillin, ampicillin, vancomycin, or teicoplanin) that is penicillin (not available in the United States), and vancomycin. To kill cephalosporins and are inhibited only by penicillin, ampicillin, teicoplanin or streptomycin at 2000 μg/mL—a phenomenon called *high-level aminoglycoside resistance*—indicates that the ineffective antimicrobial cannot participate in the interaction to produce killing. High-level resistance to gentamicin predicts that tobramycin, netilmicin, amikacin, and kanamycin will also be ineffective. In fact, even when enterococci are not highly resistant to gentamicin, it is difficult to predict the ability of these other aminoglycosides to participate in synergistic killing; consequently, they should not in general be used to treat enterococcal endocarditis.

Clearly, enterococci causing endocarditis must be tested for high-level resistance to streptokinase and gentamicin, β-lactamase production, and susceptibility to penicillin and ampicillin (MIC ≤ 16 μg/mL) and to vancomycin (MIC ≤ 8 μg/mL). If the isolate produces β-lactamase, ampicillin/sulbactam or vancomycin can be used as the cell wall–active component; if the penicillin/ampicillin MIC is >16 μg/mL, vancomycin can be considered; and if the vancomycin MIC is >8 μg/mL, penicillin or ampicillin may be considered. Based on the absence of high-level resistance, gentamicin or streptomycin should be used as the aminoglycoside. If there is high-level resistance to both these drugs, no aminoglycoside should be given; instead, an 8- to 12-week course of a single cell wall–active agent is suggested. If single-drug therapy fails or the isolate is resistant to all of the commonly used agents, surgical treatment is advised. The role of newer agents potentially active against multidrug-resistant enterococci (quinupristin/dalfopristin, linezolid, and daptomycin) in the treatment of endocarditis has not been established. Although the dose of gentamicin used to achieve bactericidal synergy in treating enterococcal endocarditis is smaller than that used in standard therapy, nephrotoxicity is not uncommon during treatment with recommended regimens for 4 to 6 weeks. Regimens wherein gentamicin treatment has been truncated at 2 to 3 weeks because of nephrotoxicity have been curative. Thus, discontinuation of gentamicin is recommended when progressive nephrotoxicity develops in patients with enterococcal endocarditis who have responded satisfactorily to therapy.

**STAPHYLOCOCCI** The regimens used to treat staphylococcal endocarditis are not based upon coagulase production but rather upon the presence or absence of a prosthetic valve or foreign device, the native valve(s) involved, and the resistance of the isolate to penicillin and methicillin. Penicillinase is produced by 95% of staphylococci; thus, all isolates should be considered penicillin-resistant until shown not to produce this enzyme. The addition of gentamicin (if the isolate is susceptible) to a β-lactam antibiotic to enhance therapy for native mitral or aortic valve endocarditis is optional. Its addition hastens eradication of bacteremia but does not improve survival rates. If added, gentamicin should be limited to the initial 3 to 5 days of therapy to avoid nephrotoxicity. Gentamicin generally is not added to the vancomycin regimen in this setting.

Methicillin-resistant *S. aureus* endocarditis that is uncomplicated and limited to the tricuspid or pulmonic valve—a condition occurring almost exclusively in injection drug users—can often be treated with a 2-week course that combines oxacillin or nafcillin (but not vancomycin) with gentamicin. Prolonged fevers (>5 days) during therapy suggest that these patients should receive standard therapy.

Staphyloccocal prosthetic valve endocarditis is treated for 6 to 8 weeks with a multidrug regimen. Rifampin is an essential component because it kills staphylococci that are adherent to foreign material. Two other agents (selected on the basis of susceptibility testing) are combined with rifampin to prevent in vivo emergence of resistance. Because many staphyloccoci, particularly methicillin-resistant *S. aureus* and *S. epidermidis*, are resistant to gentamicin, the utility of gentamicin should be established before rifampin treatment is begun. If the isolate is resistant to gentamicin, another aminoglycoside or a fluoroquinolone (chosen in light of susceptibility results) should be substituted.

**OTHER ORGANISMS** Endocarditis caused by *Streptococcus pneumoniae*, with a penicillin MIC ≤ 1.0 can be treated with intravenous penicillin (4 million units every 4 h), ceftriaxone (2 g/d as a single dose), or cefotaxime (at a comparable dosage). Infection caused by strains with a penicillin MIC ≥ 2.0 should be treated with vancomycin. Until the strain’s susceptibility to penicillin is established, therapy should consist of vancomycin plus ceftriaxone, especially if concurrent meningitis is suspected. *P. aeruginosa* endocarditis is treated with an antibiotic against *P. aeruginosa* and tobramycin (8 mg/kg per day in three divided doses). Endocarditis caused by *Enterobacteriaceae* is treated with a potent β-lactam antibiotic plus an aminoglycoside. *Corynebacterial* endocarditis is treated with penicillin plus an aminoglycoside (if the organism is susceptible to the aminoglycoside) or with vancomycin, which is highly bactericidal for most strains. Therapy for *Candida* endocarditis consists of amphotericin B plus flucytosine and early surgery; long-term (if not indefinite) suppression with fluconazole is used increasingly.

**Empirical Therapy** In designing and executing therapy without culture data (i.e., before culture results are known or when cultures are negative), clinical and epidemiologic clues to etiology must be weighed, and both the pathogens associated with the specific endocarditis syndrome and the hazards of suboptimal therapy must be considered. Thus, empirical therapy for acute endocarditis in an injection drug user should cover methicillin-resistant *S. aureus* and gram-negative bacilli. The initiation of treatment with vancomycin plus gentamicin immediately after blood is obtained for cultures covers these as well as many other potential causes. In treating culture-negative episodes, marantic endocarditis must be excluded and fastidious organisms sought serologically. In the absence of confounding prior antibiotic therapy, it is unlikely that *S. aureus*, coagulase-negative staphylococcal, or enterococcal infection will present with negative blood cultures. Thus, in this situation, these organisms are not the determinants of therapy for subacute endocarditis. Blood culture–negative subacute native valve endocarditis is treated with ceftriaxone plus gentamicin; these two antimicrobials plus vancomycin should be used if prosthetic valves are involved.

**Outpatient Antimicrobial Therapy** Fully compliant patients who have sterile blood cultures, are afebrile during therapy, and have no clinical or echocardiographic findings that suggest an impending complication may complete therapy as outpatients. Careful follow-up and a stable home setting are necessary, as are predictable intravenous access and selection of antimicrobials that are stable in solution.

**Monitoring Antimicrobial Therapy** The serum bactericidal titer—the highest dilution of the patient’s serum during therapy that kills 99.9% of the standard inoculum of the infecting organism—is no longer recommended for assessment of patients receiving standard regimens. However, in the treatment of endocarditis caused by unusual organisms, this measurement, although not standardized and difficult to interpret, may provide a patient-specific assessment of in vivo antibiotic effect. Serum concentrations of aminoglycosides and vancomycin should be monitored.
Surgery must be carefully considered; findings are often combined with other indications. Antibiotic toxicities, including allergic reactions, occur in 25 to 40% of patients and commonly arise during the third week of therapy. Blood tests to detect antibiotic-specific potential end-organ toxicity should be performed periodically.

In most patients, effective antibiotic therapy results in subjective improvement and resolution of fever within 5 to 7 days. Blood cultures should be repeated daily until sterile, rechecked if there is recrudescence, fever, and performed again 4 to 6 weeks after therapy to document cure. Blood cultures become sterile within 2 days after the start of appropriate therapy when infection is caused by viridans streptococci, enterococci, or HACEK organisms. In S. aureus endocarditis, β-lactam therapy results in sterile cultures in 3 to 5 days, whereas positive cultures may persist for 7 to 9 days with vancomycin treatment. When fever persists for 7 days in spite of appropriate antibiotic therapy, patients should be evaluated for paravalvular abscess and for extra-cardiac abscesses (spleen, kidney) or complications (embolic events). Recrudescence fever raises the question of these complications but also of drug reactions or complications of hospitalization. Serologic abnormalities (e.g., erythrocyte sedimentation rate, rheumatoid factor) resolve slowly and do not reflect response to treatment. Vegetations become smaller with effective therapy, but at 3 months after cure half are unchanged and 25% are slightly larger.

### SURGICAL TREATMENT
Intracardiac and central nervous system complications of endocarditis are important causes of the morbidity and mortality associated with this infection. In some cases, effective treatment for these complications requires surgery. Most of the clinical indications for surgical treatment of endocarditis are not absolute (Table 109-5). The risks and benefits as well as the timing of surgical treatment must therefore be individualized (Table 109-6).

#### Intracardiac Surgical Indications
Most surgical interventions are warranted by intracardiac findings, often detected by echocardiography. Because of the highly invasive nature of prosthetic valve endocarditis, as many as 40% of affected patients merit surgical treatment. In many patients, coincident rather than single intracardiac events necessitate surgery.

**CONGESTIVE HEART FAILURE** Moderate to severe refractory congestive heart failure caused by new or worsening valve dysfunction is the major indication for cardiac surgical treatment of endocarditis. Of patients with moderate to severe heart failure due to valve dysfunction who are treated medically, 60 to 90% die within 6 months. In the setting of similar hemodynamic dysfunction, surgical treatment is associated with mortality rates of 20 to 40% with native valve endocarditis and 35 to 55% with prosthetic valve infection. Surgery may be required to relieve functional stenosis due to large vegetations or to restore competence to damaged regurgitant valves.

#### PERIVALVULAR INFECTION
This complication, which occurs in 10 to 15% of native valve and 45 to 60% of prosthetic valve infections, is suggested by persistent unexplained fever during appropriate therapy, new electrocardiographic conduction disturbances, and pericarditis. Extension can occur from any valve but is most common with aortic valve infection. TEE with color Doppler is the test of choice to detect perivalvular abscesses (sensitivity ≥ 85%). Although occasional perivalvular infections are cured medically, surgery is warranted when fever persists, fistulas develop, prostheses are dehisced and unstable, and invasive infection relapses after appropriate treatment. Cardiac rhythm must be monitored since high-grade heart block may require insertion of a pacemaker.

#### UNCONTROLLED INFECTION
Continued positive blood cultures or otherwise unexplained persistent fevers (in patients with either blood culture–positive or –negative endocarditis) despite optimal antibiotic therapy may reflect uncontrolled infection and warrant surgery. Surgical treatment is also advised for endocarditis caused by those organisms against which clinical experience indicates that effective antimicrobial therapy is still possible.

\[ \text{Prophylaxis is optional for high-risk patients undergoing bronchoscopy or gastrointestinal procedures.} \]

\[ \text{This category includes infections caused by yeasts, fungi, P. aeruginosa, other highly resistant gram-negative bacilli, Brucella species, and probably C. burnetii.} \]

\[ \text{S. aureus Endocarditis} \]

\[ \text{Mortality rates for S. aureus prosthetic valve endocarditis exceed 70% with medical treatment but are reduced to 25% with surgical treatment. In patients with intracardiac complications associated with S. aureus prosthetic valve infection, surgical treatment reduces mortality by twentyfold. Surgical treatment should be considered for patients with S. aureus native aortic or mitral valve infection who have TTE-demonstrable vegetations and septic emboli during the initial week of therapy. Isolated tricuspid valve endocarditis, even with persistent fever, rarely requires surgery.} \]

\[ \text{Prevention of Systemic Emboli} \]

\[ \text{Mortality and persisting morbidity due to emboli are largely limited to patients suffering occlusion of cerebral or coronary arteries. Echocardiographic determination of vegetation size and anatomy, although predictive of patients at high risk of systemic emboli, does not identify those patients in whom the benefits of surgery to prevent emboli clearly exceed the risks of the surgical procedure and an implanted prosthetic valve. Net benefits favoring surgery are most likely when the risk of embolism is high and other surgical benefits can be achieved simultaneously—e.g., repair of a moderately dysfunctional valve or debridement of a paravalvular abscess. Reduced overall risks of surgical intervention (e.g., use of vegetation resection and valve repair to avoid insertion of a prosthesis) make the benefit-to-risk ratio more favorable and this intervention more attractive.} \]

\[ \text{Timing of Cardiac Surgery} \]

\[ \text{In general, when indications for surgical treatment of infective endocarditis are identified, surgery should not be delayed simply to permit additional antibiotic therapy, since this course of action increases the risk of death (Table 109-6). Delay is justified only when infection is controlled and congestive heart failure is fully compensated with medical therapy. Recrudescence endocarditis involving a prosthetic valve follows surgery in 2% of patients with culture-positive native valve endocarditis and in 6 to 15% of patients with active prosthetic valve endocarditis. These risks are more acceptable than the high mortality rates that result when surgery is appropriately delayed or not performed.} \]

\[ \text{Among patients who have experienced a neurologic complication of endocarditis, further neurologic deterioration can occur as a consequence of cardiac surgery. The risk of significant neurologic exacerbation is related to the interval between the complication and surgery. Where feasible, cardiac surgery should be delayed for 2 to 3 weeks after a nonhemorrhagic embolic stroke and for 4 weeks after a} \]

\[ \text{Dosing for children: for amoxicillin, ampicillin, cephalexin, or cefadroxil, use 50 mg/kg PO; cefazolin, 25 mg/kg IV; clindamycin, 20 mg/kg PO, 25 mg/kg IV; clarithromycin, 15 mg/kg PO; gentamicin, 1.5 mg/kg IV or IM; and vancomycin, 20 mg/kg IV.} \]

\[ \text{For patients at high risk (Table 109-8), administer a half-dose 6 h after the initial dose. Do not use cephalosporins in patients with immediate hypersensitivity (urticaria, angioedema, anaphylaxis) to penicillin.} \]

\[ \text{Excludes esophageal procedures.} \]

\[ \text{Source: Adapted from AS Dajani et al: JAMA 277:1794, 1997; with permission.} \]
hemorrhagic embolic stroke. A ruptured mycotic aneurysm should be clipped and cerebral edema allowed to resolve prior to cardiac surgery.

**Extracardiac Complications** Splenic abscess develops in 3 to 5% of patients with endocarditis. Effective therapy requires either computed tomography–guided percutaneous drainage or splenectomy. Mycotic aneurysms occur in 2 to 15% of endocarditis patients; half of these cases involve the cerebral arteries and present as headaches, focal neurologic symptoms, or hemorrhage. Cerebral aneurysms should be monitored by angiography. Some will resolve with effective antimicrobial therapy, but those that persist, enlarge, or leak should be treated surgically if possible. Extracerebral aneurysms present as local pain, a mass, local ischemia, or bleeding; generally these aneurysms are treated by resection.

**OUTCOME** The outcome of infective endocarditis is affected by a variety of factors, some of which are interrelated. Factors with an adverse impact include older age, severe comorbid conditions, delayed diagnosis, involvement of prosthetic valves or the aortic valve, an invasive (S. aureus) or antibiotic-resistant (P. aeruginosa, yeast) pathogen, intracardiac complications, and major neurologic complications. Death and poor outcome often are related not to failure of antibiotic therapy but rather to the interactions of comorbidities and endocarditis-related end-organ complications. The overall survival rate for patients with native valve endocarditis caused by viridans streptococci, HACEK organisms, or enterococci (susceptible to synergistic therapy) ranges from 85 to 90%. For S. aureus native valve endocarditis in patients who do not inject drugs, survival rates are 55 to 70%, whereas 85 to 90% of injection drug users survive this infection. Prosthetic valve endocarditis beginning within 2 months of valve replacement results in mortality rates of 40 to 50%, whereas rates are only 10 to 20% in later-onset cases.

**PREVENTION** Antibiotics have been administered in conjunction with selected procedures considered to entail a risk for bacteremia and endocarditis. The benefits of antibiotic prophylaxis are not established and in fact may be modest: only 50% of patients with native valve endocarditis know that they have a valve lesion predisposing to infection, most endocarditis cases do not follow a procedure, and 35% of cases are caused by organisms not targeted by prophylaxis. Dental treatments, the procedures most widely accepted as predisposing to endocarditis, are no more frequent during the 3 months preceding this diagnosis than in uninfected matched controls. Nevertheless, an expert committee of the American Heart Association, along with similar advisory groups in other developed countries, has identified procedures that may precipitate bacteremia with organisms that cause endocarditis (Table 109-7); patients who should receive prophylaxis based on the relative risk for developing endocarditis and the severity of subsequent infection (Table 109-8); patients who are at low risk and do not require prophylaxis (Table 109-9), and regimens that may be used for prophylaxis (Table 109-10). Except for an isolated secundum atrial septal defect and a totally corrected patent ductus arteriosus, ventricular septal defect, or pulmonary stenosis, patients with congenital heart defects continue to experience high rates of endocarditis despite total surgical correction of the defect. In vulnerable patients, maintaining good dental hygiene and aggressively treating local infections may reduce the risk of endocarditis.

**FURTHER READING**

**ANATOMICAL RELATIONSHIPS: CLUES TO THE DIAGNOSIS OF SOFT TISSUE INFECTIONS**

Protection against infection of the epidermis is dependent on the mechanical barrier afforded by the stratum corneum, since the epidermis itself is devoid of blood vessels (Fig. 110-1). Disruption of this layer by burns or bites, abrasions, foreign bodies, primary dermatologic disorders (e.g., herpes simplex, varicella, and ecthyma gangrenosum), surgery, or vascular or pressure ulcer allows penetration of bacteria to the deeper structures. Similarly, the hair follicle can serve as a portal either for components of the normal flora (e.g., Staphylococcus) or for extrinsic bacteria (e.g., Pseudomonas in hot-tub folliculitis). Intracellular infection of the squamous epithelium with vesicle formation may arise from cutaneous inoculation, as in infection with herpes simplex virus (HSV) type 1; from the dermal capillary plexus, as in varicella and infections due to other viruses associated with viremia; or from cutaneous nerve roots, as in herpes zoster. Bacteria infecting the epidermis, such as Streptococcus pyogenes, may be translocated laterally to deeper structures via lymphatics, an event that results in the rapid superficial spread of erysipelas. Later, engorgement or obstruction of lymphatics causes flaccid edema of the epidermis, another characteristic of erysipelas.

The rich plexus of capillaries beneath the dermal papillae provides nutrition to the stratum germinativum, and physiologic responses of this plexus produce important clinical signs and symptoms. For ex-

**FIGURE 110-1** Structural components of the skin and soft tissue, superficial infections, and infections of the deeper structures. The rich capillary network beneath the dermal papillae plays a key role in the localization of infection and in the development of the acute inflammatory reaction.
amplified, infective vasculitis of the plexus results in petechiae, Osler’s nodes, Janeway lesions, and palpable purpura, which, if present, are important clues to the existence of endocarditis (Chap. 109). In addition, metastatic infection within this plexus can result in cutaneous manifestations of disseminated fungal infection (Chap. 187), gonococcal infection (Chap. 128), Salmonella infection (Chap. 137), Pseudomonas infection (i.e., erythema gangrenosum; Chap. 136), meningococcemia (Chap. 127), and staphylococcal infection (Chap. 120). The plexus also provides access for bacteria to the circulation, thereby facilitating local spread or bacteremia. The postcapillary venules of this plexus are a major site of polymorphonuclear leukocyte sequestration, diapedesis, and chemotaxis to the site of cutaneous infection.

Exaggeration of these physiologic mechanisms by excessive levels of cytokines or bacterial toxins causes leukostasis, venous occlusion, and pitting edema. Edema with purple bullae, ecchymosis, and cutaneous anesthesia suggests loss of vascular integrity and necessitates exploration of the deeper structures for evidence of necrotizing fasciitis or myonecrosis. An early diagnosis requires a high level of suspicion in instances of unexplained fever and of pain and tenderness in the soft tissue, of suspicion in instances of unexplained fever and of pain and tenderness in the soft tissue, even in the absence of acute cutaneous inflammation.

**INFECTIONS ASSOCIATED WITH VESICLES** (Table 110-1) Vesicle formation due to infection is caused by viral proliferation within the epidermis. In varicella and variola, viremia precedes the onset of a diffuse centrifetal rash that progresses from macules to vesicles, then to pustules, and finally to scabs over the course of 1 to 2 weeks. Vesicles of varicella have a “dewdrop” appearance and develop in crops randomly about the trunk, extremities, and face over 3 to 4 days (see Fig. 164-1). Herpes zoster occurs in a single dermatome; the appearance of vesicles is preceded by pain for several days (see Figs. 164-2 and 164-3). Zoster may occur in persons of any age but is most common among immunosuppressed individuals and elderly patients, whereas most cases of varicella occur in young children. Vesicles due to HSV are found on or around the lips (HSV-1) or genitals (HSV-2) but may appear on the head and neck of young wrestlers (herpes gladiatorum) or on the digits of health care workers (herpetic whitlow). Recurrent herpes labialis (HSV-1) and herpes genitalis are common following primary infection. Coxsackievirus A16 characteristically causes vesicles on the hands, feet, and mouth of children. Orf is caused by a DNA virus related to smallpox virus and infects the fingers of individuals who work around goats and sheep. Molluscum contagiosum virus induces flaccid vesicles on the skin of healthy and immunocompromised individuals. Although variola (smallpox) in nature was eradicated as of 1977, recent terrorist events have renewed interest in this devastat-

</table>
ing infection (see Chap. 205). Viremia beginning after an incubation period of 12 days is followed by a diffuse maculopapular rash, with rapid evolution to vesicles, pustules, and then scabs. Secondary cases can occur among close contacts.

Rickettsialpox begins after mite-bite inoculation of *Rickettsia akari* into the skin. A papule with a central vesicle evolves to form a 1- to 2.5-cm painless crusted black eschar with an erythematous halo and into the skin. A papule with a central vesicle evolves to form a 1- to 2.5-cm painless crusted black eschar with an erythematous halo.

**INFECTIONS ASSOCIATED WITH BULLAE** (Table 110-1) Staphylococcal scalded-skin syndrome (SSSS) in neonates is caused by a toxin (exfoliatin) from phage group II *S. aureus*. SSSS must be distinguished from toxic epidermal necrolysis (TEN), which occurs primarily in adults, is drug-induced, and has a higher mortality. Punch biopsy with frozen section is useful in making this distinction since the cleavage plane is the stratum corneum in SSSS (Fig. 110-1) and the stratum granulosum in TEN. Intravenous γ-globulin is a promising treatment for TEN. Necrotizing fasciitis and gas gangrene also induce bulla formation (see “Necrotizing Fasciitis,” below). Halophilic vibrio infection can be as aggressive and fulminant as necrotizing fasciitis; a helpful clue in its diagnosis is a history of exposure to waters of the Gulf of Mexico or the Atlantic seaboard or (in a patient with cirrhosis) the ingestion of raw seafood. The etiologic organism (*Vibrio vulnificus*) is highly susceptible to tetracycline.

**INFECTIONS ASSOCIATED WITH CRUSTED LESIONS** (Table 110-1) Impetigo contagiosa is caused by *S. pyogenes*, and bullous impetigo is due to *S. aureus* (see Fig. 121-2). Both skin lesions may have an early bullous stage but then appear as thick crusts with a golden-brown color. Strep-tococcal lesions are most common among children 2 to 5 years of age, and epidemics may occur in settings of poor hygiene, particularly among children of lower socioeconomic status in tropical climates. It is important to recognize impetigo contagiosa because of its relationship to poststreptococcal glomerulonephritis. Rheumatic fever is not a complication of skin infection caused by *S. pyogenes*. Superficial dermatophyte infection (ringworm) can occur on any skin surface, and skin scrapings with KOH staining are diagnostic. Primary infections with dimorphic fungi such as *Blastomyces dermatitidis* and *Sporothrix schenckii* can initially present as crusted skin lesions resembling ringworm. Disseminated infection with *Coccidioides immitis* can also involve the skin, and biopsy and culture should be performed on crusted lesions in patients from endemic areas. Crusted nodular lesions caused by *Mycobacterium chelonae* have been described in HIV-seropositive patients. Treatment with clarithromycin looks promising.

**FOLLICULITIS** (Table 110-1) Hair follicles serve as portals for a number of bacteria, although *S. aureus* is the most common cause of localized folliculitis. Sebaceous glands empty into hair follicles and ducts and, if blocked, form sebaceous cysts, which may resemble staphylococcal abscesses or may become secondarily infected. Infection of sweat glands (hidradenitis suppurativa) can also mimic infection of hair follicles, particularly in the axillae. Chronic folliculitis is uncommon except in acne vulgaris, where constituents of the normal flora (e.g., *Propionibacterium acnes*) may play a role.

Diffuse folliculitis occurs in two settings. “Hot-tub folliculitis” is caused by *Pseudomonas aeruginosa* in waters that are insufficiently chlorinated and maintained at temperatures between 37 and 40°C. Infection is usually self-limited, though bacteremia and shock have been reported. Swimmer’s itch occurs when a skin surface is exposed to water infected with freshwater avian schistosomes. Warm water temperatures and alkaline pH are suitable for mollusks that serve as intermediate hosts between birds and humans. Free-swimming schistosomal cercariae readily penetrate human hair follicles or pores but quickly die and elicit a brisk allergic reaction, causing intense itching and erythema.

**PAPULAR AND NODULAR LESIONS** (Table 110-1) Raised lesions of the skin occur in many different forms. *Mycobacterium marinum* infections of the skin may present as cellulitis or as raised erythematous nodules. Erythematous papules are early manifestations of cat-scratch disease (primary site of inoculation) and bacillary angiomatosis (*Bartonella henselae*). Raised serpiginous or linear eruptions are characteristic of cutaneous larva migrans, which is caused by burrowing larvae of dog or cat hookworms (*Ankylostoma braziliense*) and which humans acquire through contact with soil that has been contaminated with dog or cat feces. Similar burrowing raised lesions are present in dracunculiasis caused by migration of the adult female nematode *Dracunculus medinensis*. Nodules caused by *Onchocerca volvulus* may range from 1 to 10 cm in diameter and occur largely in persons bitten by *Simulium* flies in Africa. The nodules contain the adult worm encased in fibrous tissue. Migration of microfilariae into the eyes may result in blindness. Verruca peruana is caused by *Bartonella bacilliformis*, which is transmitted to humans by the sandfly *Phlebotomus*. This condition can take the form of single gigantic lesions (several centimeters in diameter) or multiple small lesions (several millimeters in diameter). Numerous subcutaneous nodules may also be present in cysticercosis caused by larvae of *Taenia solium*. Multiple erythematous papules develop in scrofulomiasis; each represents a cerarial invasion site.

Skin nodules as well as thickened subcutaneous tissue are prominent features of lepromatous leprosy. Large nodules or gummas are features of tertiary syphilis, whereas flat papulosquamous lesions are characteristic of secondary syphilis. Human papillomavirus may cause singular warts (verruca vulgaris) or multiple warts in the anogenital area (condyloma acuminata). The latter are major problems in HIV-infected individuals.

**ULCERS WITH OR WITHOUT ESCHARS** (Table 110-1) Cutaneous anthrax begins as a pruritic papule, which develops within days into an ulcer with surrounding vesicles and edema and then into an enlarging ulcer with a black eschar. Cutaneous anthrax may cause chronic nonhealing ulcers with an overlying dirty-gray membrane, although lesions may also mimic psoriasis, eczema, or impetigo. Ulceroglandular tularemia may have associated ulcerated skin lesions with painful regional adenopathy. Although buboes are the major cutaneous manifestation of plague, ulcers with eschars, papules, or pustules are also present in 25% of cases. *Mycobacterium ulcerans* typically causes chronic skin ulcers on the extremities of individuals living in the tropics. *Mycobacterium leprae* may be associated with cutaneous ulcerations in patients with lepromatous leprosy related to Lucio’s phenomenon, in which immune-mediated destruction of tissue bearing high concentrations of *M. leprae* bacilli occurs, usually several months after initiation of effective therapy. *Mycobacterium tuberculosis* may also cause ulcerations, papules, or erythematous macular lesions of the skin in both normal and immunocompromised patients.

Decubitus ulcers are due to tissue hypoxia secondary to pressure-induced vascular insufficiency and may become secondarily infected with components of the skin and gastrointestinal flora, including anaerobes. Ulcerative lesions on the anterior skins may be due to pyoderma gangrenosum, which must be distinguished from similar lesions of infectious etiology by histologic evaluation of biopsy sites. Ulcerated lesions on the genitals may be either painful (chancroid) or painless (primary syphilis).

**ERYSIPelas** (Table 110-1) Erysipelas is due to *S. pyogenes* and is characterized by an abrupt onset of fiery-red swelling of the face or extremities. The distinctive features of erysipelas are well-defined indurated margins, particularly along the nasolabial fold; rapid progression; and intense pain (see Fig. 121-3). Flaccid bullae may develop during the second or third day of illness, but extension to deeper soft tissues is rare. Treatment with penicillin is effective; swelling may progress despite appropriate treatment, although fever, pain, and the intense red color diminish. Desquamation of the involved skin
occurs 5 to 10 days into the illness. Infants and elderly adults are most commonly afflicted, and the severity of systemic toxicity varies.

**CELLULITIS** (Table 110-1) Cellulitis is an acute inflammatory condition of the skin that is characterized by localized pain, erythema, swelling, and heat. Cellulitis may be caused by indigenous flora colonizing the skin and appendages (e.g., *S. aureus* and *S. pyogenes*) or by a wide variety of exogenous bacteria. Because the exogenous bacteria involved in cellulitis occupy unique niches in nature, a thorough history (including epidemiologic data) provides important clues to etiology. When there is drainage, an open wound, or an obvious portal of entry, Gram’s stain and culture provide a definitive diagnosis. In the absence of these findings, the bacterial etiology of cellulitis is difficult to establish. In some cases staphylococcal and streptococcal cellulitis may have similar features. Even with needle aspiration of the leading edge or a punch biopsy of the cellulitis tissue itself, cultures are positive in only 20% of cases. This observation suggests that relatively low numbers of bacteria may cause cellulitis and that the expanding area of erythema within the skin may be a direct effect of extracellular toxins or of the soluble mediators of inflammation elicited by the host.

Bacteria may gain access to the epidermis through cracks in the skin, abrasions, cuts, burns, insect bites, surgical incisions, and intravenous catheters. Cellulitis caused by *S. aureus* spreads from a central localized infection, such as an abscess, folliculitis, or an infected foreign body (e.g., a splinter, a prosthetic device, or an intravenous catheter). In contrast, cellulitis due to *S. pyogenes* is a more rapidly spreading, diffuse process frequently associated with lymphangitis and fever. Recurrent streptococcal cellulitis of the lower extremities may be caused by organisms of group A, C, or G in association with chronic venous stasis or with saphenous venectomy for coronary artery bypass surgery. Streptococci also cause recurrent cellulitis among patients with chronic lymphedema resulting from elephantiasis, lymph node dissection, or Milroy’s disease. Recurrent staphylococcal cutaneous infections are more common among individuals who have eosinophilia or elevated serum levels of IgE (Job’s syndrome) and among nasal carriers of staphylococci. Cellulitis caused by *Streptococcus agalactiae* (group B *Streptococcus*) occurs primarily in elderly patients and those with diabetes mellitus or peripheral vascular disease. *Haemophilus influenzae* typically causes periiorbital cellulitis in children in association with sinunasitis, otitis media, or epiglottitis. It is unclear whether this form of cellulitis will (like meningitis) become less common or whether this form of cellulitis will (like meningitis) become less common as a result of the impressive efficacy of the *H. influenzae* type b vaccine.

Many other bacteria also cause cellulitis. Fortunately, these organisms occur in such characteristic settings that a good history provides useful clues to the diagnosis. Cellulitis associated with cat bites and, to a lesser degree, with dog bites is commonly caused by *Pasteurella multocida*, although in the latter case *Staphylococcus intermedius* and *Capnocytophaga canimorsus* (formerly DF-2) must also be considered. Sites of cellulitis and abscesses associated with dog bites and human bites also contain a variety of anaerobic organisms, including *Fusobacterium*, *Bacteroides*, aerobic and anaerobic streptococci, and *Eikenella corrodens*. *Pasteurella* is notoriously resistant to dicloxacinill and nafcillin but is sensitive to all other β-lactam antimicrobials as well as to quinolones, tetracycline, and erythromycin. Ampicillin/clavulanate, ampicillin/sulbactam, and cefoxitin are good choices for the treatment of animal or human bite infections. *Aeromonas hydrophilia* causes aggressive cellulitis in tissues surrounding lacerations sustained in fresh water (lakes, rivers, and streams). This organism remains sensitive to aminoglycosides, fluoroquinolones, chloramphenicol, trimethoprim-sulfamethoxazole, and third-generation cephalosporins; it is resistant to ampicillin, however.

*P. aeruginosa* causes three types of soft tissue infection: ecthyma gangrenosum in neurotrophic patients, hot-tub folliculitis, and cellulitis following penetrating trauma. Most commonly, *P. aeruginosa* is introduced into the open tissues when a puncture wound is made. Treatment includes surgical inspection and drainage, particularly if the injury also involves bone or joint capsule. Choices for empirical treatment while antimicrobial susceptibility data are awaited include an aminoglycoside, a third-generation cephalosporin (cefotaxime, cefoperazone, or cefotaxime), a semisynthetic penicillin (ticarcillin, mezlocillin, or piperacillin), or a fluoroquinolone (although drugs of the last class are not indicated for the treatment of children <13 years old).

Gram-negative bacillary cellulitis, including that due to *P. aeruginosa*, is most common among hospitalized, immunocompromised hosts. Cultures and sensitivity tests are critically important in this setting because of multidrug resistance (Chap. 136).

The gram-positive aerobic rod *Erysipelothrix rhusiopathiae* is most often associated with fish and domestic swine and causes cellulitis primarily in bone renderers and fishmongers. *E. rhusiopathiae* remains susceptible to most β-lactam antibiotics (including penicillin), erythromycin, clindamycin, tetracycline, and cephalosporins but is resistant to sulfonamides, chloramphenicol, and vancomycin. Its resistance to vancomycin, which is unusual among gram-positive bacteria, is of potential clinical significance since this agent is sometimes used in empirical therapy for skin infection. Fish food containing the water flea *Daphnia* is sometimes contaminated with *M. marinum*, which can cause cellulitis or granulomas on skin surfaces exposed to the water in aquariums or injured in swimming pools. Rifampin plus ethambutol has been an effective therapeutic combination in some cases, although no comprehensive studies have been undertaken. In addition, some strains of *M. marinum* are susceptible to tetracycline or to trimethoprim-sulfamethoxazole.

**NECROTIZING FASCITIS** (Table 110-1) Necrotizing fasciitis, formerly called streptococcal gangrene, may be associated with group A *Streptococcus* or mixed aerobic-anaerobic bacteria or may occur as part of gas gangrene caused by *Clostridium perfringens*. Early diagnosis may be difficult when pain or unexplained fever is the only presenting manifestation. Swelling then develops and is followed by brawny edema and tenderness. With progression, dark red induration of the epidermis appears, along with bullae filled with blue or purple fluid. Later the skin becomes friable and takes on a bluish, maroon, or black color. By this stage, thrombosis of blood vessels in the dermal papillae (Fig. 110-1) is extensive. Extension of infection to the level of the deep fascia causes this tissue to take on a brownish-gray appearance. Rapid spread occurs along fascial planes, through venous channels and lymphatics. Patients in the later stages are toxic and frequently manifest shock and multiorgan failure.

Necrotizing fasciitis caused by mixed aerobic-anaerobic bacteria begins with a breach in the integrity of a mucous membrane barrier, such as the mucosa of the gastrointestinal or genitourinary tract. The portal can be a malignancy, diverticulum, hemorrhoid, anal fissure, or urethral tear. Other predisposing factors include peripheral vascular disease, diabetes mellitus, surgery, and penetrating injury to the abdomen. Leakage into the perineal area results in a syndrome called *Fournier’s gangrene*, characterized by massive swelling of the scrotum and penis with extension into the perineum or the abdominal wall and legs.

Necrotizing fasciitis caused by *S. pyogenes* has increased in frequency and severity since 1985. It frequently begins deep at the site of a nonpenetrating minor trauma, such as a bruise or a muscle strain. Seeding of the site via transient bacteremia is likely, although most patients deny antecedent streptococcal infection. Alternatively, *S. pyogenes* may reach the deep fascia from a site of cutaneous infection or penetrating trauma. Toxicity is severe, and renal impairment may precede the development of shock. In 20 to 40% of cases, myositis occurs concomitantly, and, as in gas gangrene (see below), serum creatine phosphokinase values may be markedly elevated. Necrotizing fasciitis due to mixed aerobic-anaerobic bacteria may be associated with gas in the deep tissue, but gas is not usually present when the causative organism is *S. pyogenes*. Prompt surgical exploration down to the deep fascia and muscle is essential. Necrotic tissue must be surgically removed, and Gram’s staining and culture of excised tissue are useful
in establishing whether group A streptococci, mixed aerobic-anaerobic bacteria, or Clostridium species are present (see “Treatment,” below).

**MYOSITIS/MYONECROSIS** (Table 110-1) Muscle involvement can occur with viral infection (e.g., influenza, dengue, or coxsackievirus B infection) or parasitic infection (e.g., trichinellosis, cisticercosis, or toxoplasmosis). Although myalgia can occur in most of these infections, severe muscle pain is the hallmark of pleurodynia (coxsackievirus B), trichinellosis, and bacterial infection. Acute rhodomyelitis predictably occurs with clostridial and streptococcal myositis but may also be associated with influenza virus, echovirus, coxsackievirus, Epstein-Barr virus, and *Legionella* infection.

Pyomyositis is usually due to *S. aureus*, is common in tropical areas, and generally has no known portal of entry. Infection remains localized, and shock does not develop unless organisms produce toxic shock syndrome toxin 1 or certain enteroxins and the patient lacks antibodies to the toxin produced by the infecting organisms. In contrast, *S. pyogenes* may induce primary myositis (referred to as streptococcal necrotizing myositis) in association with severe systemic toxicity. Myonecrosis occurs concomitantly with necrotizing fasciitis in ~50% of cases. Both are part of the streptococcal toxic shock syndrome.

Gas gangrene usually follows severe penetrating injuries that result in interruption of the blood supply and introduction of soil into wounds. Such cases of traumatic gangrene are usually caused by the clostridial species *C. perfringens*, *C. septicum*, or *C. histolyticum*. Rarely, latent or recurrent gangrene can occur years after penetrating trauma; dormant spores that reside at the site of previous injury are most likely responsible. Spontaneous nontraumatic gangrene among patients with neutropenia, gastrointestinal malignancy, diverticulosis, or recent radiation therapy to the abdomen is caused by several clostridial species, of which *C. septicum* is the most commonly involved. The tolerance of this anaerobe to oxygen probably explains why it can initiate infection spontaneously in normal tissue anywhere in the body. Synergistic nonclostridial anaerobic myonecrosis, also known as necrotizing cutaneous myositis and synergistic necrotizing cellulitis, is a variant of necrotizing fasciitis caused by mixed aerobic and anaerobic bacteria with the exclusion of clostridial organisms (see “Necrotizing Fasciitis,” above).

**DIAGNOSIS** This chapter has emphasized the physical appearance and location of lesions within the soft tissues as important diagnostic clues. The temporal progression of the lesions as well as the patient’s travel history, animal exposure or bite history, age, underlying disease status, and lifestyle are also crucial considerations in the formulation of a narrowed differential diagnosis. However, even the astute clinician may find it challenging to diagnose all infections of the soft tissues by history and inspection alone. Soft tissue radiography, computed tomography, and magnetic resonance imaging may be useful in determining the depth of infection and should be performed in patients with rapidly progressing lesions or in those with evidence of systemic inflammatory response syndrome. These tests are particularly valuable in the United States but have reached 70 to 100% in some other countries. Most, but not all, erythromycin-resistant group A streptococci are susceptible to clindamycin. Approximately 90 to 95% of *Staphylococcus aureus* strains are sensitive to clindamycin.

*a Pasteurella multocida, a species commonly associated with both dog and cat bites, is resistant to cephalaxin, dicloxacinil, clindamycin, and erythromycin. *Eikenella corrodens*, a bacterium commonly associated with human bites, is resistant to clindamycin, penicillinase-resistant penicillins, and metronidazole but is sensitive to trimethoprim-sulfamethoxazole and fluoroquinolones.

*b The frequency of erythromycin resistance in group A *Streptococcus* is currently ~5%
for defining a localized abscess or detecting gas in tissue. Unfortunately, they may reveal only soft tissue swelling and thus be not specific for fulminant infections such as necrotizing fasciitis or myonecrosis caused by group A Streptococcus, where gas is not found in lesions.

Aspiration of the leading edge or punch biopsy with frozen section may be helpful if the results are positive, but false-negative results occur in ~80% of cases. There is some evidence that aspiration alone may be superior to injection and aspiration using normal saline. Frozen sections are especially useful in distinguishing SSTSS from TEN and are quite valuable in cases of necrotizing fasciitis. Open surgical inspection with debridement as indicated is clearly the best way to determine the extent and severity of infection and to obtain material for Gram’s staining and culture. Such an aggressive approach is important and may be lifesaving if undertaken early in the course of fulminant infections where there is evidence of systemic toxicity.

**TREATMENT**

A full description of the treatment of all the clinical entities described herein is beyond the scope of this chapter. As a guide to the clinician in selecting appropriate treatment, the antimicrobial agents useful in the most common and the most fulminant cutaneous infections are listed in Table 110-2.

Early and aggressive surgical exploration is essential in patients with suspected necrotizing fasciitis, myositis, or gangrene in order to (1) visualize the deep structures, (2) remove necrotic tissue, (3) reduce compartment pressure, and (4) obtain suitable material for Gram’s staining and for aerobic and anaerobic cultures. Appropriate empirical antibiotic treatment for mixed aerobic-anaerobic infections could consist of ampicillin/sulbactam, cefoxitin, or the following combination: (1) clindamycin (600 to 900 mg intravenously every 8 h) or metronidazole (750 mg every 6 h) plus (2) ampicillin or ampicillin/sulbactam (2 to 3 g intravenously every 6 h) plus (3) gentamicin (1.0 to 1.5 mg/kg every 8 h). Group A streptococcal and clostridial infection of the fascia and/or muscle carries a mortality rate of 20 to 50% with penicillin treatment. In experimental models of streptococcal and clostridial necrotizing fasciitis/myositis, clindamycin has exhibited markedly superior efficacy, but no comparative trials have been performed in humans. Hyperbaric oxygen treatment may also be useful in gas gangrene due to clostridial species. Antibiotic treatment should be continued until all signs of systemic toxicity have resolved, all devitalized tissue has been removed, and granulation tissue has developed (Chaps. 121, 126, and 148).

In summary, infections of the skin and soft tissues are diverse in presentation and severity and offer a great challenge to the clinician. This chapter provides an approach to diagnosis and understanding of the pathophysiologic mechanisms involved in these infections. More in-depth information is found in chapters on specific infections.

### 111 OSTEOMYELITIS

**Jeffrey Parsonnet, James H. Maguire**

Osteomyelitis, an infection of bone, is caused most commonly by pyogenic bacteria and mycobacteria. As a useful framework for evaluating the patient and planning treatment, cases are classified on the basis of the causative agent; the route, duration, and anatomical location of infection; and local and systemic host factors.

**PATHOGENESIS AND PATHOLOGY**

Microorganisms enter bone by the hematogenous route, by direct introduction from a contiguous focus of infection, or by a penetrating wound. Trauma, ischemia, and foreign bodies enhance the susceptibility of bone to microbial invasion by exposing sites to which bacteria can bind. Phagocytes attempt to contain the infection and, in the process, release enzymes that lyse bone. Bacteria escape host defenses by adhering tightly to damaged bone, by entering and persisting within osteoblasts, and by coating themselves and underlying surfaces with a protective polysaccharide-rich biofilm. Pus spreads into vascular channels, raising intraosseous pressure and impairing the flow of blood; as the untreated infection becomes chronic, ischemic necrosis of bone results in the separation of large devascularized fragments (sequestra). When pus breaks through the cortex, subperiosteal or soft tissue abscesses form, and the elevated periosteum deposits new bone (an involucrum) around the sequestrum.

Microorganisms, infiltrates of neutrophils, and congested or thrombosed blood vessels are the principal histologic findings of acute osteomyelitis. The distinguishing feature of chronic osteomyelitis is necrotic bone, which is characterized by the absence of living osteocytes. Mononuclear cells predominate in chronic infections, and granulation and fibrous tissues replace bone that has been resorbed by osteoclasts. In the chronic stage, organisms may be too few to be seen on staining.

**HEMATOGENOUS OSTEOMYELITIS**

Hematogenous infection accounts for ~20% of cases of osteomyelitis and primarily affects children, in whom the long bones are infected, and older adults and intravenous drug users, in whom the spine is the most common site of infection.

Acute Hematogenous Osteomyelitis Infection usually involves a single bone, most commonly the tibia, femur, or humerus in children and vertebral bodies in older adults and injection drug users. Bacteria settle in the well-perfused metaphysis of growing bones where functioning phagocytes are scarce, a network of venous sinusoids slows the flow of blood, and fenestrations in capillaries allow organisms to escape into the extravascular space. Because vascular anatomy changes with age, hematogenous infection of long bones is uncommon during adulthood and, when it occurs, usually involves the diaphysis.

On presentation, the child with osteomyelitis usually appears acutely ill, with high fever, chills, and localized pain and tenderness and often with restriction of movement or difficulty bearing weight. Cutaneous erythema and swelling indicate extension of pus through the cortex. During infancy and after puberty, infection may spread through the epiphysis into the joint space. In children of other ages, extension of infection through the cortex results in involvement of joints if the metaphysis is intracapsular. Thus, septic arthritis of the elbow, shoulder, and hip may complicate osteomyelitis of the proximal radius, humerus, and femur, respectively. In children, the source of bacteremia is usually apparent. A history is often obtained of recent blunt trauma to the area involved; presumably, this event results in a small intraosseous hematoma or vascular obstruction. Adults with osteomyelitis may present in the context of an apparent infection elsewhere, such as the lung, sinuses, or urinary tract, or without an obvious source of bacteremia.

Plain radiographs obtained early in the course of infection may show soft tissue swelling, but the first change in bone—a periosteal

**FURTHER READING**

reaction—is not evident until at least 10 days after the onset of infection. Lytic changes can be detected after 2 to 6 weeks, when 50 to 75% of bone density has been lost. Rarely, a well-circumscribed lytic lesion, or Brodie’s abscess, is seen in a child who has been in pain for several months but has had no fever.

**Vertebral Osteomyelitis**

The vertebral bodies are the most common sites of acute hematogenous osteomyelitis in adults. Organisms reach the well-perfused vertebral body via spinal arteries and quickly spread from the end plate into the disk space and then to the adjacent vertebral body. The infection may originate in the urinary tract, and it does so particularly often among men over age 50. Other sources of bacteremia include endocarditis, dental abscess, soft tissue infection, and a contaminated intravenous line; these sources may or may not be obvious. Diabetes mellitus, hemodialysis, and injection drug use carry an increased risk of spinal infection. Many patients have a history of degenerative joint disease involving the spine, and some report an episode of trauma preceding the onset of infection. Penetrating injuries and surgical procedures to the spine may cause nonhematogenous vertebral osteomyelitis or infection localized to the disk.

Most patients with vertebral osteomyelitis report neck or back pain; patients may describe atypical pain in the chest, the abdomen, or an extremity that is due to irritation of nerve roots. Symptoms are localized to the lumbar spine more often than to the thoracic spine (≥50% vs. 35% of cases), and the cervical spine in pyogenic infections, but the thoracic spine is involved most commonly in tuberculous spondylitis (Pott’s disease). More than 50% of patients experience a subacute illness in which a vague, dull pain gradually intensifies over 2 to 3 months. Fever is usually low grade or absent, but some patients recall having had an episode of fever and chills prior to or at the onset of pain. An acute presentation with high fever and toxicity is less common and suggests ongoing bacteremia. Percussion over the involved vertebra elicits tenderness, and physical examination may reveal spasm of the paraspinal muscles and limitation of motion.

Laboratory findings at the time of presentation include a normal or modestly elevated white blood cell count and, almost invariably, an increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level. Blood cultures are positive only 20 to 50% of the time.

Usually, by the time the patient seeks medical attention, plain radiographs show irregular erosions in the end plates of adjacent vertebral bodies and narrowing of the intervening disk space. This radiographic pattern is virtually diagnostic of bacterial infection because tumors and other diseases of the spine rarely cross the disk space. Computed tomography (CT) or magnetic resonance imaging (MRI) may demonstrate epidural, paraspinal, retropharyngeal, mediastinal, retroperitoneal, or psoas abscesses that originate in the spine.

A spinal epidural abscess may evolve suddenly or over several weeks; the classic clinical presentation is spinal pain progressing to radicular pain and/or weakness. Irreversible paralysis may result from failure to recognize epidural abscess before the development of neurologic deficits. MRI is the best procedure for detection of epidural abscesses and should be performed in all cases of vertebral osteomyelitis accompanied by subjective weakness or objective neurologic abnormalities.

**Microbiology**

More than 95% of cases of hematogenous osteomyelitis are caused by a single organism. *Staphylococcus aureus* accounts for 50% of isolates. Other common pathogens include group B streptococci and *Escherichia coli* during the newborn period and group A streptococci in early childhood. Vertebral osteomyelitis is due to *E. coli* and other enteric bacilli in ~25% of cases. *S. aureus*, *Pseudomonas aeruginosa*, and *Serratia* infections are associated with intravenous drug use in some parts of the United States and may involve the sacroiliac, sternoclavicular, or pubic joints as well as the spine. *Salmonella* spp. and *S. aureus* are the major causes of long-bone osteomyelitis complicating sickle cell anemia and other hemoglobinopathies. Tuberculosis and brucellosis affect the spine more often than other bones. Other common sites of tuberculous osteomyelitis include the small bones of the hands and feet, the metaphyses of long bones, the ribs, and the sternum.

Unusual causes of hematogenous osteomyelitis include disseminated histoplasmosis, coccidioidomycosis, and blastomycosis in endemic areas. Immunocompromised persons on rare occasions develop osteomyelitis due to atypical mycobacteria, *Bartonella henselae*, or *Pneumocystis* or to species of *Candida*, *Cryptococcus*, or *Aspergillus*. Hematogenous osteomyelitis with *Mycobacterium bovis* has been reported following intravesicular instillation of bacille Calmette-Guérin (BCG) for cancer of the bladder. The etiology of chronic relapsing multifocal osteomyelitis, an inflammatory condition of children that is characterized by recurrent episodes of painful lytic lesions in multiple bones, has not been identified.

**OSTEOMYELITIS SECONDARY TO A CONTIGUOUS FOCUS OF INFECTION**

**Clinical Features** This broad category of osteomyelitis accounts for ~80% of all cases and occurs most commonly in adults. It includes infections introduced by penetrating injuries, such as bites, puncture wounds, and open fractures; by surgical procedures; and by direct extension of infection from adjacent soft tissues. Generalized vascular insufficiency and the presence of a foreign body are important predisposing factors and make infection more difficult to cure.

Frequently, the diagnosis of this type of osteomyelitis is not made until the infection has already become chronic. The pain, fever, and inflammatory signs due to acute infection may be attributed to the original injury or to overlying soft tissue infection. An indolent infection may become apparent only weeks or months later, when a sinus tract develops, a surgical wound breaks down, or a fracture fails to heal. It may be impossible to distinguish radiographic abnormalities due to osteomyelitis from those due to the precipitating condition.

A special type of contiguous-focus osteomyelitis occurs in the setting of peripheral vascular disease and nearly always involves the small bones of the feet of adult diabetic patients. This type of infection is a major cause of morbidity and hospitalization for patients with diabetes and results in many thousands of amputations per year. Diabetic neuropathy exposes the foot to frequent trauma and pressure sores, and the patient may be unaware of infection as it spreads into bone. Poor tissue perfusion impairs normal inflammatory responses and wound healing and creates a milieu that is conducive to anaerobic infections. It is often during the evaluation of a nonhealing ulcer, a swollen toe, or acute cellulitis that a radiograph provides the first evidence of osteomyelitis. If bone is palpable during examination of the base of an ulcer with a blunt surgical probe, osteomyelitis is likely.

**Microbiology** *S. aureus* is a pathogen in more than half of cases of contiguous-focus osteomyelitis. However, in contrast to hematogenous osteomyelitis, these infections are often polymicrobial and are more likely to involve gram-negative and anaerobic bacteria. Hence a mixture of staphylococci, streptococci, enteric organisms, and anaerobic bacteria may be isolated from a diabetic foot infection or pelvic osteomyelitis underlying a decubitus ulcer. Aerobic and anaerobic bacteria cause osteomyelitis following surgery or soft tissue infection of the oropharynx, paranasal sinuses, gastrointestinal tract, or female genital tract. A human bite may result in mixed infection of the hand, with anaerobes included among the etiologic agents. *S. aureus* is the principal cause of postoperative infections; coagulase-negative staphylococci are common pathogens after implantation of orthopedic appliances; and these organisms as well as gram-negative enteric bacilli, atypical mycobacteria, and *Mycoplasma* may cause sternal osteomyelitis after cardiac surgery. Infection with *P. aeruginosa* is frequently associated with puncture wounds of the foot (especially by a nail through a sneaker) or with thermal burns, and *Pasteurella multocida* infection commonly follows cat bites.

**CHRONIC OSTEOMYELITIS** With prompt treatment, fewer than 5% of cases of acute hematogenous osteomyelitis progress to chronic osteomyelitis. Chronic osteomyelitis is more likely to develop in contiguous-focus than in hematogenous osteomyelitis. The presence of a foreign body makes establishment of chronic infection especially likely.
A protracted clinical course, long periods of quiescence, and recurrent exacerbations are characteristic of chronic osteomyelitis. Sinus tracts between bone and skin may drain purulent material and occasionally pieces of necrotic bone. An increase in drainage, pain, or ESR signals an exacerbation. Fever is unusual except when obstruction of a sinus tract leads to soft tissue infection. Rare late complications include pathologic fractures, squamous cell carcinoma of the sinus tract, and amyloidosis.

**DIAGNOSIS** Early diagnosis of acute osteomyelitis is critical because prompt antibiotic therapy may prevent the necrosis of bone. The ESR and CRP levels are elevated in most cases of active osteomyelitis, including those in which constitutional symptoms and leukocytosis are lacking. These findings are not specific to osteomyelitis, however, and the ESR is occasionally normal in early infections. Baseline values are often useful in monitoring the efficacy of treatment. A variety of radiologic tests are available for evaluation of osteomyelitis (Table 111-1). Evaluation usually begins with plain radiographs because of their ready availability, although they frequently show no abnormalities during early infection. Three-phase bone scans (99mTc-monodiphosphonate) offer high sensitivity but often have low specificity, especially in the presence of underlying bony abnormalities. There is a lack of consensus over the optimal use of other radionuclide studies, and there is considerable variation between institutions in their use. Although the use of MRI (Fig. 111-1) is expanding because of high sensitivity and specificity, this modality is not available at all institutions.

The role of diagnostic imaging in chronic osteomyelitis is to detect active infection and delineate the extent of debridement necessary to remove necrotic bone and abnormal soft tissues. Although plain films accurately reflect chronic changes, CT is more sensitive for the detection of sequestra, sinus tracts, and soft tissue abscesses. Both CT and ultrasound are useful for guiding percutaneous aspiration of subperiosteal and soft tissue fluid collections. Sequential technetium and gallium or indium scans may help determine whether infection is active and may distinguish infection from noninflammatory bone changes. MRI provides superior information about the anatomical extent of infection but does not always distinguish osteomyelitis from healing fractures and tumors. MRI is particularly useful in distinguishing cellulitis from osteomyelitis in the diabetic foot; however, no imaging modality consistently distinguishes infection from neuropathic osteopathy.

Appropriate samples for microbiologic studies should be obtained in all cases of suspected osteomyelitis before the initiation of antimicrobial therapy. Blood cultures are indicated in acute cases and are positive in more than one-third of cases of hematogenous osteomyelitis in children and in 25% of cases of vertebral osteomyelitis in adults. The presence of sepsis occasionally requires initiation of empirical therapy after blood samples alone have been obtained for culture. If blood cultures are negative, samples from needle aspiration of pus in bone or soft tissues or from a bone biopsy should be obtained for culture; in the case of vertebral osteomyelitis, these samples can usually be obtained with the guidance of fluoroscopy or CT scan.

The results of culture of specimens obtained by swabbing of a sinus tract or the base of an ulcer correlate poorly with the organisms infecting the bone. For this reason, in cases of chronic osteomyelitis and contiguous-focus osteomyelitis, samples for aerobic and anaerobic culture should be obtained from several sites by percutaneous needle aspiration, percutaneous biopsy, or intraoperative biopsy at the time of debridement. Isolates of coagulase-negative staphylococci and other organisms of low virulence should not automatically be disregarded as contaminants, especially in the presence of prosthetic materials. Special culture media may be necessary for the isolation of mycobacteria, fungi, and less common pathogens. In some cases, histopathologic examination of biopsy specimens may be the only way to make a diagnosis.

### Table 111-1 Diagnostic Imaging Studies for Osteomyelitis

<table>
<thead>
<tr>
<th>Type of Study</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Plain radiographs</td>
<td>Insensitive, especially in early osteomyelitis. May show periosteal elevation after 10 days, lytic changes after 2–6 weeks. Useful to look for anatomical abnormalities (e.g., fractures, bony variants, or deformities), foreign bodies, and soft tissue gas.</td>
</tr>
<tr>
<td>Three-phase bone scan (99mTc-MDP)</td>
<td>Characteristic finding in osteomyelitis: increased uptake in all three phases of scan. Highly sensitive (~95%) in acute infection; somewhat less sensitive if blood flow to bone is poor. Specificity moderate if plain films are normal, but poor in presence of neuropathic arthropathy, fractures, tumor, infection. Examples: 99mTc-citrate, 111In-labeled WBCs. 111In-WBCs more specific than gallium but not always available. Often used in conjunction with bone scan because its greater specificity for inflammation than 99mTc-MDP helps to distinguish infections from noninfectious processes.</td>
</tr>
<tr>
<td>Other radionuclide scans</td>
<td>Ultrasound May detect subperiosteal fluid collection or soft tissue abscess adjacent to bone, but largely supplanted by CT and MRI. CT Limited role in acute osteomyelitis. In chronic osteomyelitis, excellent for detection of sequestrum, cortical destruction, soft tissue abscesses, and sinus tracts. Use may be limited by metallic foreign body. MRI As sensitive as 99mTc-MDP bone scan for acute osteomyelitis (~95%); detects changes in water content of marrow before disruption of cortical bone. High specificity (~87%), with better anatomical detail than nuclear studies. Procedure of choice for vertebral osteomyelitis because of high sensitivity for epidural abscess. Use may be limited by metallic foreign body.</td>

**Abbreviations:** CT, computed tomography; MDP, monodiphosphonate; MRI, magnetic resonance imaging; WBCs, white blood cells.
likely pathogens. Empirical therapy in most cases should include high doses of an agent active against *S. aureus* (such as oxacillin, nafcillin, cefazolin, or vancomycin) and—if gram-negative organisms are likely to be involved—a third-generation cephalosporin, an aminoglycoside, or a fluoroquinolone.

Specific intravenous therapy is based on the in vitro susceptibility of the organism(s) isolated from bone or blood. At-home intravenous administration of antibiotics or oral therapy is appropriate for motivated and medically stable patients and represents a significant advance in management. Antibiotics that require infrequent dosing, such as ceftriaxone, may facilitate home therapy. Many antibiotics can be given automatically by portable infusion pump, which decreases otherwise caused by the frequent administration of drug. Use of a peripherally inserted central catheter (PICC line) also facilitates outpatient administration of antibiotics. Outpatient therapy requires close coordination of nursing, pharmacy, and physician care, with clear delineations of responsibility for monitoring safety and efficacy.

Children with acute hematogenous osteomyelitis routinely receive oral antibiotics after 5 to 10 days of parenteral therapy if signs of active infection have resolved; such treatment has been as successful as standard parenteral therapy. The doses of oral penicillins or cephalosporins required for the treatment of osteomyelitis are several times higher than the doses of these drugs given for common infections. Adults may not tolerate these high doses as well as children, and, except in the case of the fluoroquinolones and rifampin, few data support the use of oral antibiotics by adults. For treatment of osteomyelitis due to Enterobacteriaceae, oral administration of a fluoroquinolone has been as successful as intravenous administration of β-lactam antibiotics.

**Caution should be exercised in the use of fluoroquinolones as the sole agents for treatment of infection due to *S. aureus* or *P. aeruginosa* because resistance may develop during therapy. Addition of rifampin to a fluoroquinolone or a β-lactam agent has yielded encouraging results in infections due to *S. aureus*, but potential drug toxicity and drug interactions make this option desirable only for selected patients, such as those with necrotic bone that cannot be adequately debrided. Oral administration of clindamycin (300 to 450 mg every 6 h) or metronidazole (500 mg every 8 h) results in high drug levels in serum and can take the place of intravenous regimens for the treatment of *Bacteroides* infections. Oral clindamycin has produced good results for continuation treatment of osteomyelitis due to *S. aureus*, but consultation with the microbiology laboratory is advisable because of inducible resistance exhibited by some strains. The bacteriostatic drug linezolid (600 mg by mouth every 12 h) and the bactericidal drug daptomycin (4 to 6 mg/kg per day intravenously) have been used successfully in a small number of patients with infection caused by methicillin-resistant *S. aureus* and vancomycin-resistant *Enterococcus*, but data are currently insufficient to recommend their routine use. Data do not support the routine use of the serum minimal bactericidal concentration in guiding therapy.**

**Acute Hematogenous Osteomyelitis** Early treatment of acute hematogenous osteomyelitis of childhood with 4 to 6 weeks of an appropriate antibiotic is usually successful; treatment for <3 weeks has resulted in a 10-fold greater rate of failure. Surgical intervention in childhood cases is indicated for intraosseous or subperiosteal abscesses, concomitant septic arthritis, and failure of the acute signs of infection to improve in 24 to 48 h. Acute hematogenous osteomyelitis of bones other than the spine in adults often requires surgical debridement.

**Vertebral Osteomyelitis** A 4- to 6-week course of treatment with an appropriate antibiotic is usually sufficient to cure vertebral osteomyelitis. Failure of the ESR to drop by two-thirds or more of its pretreatment level or of CRP to normalize is an indication for reevaluation and (possibly) longer treatment. Surgery is seldom necessary, even in cases of many months’ duration, except in instances of spinal instability, new or progressive neurologic deficits, or large soft-tissue abscesses that cannot be drained percutaneously. All but small and asymptomatic epideral abscesses should be surgically drained. Patients should maintain bed rest until back pain has declined to the point at which ambulation is possible. Body casts are no longer used except for comfort.

**Contiguous-Focus Osteomyelitis** Even when diagnosed early, contiguous-focus osteomyelitis usually requires surgery in addition to 4 to 6 weeks of appropriate antibiotic therapy because of underlying soft tissue infection or damage to bone from an injury or surgery. A 2-week course of antibiotics following thorough debridement and soft tissue coverage has yielded excellent results in the treatment of superficial osteomyelitis involving only the outer cortex of bone.

**Chronic Osteomyelitis** The risks and benefits of aggressive therapy for chronic osteomyelitis should be weighed before any attempt is made to eradicate the infection. Some patients with extensive disease prefer to live with their infections rather than undergo multiple surgical procedures, take prolonged courses of antimicrobial therapy, and face the
risk of loss of an extremity. Such persons often benefit from intermittent courses of oral antibiotics to suppress acute exacerbations.

Once the decision has been made to treat chronic osteomyelitis aggressively, the patient’s nutritional and metabolic status should be optimized to expedite healing of soft tissues and bone. Antibiotic administration should be started several days before surgery to reduce inflammation if the etiology of the infection is known; if not, antibiotic therapy should be withheld until debridement. A 4- to 6-week course of appropriate antibiotic therapy is given postoperatively on the basis of the susceptibility pattern of organisms isolated from bone. The benefit of prolonged oral antibiotic therapy after 4 to 6 weeks of parenteral therapy remains unproven. There is insufficient information to recommend either the routine use of hyperbaric oxygen or the use of antibiotic-impregnated methacrylate beads or other depots to deliver high levels of antibiotics to the bone. The success of therapy for chronic osteomyelitis still rests largely on the complete surgical removal of necrotic bone and abnormal soft tissues. In the past, the inability to repair large defects in bone and soft tissue limited the extent of debridement. Muscle flaps and skin grafts are now used routinely to cover large soft-tissue defects and to fill dead space, and bone grafts and vascularized bone transfer may restore a seriously compromised bone to a functional state.

Infections of recent fractures, internal fixators are often left in place, and the infection is controlled by limited debridement and suppressive antibiotic therapy. Definitive surgical/antimicrobial therapy is delayed until after bone union of the fracture is achieved. If there is nonunion of the fracture or loosening of the fixator, the appliance must be removed, the bone debrided, and an external fixator or a new internal fixator applied.

Osteomyelitis of the small bones of the feet in persons with vascular disease usually requires surgical treatment. The effectiveness of the surgery is limited by the blood supply to the site and the body’s ability to heal the wound. Revascularization of the extremity is indicated if the vascular disease involves large arteries. In cases of decreased perfusion due to small-vessel disease, foot-sparing surgery may fail, and the best option is often suppressive therapy or amputation. The duration of antibiotic therapy depends on the surgical procedure performed. When the infected bone is removed entirely but residual infection of soft tissues remains, antibiotic therapy should be given for 2 weeks; if amputation eliminates infected bone and soft tissue, standard surgical prophylaxis is given; otherwise, postoperative antibiotics must be given for 4 to 6 weeks.

FURTHER READING

112 INTRAABDOMINAL INFECTIONS AND ABSCESSES

Dennis L. Kasper, Dori F. Zaleznik

Intraperitoneal infections generally arise because a normal anatomical barrier is disrupted. This disruption may occur when the appendix, a diverticulum, or an ulcer ruptures; when the bowel wall is weakened by ischemia, tumor, or inflammation (e.g., in inflammatory bowel disease); or with adjacent inflammatory processes, such as pancreatitis or pelvic inflammatory disease, in which enzymes (in the former case) or organisms (in the latter) may leak into the peritoneal cavity. Whatever the inciting event, once inflammation develops and organisms are normally present in the peritoneal space. This fluid is serous, with a high protein content (consisting mainly of albumin) of <30 g/L and <300 white blood cells (WBCs, generally mononuclear cells) per microliter. In the presence of infection, some compartments collect fluid or pus more often than others. These compartments include the pelvis (the lowest portion), the subphrenic spaces on the right and left sides, and Morrison’s pouch, which is a posterosuperior extension of the subhepatic spaces and is the lowest part of the paravertebral groove when the patient is recumbent. The fallopian ligament separating the right and left subphrenic spaces appears to act as a barrier to the spread of infection; consequently, it is unusual to find bilateral subphrenic collections. In bacterial infections, leukocyte recruitment into the infected peritoneal cavity consists of an early influx of polymorphonuclear leukocytes (PMNs) and a prolonged subsequent phase of mononuclear cell migration. The phenotype of the infiltrating leukocytes during the course of inflammation is regulated primarily by resident-cell chemokine synthesis.

PRIMARY (SPONTANEOUS) BACTERIAL PERITONITIS Peritonitis is either primary (without an apparent source of contamination) or secondary. The types of organisms found and the clinical presentations of these two processes are different. In adults, primary bacterial peritonitis (PBP) occurs most commonly in conjunction with cirrhosis of the liver (frequently the result of alcoholism). However, the disease has been reported in adults with metastatic malignant disease, postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, systemic lupus erythematosus, and lymphedema as well as in patients with no underlying disease. PBP virtually always develops in patients with ascites. Nevertheless, it is not a common event, occurring...
in ≤10% of cirrhotic patients. The cause of PBP has not been established definitively but is believed to involve hematogenous spread of organisms in a patient in whom a diseased liver and altered portal circulation result in a defect in the usual filtration function. Organisms are able to multiply in ascites, a good medium for growth. The proteins of the complement cascade have been found in peritoneal fluid, with lower levels in cirrhotic patients than in patients with ascites of other etiologies. The opsonic and phagocytic properties of neutrophils are diminished in patients with advanced liver disease.

The presentation of PBP differs from that of secondary peritonitis. The most common manifestation is fever, which is reported in as many as 80% of patients. Ascites is found but virtually always predates infection. Abdominal pain, an acute onset of symptoms, and peritoneal irritation detected during physical examination can be helpful diagnostically, but the absence of any of these findings does not exclude this often-subtle diagnosis. It is vital to sample the peritoneal fluid of any cirrhotic patient with ascites and fever. The finding of >300 PMNs per microliter is diagnostic for PBP, according to Conn. This criterion does not apply to secondary peritonitis (see below). The microbiology of PBP is also distinctive. While enteric gram-negative bacilli such as Escherichia coli are most commonly encountered, gram-positive organisms such as streptococci, enterococci, or even pneumococci are sometimes found. In PBP, a single organism is typically isolated; anaerobes are found less frequently in PBP than in secondary peritonitis, in which a mixed flora including anaerobes is the rule. In fact, if PBP is suspected and multiple organisms including anaerobes are recovered from the peritoneal fluid, the diagnosis must be reconsidered and a source of secondary peritonitis sought.

The diagnosis of PBP is not easy. It depends on the exclusion of a primary intraabdominal source of infection. Contrast-enhanced computed tomography (CT) is very useful in identifying an intraabdominal source for infection. It may be difficult to recover organisms from cultures of peritoneal fluid, presumably because the burden of organisms is low. However, the yield can be improved if 10 mL of peritoneal fluid is placed directly into a blood culture bottle. Since bacteremia frequently accompanies PBP, blood should be cultured simultaneously. No specific radiographic studies are helpful in the diagnosis of PBP. A plain film of the abdomen would be expected to show ascites. Chest and abdominal radiography should be performed in patients with abdominal pain to exclude free air, which signals a perforation.

**TREATMENT**

Treatment for PBP is directed at the isolate from blood or peritoneal fluid. Gram’s staining of peritoneal fluid often gives negative results in PBP. Therefore, until culture results become available, empirical therapy should cover gram-negative aerobic bacilli and gram-positive cocci. Third-generation cephalosporins such as cefotaxime (2 g q8h, administered intravenously (IV)) provide reasonable initial coverage in moderately ill patients. Broad-spectrum antibiotics, such as penicillin/β-lactamase inhibitor combinations (e.g., piperacillin/tazobactam, 3.375 g q6h IV) or ceftazidime (2 g q24h IV), are also options. Empirical coverage for anaerobes is not necessary. After the infecting organism is identified, therapy should be narrowed to target the specific pathogen. Patients with PBP usually respond within 72 h to appropriate antibiotic therapy. Antimicrobial therapy can be administered for as little as 5 days if rapid improvement occurs and blood cultures are negative, but a course of up to 2 weeks may be required for patients with bacteremia and for those whose improvement is slow. Persistence of leukocytes in the ascitic fluid after therapy should initiate a search for additional diagnoses.

**Prevention**

PBP has a high rate of recurrence. Up to 70% of patients reportedly experience a recurrence within 1 year. Antibiotic prophylaxis reduces the rate of recurrence to <20%. Recommended prophylactic regimens include fluoroquinolones (ciprofloxacin, 750 mg weekly; norfloxacin, 400 mg/d) or trimethoprim-sulfamethoxazole (one double-strength tablet per day). However, long-term administration of broad-spectrum antibiotics in this setting has been shown to increase the risk of severe hospital-acquired staphylococcal infections and of high-level resistance to antibiotics.

**SECONDARY PERITONITIS**

Secondary peritonitis develops when bacteria contaminate the peritoneum as a result of spillage from an intraabdominal viscus. The organisms found almost always constitute a mixed flora in which facultative gram-negative bacilli and anaerobes predominate, especially when the contaminating source is colonic. Early in the course of infection, when the host response is directed toward containment of the infection, exudate containing fibrin and PMNs is found. Early death in this setting is attributable to gram-negative bacillary sepsis and to potent endotoxins circulating in the bloodstream (Chap. 254). Gram-negative bacilli, particularly E. coli, are common bloodstream isolates, but Bacteroides fragilis bacteremia occurs as well. The severity of abdominal pain and the clinical course depend on the inciting process. The species of organisms isolated from the peritoneum also vary with the source of the initial process and the normal flora present at that site. Secondary peritonitis can result primarily from chemical irritation or bacterial contamination. For example, as long as the patient is not achlorhydric, a ruptured gastric ulcer will release low-pH gastric contents that will serve as a chemical irritant. The normal flora of the stomach comprises the same organisms found in the oropharynx (Chap. 148) but in lower numbers. The surfaces of teeth contain ~10^8 aerobic and 10^7 anaerobic organisms per milliliter of saliva; the normally acidic stomach contains an equal ratio of aerobic and anaerobic species, but in concentrations more in the range of 10^5/mL. After meals, when gastric acidity is highest, this number may fall to 10^3/mL. Thus, the bacterial burden in a ruptured gastric ulcer—or even a duodenal ulcer—is negligible compared with that in a ruptured appendix. The normal flora of the colon below the ligament of Treitz contains ~10^11 anaerobic organisms per gram of feces but only 10^6 aerobes per gram; therefore, anaerobic species account for 99% of the bacteria. Leakage of colonic contents (pH 7 to 8) does not cause significant chemical peritonitis, but infection is intense because of the heavy bacterial load.

Depending on the inciting event, local symptoms may initially be found in secondary peritonitis—for example, epigastric pain from a ruptured gastric ulcer. In appendicitis (Chap. 281), the initial presenting symptoms are often vague, with periumbilical discomfort and nausea followed in a number of hours by pain more localized to the right lower quadrant. Unusual locations of the appendix (including a retrocecal position) can complicate this presentation further. Once infection has spread to the peritoneal cavity, however, pain increases, particularly with infection involving the parietal peritoneum, which is innervated extensively. Patients usually lie motionless, often with knees drawn up to avoid stretching the nerve fibers of the peritoneal cavity. Coughing and sneezing, which increase pressure within the peritoneal cavity, are associated with sharp pain. There may or may not be pain localized to the infected or diseased organ from which secondary peritonitis has arisen. Patients with secondary peritonitis generally have abnormal findings on abdominal examination, with marked voluntary and involuntary guarding of the anterior abdominal musculature. Later findings include tenderness, especially rebound tenderness. In addition, there may be localized findings in the area of the inciting event. In general, patients are febrile, with marked leukocytosis and a left shift of the WBCs to earlier granulocyte forms.

While recovery of organisms from peritoneal fluid is easier in secondary than in primary peritonitis, a tap of the abdomen is rarely the procedure of choice in secondary peritonitis. An exception is in cases involving trauma, where the possibility of a hemoperitoneum may need to be excluded early. Etiologic studies to find the source of peritoneal contamination should be undertaken.
Treatment for secondary peritonitis includes early administration of antibiotics aimed particularly at aerobic gram-negative bacilli and anaerobes (see below). Mild to moderate disease can be treated with many drugs covering these organisms, including broad-spectrum penicillin/β-lactamase inhibitor combinations (e.g., ticarcillin/clavulanate, 3.1 g q8h IV) or ceftoxitin (2 g q24h IV). Patients requiring hospitalization in intensive care should receive imipenem (500 mg q6h IV), meropenem (1 g q8h IV), or combinations of drugs, such as ampicillin plus metronidazole plus ciprofloxacin. Secondary peritonitis usually requires both surgical intervention to address the inciting process and antibiotic administration to treat early bacteremia, to decrease the incidence of abscess formation and wound infection, and to prevent more distant spread of infection. Whereas surgery is rarely indicated in PBP in adults, it may be life-saving in secondary peritonitis.

PERITONITIS IN PATIENTS UNDERGOING CAPD A third type of peritonitis arises in patients who are undergoing continuous ambulatory peritoneal dialysis (CAPD). Unlike primary and secondary peritonitis, which are caused by endogenous bacteria, peritonitis in CAPD patients usually involves skin organisms. The pathogenesis of infection is similar to that of intravascular-device infection, in which skin organisms migrate along the catheter, which both serves as an entry point and exerts the effects of a foreign body. Exit-site or tunnel infection may or may not accompany CAPD peritonitis. Like PBP, CAPD peritonitis is usually caused by a single organism. Peritonitis is, in fact, the most common reason for discontinuation of CAPD. Improvements in equipment design, especially that of the Y-set connector, have resulted in a decrease from one case of peritonitis per 9 months of CAPD to one case per 15 months.

The clinical presentation of CAPD peritonitis resembles that of secondary peritonitis in that diffuse pain and peritoneal signs are common. The dialysate is usually cloudy and contains >100 WBCs per microliter, >50% of which are neutrophils. The most common etiologic organism is coagulase-negative Staphylococcus, which accounts for ~30% of cases. Staphylococcus aureus causes ~10% of cases, is more commonly identified among patients who are nasal carriers of the organism, and is the most frequent pathogen in those with an overt exit-site infection. Gram-negative bacilli and fungi such as Candida species are also found. Vancomycin-resistant enterococci (VRE) and vancomycin-intermediate S. aureus (VISA) have been reported to produce peritonitis in CAPD patients. The finding of more than one organism in dialysate culture should prompt a search for a cause of secondary peritonitis. As with primary peritonitis, culture of dialysate fluid in blood culture bottles improves the yield. To facilitate diagnosis, several hundred milliliters of removed dialysis fluid should be concentrated by centrifugation before culture.

Empirical therapy for CAPD peritonitis should be directed at S. aureus, coagulase-negative Staphylococcus, and gram-negative bacilli until the results of cultures are available. Since the advent of VRE and VISA, a first-generation cephalosporin such as cefazolin and a third-generation cephalosporin such as cefazidime constitute the treatment of choice. A loading dose of cefazolin is administered intraperitoneally along with cefazidime; doses depend on the dialysis method and the patient’s renal function. If methicillin-resistant S. aureus is a relatively common isolate in a community, vancomycin may be a reasonable first choice for empirical therapy, especially in a toxic-appearing patient or a patient with an overt exit-site infection. The dose (2 g) is allowed to remain in the peritoneal cavity for 6 h. If the patient is severely ill, intravenous antibiotics similar to those in the dialysis bag should be added to the regimen at doses appropriate for the patient’s degree of renal failure. The clinical response to an empirical treatment regimen should be rapid; if the patient has not responded after 48 h of treatment, catheter removal should be considered.
ceral organ such as the liver, where they may develop either on the surface of the organ or within it. Periappendiceal and diverticular abscesses occur commonly. Diverticular abscesses are least likely to rupture. Infections of the female genital tract and pancreatitis are also among the more common causative events. When abscesses occur in the female genital tract—either as a primary infection (e.g., tubo-ovarian abscess) or as an infection extending into the pelvic cavity or peritonemum—B. fragilis figures prominently among the organisms isolated. B. fragilis is not found in large numbers in the normal vaginal flora. It is encountered less commonly in pelvic inflammatory disease and endometritis, for example, without an associated abscess. In pancreatitis with leakage of damaging pancreatic enzymes, inflammation is prominent. Therefore, clinical findings such as fever, leukocytosis, and even abdominal pain do not distinguish pancreatitis itself from complications such as pancreatic pseudocyst, pancreatic abscess (Chap. 294), or intra-abdominal collections of pus. Especially in cases of necrotizing pancreatitis, in which the incidence of local pancreatic infection may be as high as 30%, needle aspiration under CT guidance is performed as often as once a week to sample fluid for culture. Many centers prescribe prophylactic antibiotics to prevent infection in patients with necrotizing pancreatitis. Imipenem is the drug most frequently used for this purpose since it reaches high tissue levels in the pancreas (although it is not unique in this regard). If needle aspiration yields infected fluid, most experts agree that surgery is superior to percutaneous drainage.

**DIAGNOSIS** A variety of scanning procedures have considerably facilitated the diagnosis of intra-abdominal abscesses. Abdominal CT probably has the highest yield, although ultrasonography is particularly useful for the right upper quadrant, kidneys, and pelvis. Both indium-labeled WBCs and gallium tend to localize in abscesses and may be useful in finding a collection. Since gallium is taken up in the bowel, indium-labeled WBCs may have a slightly greater yield for abscesses near the bowel. Neither indium-labeled WBC nor gallium scans serve as a basis for a definitive diagnosis, however; both need to be followed by other, more specific studies, such as CT, if an area of possible abnormality is identified. Abscesses contiguous with or contained within outpouchings of bowel are particularly difficult to diagnose with scanning procedures. Occasionally, a barium enema may detect a diverticular abscess not diagnosed by other procedures, although barium should not be injected if a free perforation is suspected. If one study is negative, a second study sometimes reveals a collection. Although exploratory laparotomy has been less commonly used since the advent of CT, this procedure still must be undertaken on occasion if an abscess is strongly suspected on clinical grounds.

**RX TREATMENT**

An algorithm for the management of patients with intra-abdominal abscesses is presented in Fig. 112-1. The treatment of intra-abdominal infections involves the determination of the initial focus of infection, the administration of broad-spectrum antibiotics targeted at organisms involved in the associated infection, and the performance of a drainage procedure if one or more definitive abscesses have already formed. Antimicrobial therapy, in general, is adjunctive to drainage and/or surgical correction of an underlying lesion or process in intra-abdominal abscesses. Unlike the intra-abdominal abscesses precipitated by most infections, for which drainage of some kind is generally required, abscesses associated with diverticulitis usually well off locally after rupture of a diverticulum, so that surgical intervention is not routinely required.

A number of antimicrobial agents exhibit excellent activity against aerobic gram-negative bacilli. Since mortality in intra-abdominal sepsis is linked to gram-negative bacteremia, empirical therapy for intra-abdominal infection always needs to include adequate coverage of gram-negative aerobic, facultative, and anaerobic organisms. Even if anaerobes are not cultured from clinical specimens, they still must be covered by the therapeutic regimen. Broad-spectrum empirical antibiotic therapy should be the same as that discussed above for secondary peritonitis.

**VISCERAL ABSCESSES** - Liver Abscesses The liver is the organ most subject to the development of abscesses. In one study of 540 intra-abdominal abscesses over a 12-year period, 26% of these abscesses were visceral. Liver abscesses made up 13% of the total number of abscesses, or 48% of all visceral abscesses. Liver abscesses may be solitary or multiple; they may arise from hematogenous spread of bacteria or from local spread from contiguous sites of infection within the peritoneal cavity. In the past, appendicitis with rupture and subsequent spread of infection was the most common route for the development of a liver abscess. Currently, associated disease of the biliary tract is most often the etiology. Suppurative pylephlebitis (suppurative thrombosis of the portal vein), usually arising from infection in the pelvis but sometimes from infection elsewhere in the peritoneal cavity, is another common source for bacterial seeding of the liver.

Fever is the most common presenting sign of liver abscess. Some patients, particularly those with active associated disease of the biliary tract, have symptoms and signs localized to the right upper quadrant, including pain, guarding, punch tenderness, and even rebound tenderness. Nonspecific symptoms, such as chillis, anorexia, weight loss, nausea, and vomiting, may also develop. Only 50% of patients with liver abscesses, however, have hepatomegaly, right-upper-quadrant tenderness, or jaundice; thus, half of patients have no symptoms or signs that would direct attention to the liver. Fever of unknown origin (FUO) may be the only presenting manifestation of liver abscess, especially in the elderly. Diagnostic studies of the abdomen, especially the right upper quadrant, should be a part of any FUO workup. The single most reliable laboratory finding is an elevated serum concentration of alkaline phosphatase, which is documented in 70% of patients with liver abscesses. Other tests of liver function may yield normal results, but 50% of patients have elevated serum levels of bilirubin, and 48% have elevated concentrations of aspartate aminotransferase. Other associated laboratory findings include leukocytosis in 77% of patients, anemia (usually normochromic, normocytic) in 50%, and hypobalbuminemia in 33%. Concomitant bacteremia is found in one-third of patients. A liver abscess is sometimes suggested by chest radiography, especially if a new elevation of the right hemidiaphragm is seen; other suggestive findings include a right basilar infiltrate and a right pleural effusion.

Imaging studies are the most reliable methods for diagnosing liver abscesses. These studies include ultrasonography, CT (Fig. 112-2), indium-labeled WBC or gallium scans, and magnetic resonance im-

---

aging. In an occasional case, more than one such study may be required. Organisms recovered from liver abscesses vary with the etiology. In liver infection arising from the biliary tree, enteric gram-negative aerobic bacilli and enterococci are common isolates. Unless previous surgery has been performed, anaerobes are not generally involved in liver abscesses arising from biliary infections. In contrast, in liver abscesses arising from pelvic and other intraperitoneal sources, a mixed flora including both aerobic and anaerobic species is common; \textit{B. fragilis} is the species most frequently isolated. With hematogenous spread of infection, usually only a single organism is encountered; this species may be \textit{S. aureus} or a streptococcal species such as \textit{S. milleri}. Results of cultures obtained from drain sites are not reliable for defining the etiology of infections. Liver abscesses may also be caused by \textit{Candida} species; such abscesses usually follow fungemia in patients receiving chemotherapy for cancer and often present when neutrophils return after a period of neutropenia. However, the recovery of \textit{Candida} from a drain site does not necessarily implicate this organism as a cause of infection. Amebic liver abscesses are not an uncommon problem (Chap. 194). Amebic serologic testing gives positive results in $\gtrsim 95\%$ of cases; thus, a negative result helps to exclude this diagnosis.

**TREATMENT**

While drainage—either percutaneous (with a pigtail catheter kept in place) or surgical—remains the mainstay of therapy for intraabdominal abscesses (including liver abscesses), there is growing interest in medical management alone for pyogenic liver abscesses. The drugs used for empirical broad-spectrum antibiotic therapy include the same ones used in intraabdominal sepsis and secondary bacterial peritonitis. Usually, a diagnostic aspirate of abscess contents should be obtained before the initiation of empirical therapy, with antibiotic choices adjusted when the results of Gram’s staining and culture become available. Cases treated without definitive drainage generally require longer courses of antibiotic therapy. When percutaneous drainage was compared with open surgical drainage, the average length of hospital stay for the former was almost twice that for the latter, although both the time required for fever to resolve and the mortality rate were the same for the two procedures. Mortality was appreciable despite treatment, averaging 15\%. Several factors may predict the failure of percutaneous drainage and therefore may favor primary surgical intervention. These factors include the presence of multiple, sizable abscesses; viscous abscess contents that tend to plug the catheter; associated disease (e.g., disease of the biliary tract) that requires surgery; or the lack of a clinical response to percutaneous drainage in 4 to 7 days.

Treatment of candidal liver abscesses usually entails lengthy administration of amphotericin B, although reports have described successful maintenance therapy with fluconazole after an initial course of amphotericin (Chap. 187).

**Splenic Abscesses** Splenic abscesses are much less common than liver abscesses. The incidence of splenic abscesses has ranged from 0.14 to 0.7\% in various autopsy series. The clinical setting and the organisms isolated usually differ from those for liver abscesses. The degree of clinical suspicion for splenic abscess needs to be high, as this condition is frequently fatal if left untreated. Even in the most recently published series, diagnosis was made only at autopsy in 37\% of cases. While splenic abscesses may arise occasionally from contiguous spread of infection or from direct trauma to the spleen, hematogenous spread of infection is the usual mode of development. Bacterial endocarditis is the most common associated infection (Chap. 109). Splenic abscesses can develop in patients who have received extensive immunosuppressive therapy (particularly those with malignancy involving the spleen) and in patients with hemoglobinopathies or other hematologic disorders (especially sickle cell anemia).

While $\gtrsim 50\%$ of patients with splenic abscesses have abdominal pain, the pain is localized to the left upper quadrant in only half of these cases. Splenomegaly is found in $\gtrsim 50\%$ of cases. Fever and leukocytosis are generally present; the development of fever preceded diagnosis by an average of 20 days in one series. Left-sided chest findings may include abnormalities to auscultation, and chest radiographic findings may include an infiltrate or a left-sided pleural effusion. When splenic abscesses are being considered in a differential diagnosis, CT scan of the abdomen has been the most sensitive diagnostic tool. Ultrasonography can yield the diagnosis, but cases have been missed with this modality. Liver-spleen scan or gallium scan may also be useful. Streptococcal species are the most common bacterial isolates from splenic abscesses, and \textit{S. aureus} is the next most common; presumably these prevalences reflect the bacterial cause of the associated endocarditis. An increase in the frequency of isolation of gram-negative aerobic organisms from splenic abscesses has been reported; these organisms often derive from a urinary tract focus, with associated bacteremia, or from another intraabdominal source. \textit{Salmonella} species are seen fairly commonly, especially in patients with sickle cell hemoglobinopathy. Anaerobic species accounted for only 5\% of isolates in the largest collected series, but the reporting of a number of “sterile abscesses” may indicate that optimal techniques for the isolation of anaerobes were not employed.

**TREATMENT**

Because of the high mortality figures reported for splenic abscesses, the treatment of choice is splenectomy with adjunctive antibiotics. However, percutaneous drainage has been successful. The most important factor in successful treatment of splenic abscesses is early consideration of the diagnosis.

**Perinephric and Renal Abscesses** Perinephric and renal abscesses are not common: The former accounted for only $\sim 0.02\%$ of hospital admissions and the latter for $\sim 0.2\%$ in Altemeier’s series of 540 intraabdominal abscesses. While liver abscesses generally arise from contiguous foci of infection or track from other intraabdominal sources and splenic abscesses usually arise from hematogenous spread (e.g., spread from bacterial endocarditis), perinephric and renal abscesses have a different pathogenesis. Before antibiotics became available, most renal and perinephric abscesses were hematogenous in origin, with \textit{S. aureus} most commonly recovered. Now, in contrast, $\gtrsim 75\%$ of perinephric and renal abscesses are hematogenous in origin, with \textit{S. aureus} most commonly recovered. Now, in contrast, $\gtrsim 75\%$ of perinephric and renal abscesses are hematogenous in origin, with \textit{S. aureus} most commonly recovered.

Bacteria may directly invade the renal parenchyma from medulla to cortex. Local vascular channels within the kidney may also facilitate the transport of organisms. Areas of abscess developing within the parenchyma may rupture into the perinephric space.
kidsneys and adrenal glands are surrounded by a layer of perirenal fat that, in turn, is surrounded by Gerota’s fascia, which extends superiorly to the diaphragm and inferiorly to the pelvic fat. When abscesses extend into the perinephric space, tracking may occur through Gerota’s fascia into the psoas or transversalis muscles, into the anterior peritoneal cavity, superiorly to the subdiaphragmatic space, or inferiorly to the pelvis. Of the several risk factors that have been associated with the development of perinephric abscesses, the most important is the presence of concomitant nephrolithiasis producing local obstruction to urinary flow. Of patients with perinephric abscess, 20 to 60% have renal stones. In addition, other structural abnormalities of the urinary tract, a history of urologic surgery, trauma, and diabetes mellitus have all been identified as risk factors.

The organisms most frequently encountered in perinephric and renal abscesses are *E. coli*, *Proteus* species, and *Klebsiella* species. *E. coli*, the aerobic species most commonly found in the colonic flora, seems to have unique virulence properties in the urinary tract, including factors promoting adherence to uroepithelial cells. The urease of *Proteus* species splits urea, thereby creating a more alkaline and more hospitable environment for bacterial proliferation. *Proteus* species are frequently found in association with large struvite stones caused by the precipitation of magnesium ammonium sulfate in an alkaline environment. These stones serve as a nidus for recurrent urinary tract infection. While a single bacterial species is usually recovered from a perinephric or renal abscess, multiple species may also be found. If a urine culture is not contaminated with periurethral flora and is found to contain more than one organism, a perinephric abscess or renal abscess should be considered in the differential diagnosis.

*Candida* species should be considered in the etiology of renal abscesses. This fungus may spread to the kidney via the hematogenous route or by ascension from the bladder. The hallmark of the latter route of infection is ureteral obstruction with large fungal balls.

The presentation of perinephric and renal abscesses is quite nonspecific. Flank pain and abdominal pain are common. At least 50% of patients are febrile. Pain may be referred to the groin or leg, particularly with extension of infection. The diagnosis of perinephric abscess, like that of splenic abscess, is frequently delayed, and the mortality rate in some series is appreciable, although lower than in the past. Perinephric or renal abscess should be most seriously considered when a patient presents with symptoms and signs of pyelonephritis and remains febrile after 4 or 5 days, by which time the fever should have resolved. Moreover, when a urine culture yields a polymicrobial flora, when a patient is known to have renal stone disease, or when fever and pyuria coexist with a sterile urine culture, the diagnosis of perinephric or renal abscess should be entertained.

Renal ultrasonography and abdominal CT are the most useful diagnostic modalities. If a renal abscess or perinephric abscess is diagnosed, nephrolithiasis should be excluded, especially when a high urinary pH suggests the presence of a urea-splitting organism.

**ACUTE INFECTIOUS DIARRHEAL DISEASES AND BACTERIAL FOOD POISONING**

**Part VI Infectious Diseases**

Ranging from mild annoyances during vacations to devastating dehydrating illnesses that can kill within hours, acute gastroenteritis ranks second only to acute upper respiratory illnesses as the most common diseases worldwide. In children <5 years old, attack rates range from 2 to 3 illnesses per child per year in developed countries to as high as 10 to 18 illnesses per child per year in developing countries. In Asia, Africa, and Latin America, acute diarrheal illnesses are not only a leading cause of morbidity in children—with an estimated 1 billion cases per year—but also a major cause of mortality, being responsible for 4 to 6 million deaths per year, or a sobering total of 12,600 deaths per day. In some areas, >50% of childhood deaths are directly attributable to acute diarrheal illnesses. In addition, by contributing to malnutrition and thereby reducing resistance to other infectious agents, gastrointestinal illnesses may be indirect factors in a far greater burden of disease.

The wide range of clinical manifestations of acute gastrointestinal illnesses is matched by the wide variety of infectious agents involved, including viruses, bacteria, and parasitic pathogens (Table 113-1). This

**TREATMENT**

Treatment for perinephric or renal abscesses, like that for intra-abdominal abscesses, includes drainage of pus and antibiotic therapy directed at the organism(s) recovered. For perinephric abscesses, percutaneous drainage is usually successful.

**Psoas Abscesses** The psoas muscle is another location in which abscesses are encountered. Psoas abscesses may arise from a hematogenous source, by contiguous spread from an intraabdominal or pelvic process, or by contiguous spread from nearby bony structures (e.g., vertebral bodies). Associated osteomyelitis due to spread from bone to muscle or from muscle to bone is common in psoas abscesses. When Pott’s disease was common, *Mycobacterium tuberculosis* was a frequent cause of psoas abscess. Currently, either *S. aureus* or a mixture of enteric organisms including aerobic and anaerobic gram-negative bacilli is usually isolated from psoas abscesses in the United States. *S. aureus* is most likely to be isolated when a psoas abscess arises from hematogenous spread or a contiguous focus of osteomyelitis; a mixed enteric flora is the most likely etiology when the abscess has an intraabdominal or pelvic source. Patients with psoas abscesses frequently present with fever, lower abdominal or back pain, or pain referred to the hip or knee. CT is the most useful diagnostic technique.

**Treatment**

Treatment includes surgical drainage and the administration of an antibiotic regimen directed at the inciting organism(s).

**Pancreatic Abscesses** See Chap. 294.

**FURTHER READING**

chapter will discuss factors that enable gastrointestinal pathogens to cause disease, will review host defense mechanisms, and will delineate an approach to the evaluation and treatment of patients presenting with acute diarrhea. Individual organisms causing acute gastrointestinal illnesses are discussed in detail in subsequent chapters.

**PATHOGENIC MECHANISMS** Enteric pathogens have developed a variety of tactics to overcome host defenses. Understanding the virulence factors employed by these organisms is important in the diagnosis and treatment of clinical disease.

**Inoculum Size** The number of microorganisms that must be ingested to cause disease varies considerably from species to species. For *Shigella*, enterohemorrhagic *Escherichia coli*, *Giardia lamblia*, or *Entamoeba*, as few as 10 to 100 bacteria or cysts can produce infection, while 10^8 to 10^9 *Vibrio cholerae* organisms must be ingested orally to cause disease. The infective dose of *Salmonella* varies widely, depending on the species, host, and food vehicle. The ability of organisms to overcome host defenses has important implications for transmission; *Shigella*, enterohemorrhagic *E. coli*, *Entamoeba*, and *Giardia* can spread by person-to-person contact, whereas under some circumstances *Salmonella* may have to grow in food for several hours before reaching an effective infective dose.

**Adherence** Many organisms must adhere to the gastrointestinal mucosa as an initial step in the pathogenic process; thus, organisms that can compete with the normal bowel flora and colonize the mucosa have an important advantage in causing disease. Specific cell-surface proteins involved in attachment of bacteria to intestinal cells are important virulence determinants. *V. cholerae*, for example, adheres to the brush border of small-intestinal enterocytes via specific surface adhesins, including the toxin-coregulated pilus and other accessory colonization factors. Different pathogenic varieties of *E. coli* have different adherence mechanisms. Enterotoxigenic *E. coli*, which causes watery diarrhea, produces an adherence protein called colonization factor antigen that is necessary for colonization of the upper small intestine by the organism prior to the production of enterotoxin. Enteropathogenic *E. coli*, an agent of diarrhea in young children, and enterohemorrhagic *E. coli*, which causes hemorrhagic colitis and the hemolytic-uremic syndrome, produce virulence determinants that allow these organisms to attach to and efface the brush border of the intestinal epithelium.

**Toxin Production** The production of one or more exotoxins is important in the pathogenesis of numerous enteric organisms. Such toxins include enterotoxins, which cause watery diarrhea by acting directly on secretory mechanisms in the intestinal mucosa; cytotoxins, which cause destruction of mucosal cells and associated inflammatory diarrhea; and neurotoxins, which act directly on the central or peripheral nervous system. Some exotoxins act by more than one mechanism; *Shigella dysenteriae* type 1, for example, produces an exotoxin that has both enterotoxic and cytotoxic activities.

The prototypical enterotoxin is cholera toxin, a heterodimeric protein composed of one A and five B subunits. The A subunit contains the enzymatic activity of the toxin, while the B subunit pentamer binds holotoxin to the enterocyte surface receptor, the ganglioside GM1. After the binding of holotoxin, a fragment of the A subunit is translocated across the eukaryotic cell membrane into the cytoplasm, where it catalyzes the ADP-ribosylation of a GTP-binding protein and causes persistent activation of adenylate cyclase. The end result is an increase of cyclic AMP in the intestinal mucosa, which increases Cl⁻ secretion and decreases Na⁺ absorption, leading to loss of fluid and the production of diarrhea.

Enterotoxigenic strains of *E. coli* may produce a protein called heat-labile enterotoxin (LT) that is similar to cholera toxin and causes secretory diarrhea by the same mechanism. Alternatively, enterotoxigenic strains of *E. coli* may produce heat-stable enterotoxin (ST), one form of which causes diarrhea by activation of guanylate cyclase and elevation of intracellular cyclic GMP. Some enterotoxigenic strains of *E. coli* produce both LT and ST.

Bacterial cytotoxins, in contrast, destroy intestinal mucosal cells and produce the syndrome of dysentery, with bloody stools containing inflammatory cells. Enteric pathogens that produce such cytotoxins include *S. dysenteriae* type 1, *Vibrio parahaemolyticus*, and *Clostridium difficile*. Shiga toxin–producing strains of *E. coli* (a group that includes enterohemorrhagic strains and whose most common serotype in the United States is O157:H7) produce potent cytotoxins that are highly related to the Shiga toxin of *S. dysenteriae* type 1. Such strains of *E. coli* have been associated with outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome.

Neurotoxins are usually produced by the responsible organism outside the host and therefore cause symptoms soon after ingestion. Included are the staphylococcal and *Bacillus cereus* toxins, which act on the central nervous system to produce vomiting.

**Invasion** Dysentery may result not only from the production of cytotoxins but also from bacterial invasion and destruction of intestinal mucosal cells. Infections due to *Shigella* and enteroinvasive *E. coli*, for example, are characterized by the organisms’ invasion of mucosal epithelial cells, intraepithelial multiplication, and subsequent spread to adjacent cells. *Salmonella*, on the other hand, causes inflammatory diarrhea by invasion of the bowel mucosa but generally is not associated with the destruction of enterocytes or the full clinical syndrome of dysentery. *Salmonella* typhi and *Yersinia enterocolitica* can penetrate intact intestinal mucosa, multiply intracellularly in Peyer’s patches and intestinal lymph nodes, and then disseminate through the body.

FIGURE 113-1  Clinical algorithm for the approach to patients with community-acquired infectious diarrhea or bacterial food poisoning. For key to superscripts: 1. Diarrhea lasting >2 days is generally defined as chronic; in such cases, many of the causes of acute diarrhea are much less likely, and a new spectrum of causes needs to be considered. 2. Fever often implies invasive disease, although fever and diarrhea may also result from infection outside the gastrointestinal tract, as in malaria. 3. Stools that contain blood or mucus indicate ulceration of the large bowel. Bloody stools without fecal leukocytes should alert the laboratory to the possibility of infection with Shiga toxin–producing enterohemorrhagic Escherichia coli. Bulky white stools suggest a small-intestinal process that is causing malabsorption. Profuse “rice-water” stools suggest cholera or a similar toxigenic process. 4. Frequent stools over a given period can provide the first warning of impending dehydration. 5. Abdominal pain may be most severe in inflammatory processes like those due to Shigella, Campylobacter, and necrotizing toxins. Painful abdominal muscle cramps, caused by electrolyte loss, can develop in severe cases of cholera. Bloating is common in giardiasis. An appendicitis–like syndrome should prompt a culture for Yersinia enterocolitica with cold enrichment. 6. Tenesmus with cold enrichment. 7. Vomiting implies an acute infection (e.g., a toxin-mediated illness or food poisoning) but can also be a feature of cases with proctitis, as in shigellosis or amebiasis. 8. Asking patients whether anyone else they know is sick is a more efficient means of identifying a common source than is constructing a list of recently eaten foods. If a common source seems likely, specific foods can be investigated. See text for a discussion of bacterial food poisoning. 9. Current antibiotic therapy or a recent history of treatment suggests Clostridium difficile diarrhea (Chap. 114). Stop antibiotic treatment if possible and consider tests for C. difficile toxins. Antibiotic use may increase the risk of other infections, such as salmonellosis. 10. See text (and Chap. 108) for a discussion of traveler’s diarrhea. HOST DEFENSES Given the enormous number of microorganisms ingested with every meal, the normal host must possess effective defense mechanisms to combat a constant influx of potential enteric pathogens. Studies of infections in patients with alterations in these defenses have led to a greater understanding of the variety of ways in which the normal host can protect itself against disease.

Normal Flora The large numbers of bacteria that normally inhabit the intestine act as an important host defense by preventing colonization by potential enteric pathogens. Persons with fewer intestinal bacteria, such as infants who have not yet developed normal enteric colonization or patients receiving antibiotics, are at significantly greater risk of developing infections with enteric pathogens. The composition of the intestinal flora is as important as the number of organisms present. More than 99% of the normal colonic flora is made up of anaerobic bacteria, and the acidic pH and volatile fatty acids produced by these organisms appear to be critical elements in resistance to colonization.

Gastric Acid The acidic pH of the stomach is an important barrier to enteric pathogens, and an increased frequency of infections due to Salmonella, G. lamblia, and a variety of helminths has been reported among patients who have undergone gastric surgery or are achlorhydric for some other reason. Neutralization of gastric acid with antacids or H₂ blockers—common among hospitalized patients—similarly increases the risk of enteric colonization. Some microorganisms, however, can survive the extreme acidity of the gastric environment; rotavirus, for example, is highly stable to acidity.

Intestinal Motility Normal peristalsis is the major mechanism for clearance of bacteria from the proximal small intestine, although gastric acidity and secreted immunoglobulins also play a role in limiting the number of organisms present. When intestinal motility is impaired—for example, by treatment with opiates or other antinmotility drugs, anatomic abnormalities (diverticula, fistulas, or afferent-loop stasis following surgery), or hypomotility states (as in diabetes mellitus or scleroderma)—the frequency of bacterial overgrowth and infection of the small bowel with enteric pathogens is much increased. Some patients in whom Shigella infection is treated with diphenoxylate hydrochloride with atropine (Lomotil) experience prolonged fever and shedding of organisms, while patients treated with opiates for mild Salmonella gastroenteritis have a higher frequency of bacteremia than those not treated with opiates.

Immunity Both cellular immune responses and antibody production play important roles in protecting susceptible hosts from enteric infections. The wide spectrum of viral, bacterial, parasitic, and fungal gastrointestinal infections in patients with AIDS highlights the significance of cell-mediated immunity in protecting the normal host from these pathogens. Humoral immunity is also important and consists of systemic IgG and IgM as well as secretory IgA. Growing evidence supports the concept of a mucosal immune system for secretory IgA or patients receiving antibiotics, are at significantly greater risk of developing infections with enteric pathogens. The composition of the intestinal flora is as important as the number of organisms present. More than 99% of the normal colonic flora is made up of anaerobic bacteria, and the acidic pH and volatile fatty acids produced by these organisms appear to be critical elements in resistance to colonization.

Gastric Acid The acidic pH of the stomach is an important barrier to enteric pathogens, and an increased frequency of infections due to Salmonella, G. lamblia, and a variety of helminths has been reported among patients who have undergone gastric surgery or are achlorhydric for some other reason. Neutralization of gastric acid with antacids or H₂ blockers—common among hospitalized patients—similarly increases the risk of enteric colonization. Some microorganisms, however, can survive the extreme acidity of the gastric environment; rotavirus, for example, is highly stable to acidity.

Intestinal Motility Normal peristalsis is the major mechanism for clearance of bacteria from the proximal small intestine, although gastric acidity and secreted immunoglobulins also play a role in limiting the number of organisms present. When intestinal motility is impaired—for example, by treatment with opiates or other antinmotility drugs, anatomic abnormalities (diverticula, fistulas, or afferent-loop stasis following surgery), or hypomotility states (as in diabetes mellitus or scleroderma)—the frequency of bacterial overgrowth and infection of the small bowel with enteric pathogens is much increased. Some patients in whom Shigella infection is treated with diphenoxylate hydrochloride with atropine (Lomotil) experience prolonged fever and shedding of organisms, while patients treated with opiates for mild Salmonella gastroenteritis have a higher frequency of bacteremia than those not treated with opiates.

Immunity Both cellular immune responses and antibody production play important roles in protecting susceptible hosts from enteric infections. When intestinal motility is impaired—for example, by treatment with opiates or other antinmotility drugs, anatomic abnormalities (diverticula, fistulas, or afferent-loop stasis following surgery), or hypomotility states (as in diabetes mellitus or scleroderma)—the frequency of bacterial overgrowth and infection of the small bowel with enteric pathogens is much increased. Some patients in whom Shigella infection is treated with diphenoxylate hydrochloride with atropine (Lomotil) experience prolonged fever and shedding of organisms, while patients treated with opiates for mild Salmonella gastroenteritis have a higher frequency of bacteremia than those not treated with opiates.
**Physical Examination** The examination of patients for signs of dehydration provides essential information about the severity of the diarrheal illness and the need for rapid therapy. Mild dehydration is indicated by thirst, dry mouth, decreased axillary sweat, decreased urine output, and slight weight loss. Signs of moderate dehydration include an orthostatic fall in blood pressure, skin tenting, and sunken eyes (or, in infants, a sunken fontanelle). Signs of severe dehydration range from hypotension and tachycardia to confusion and frank shock.

**Diagnostic Approach** After the severity of illness is assessed, the most important distinction that the clinician must make is between inflammatory and noninflammatory disease. Using the history and epidemiologic features of the case as guides in making this distinction, the clinician can rapidly evaluate the need for further efforts to define a specific etiology and for therapeutic intervention. Examination of a stool sample is an important supplement to the narrative history. Grossly bloody or mucoid stool suggests an inflammatory process. A test for fecal leukocytes (preparation of a thin smear of stool on a glass slide, addition of a drop of methylene blue, and examination of the wet mount) can suggest inflammatory disease in patients presenting with diarrhea, although the predictive value of this test is still debated. A test for fecal lactoferrin, which is a marker of fecal leukocytes, is more sensitive and is available in latex agglutination and enzyme-linked immunosorbent assay formats. Causes of acute infectious diarrhea, categorized as inflammatory and noninflammatory, are listed in Table 113-1.

### EPIDEMIOLOGY ■ Travel History

Of the several million people who travel from temperate industrialized countries to tropical regions of Asia, Africa, and Central and South America each year, 20 to 50% experience a sudden onset of abdominal cramps, anorexia, and watery diarrhea; thus traveler’s diarrhea is the most common travel-related illness (Chap. 114). The time of onset is usually 3 days to 2 weeks after the traveler’s arrival in a tropical area; most cases begin within the first 3 to 5 days. The illness is generally self-limited, lasting 1 to 5 days. The high rate of diarrhea among travelers to underdeveloped areas is related to the ingestion of contaminated food or water.

The organisms that cause traveler’s diarrhea vary considerably with location (Table 113-2). In all areas, enterotoxigenic *E. coli* is the most common isolate from persons with the classic secretory traveler’s diarrhea syndrome.

### Location

Day-care centers have particularly high attack rates of enteric infections. Rotavirus is a common agent among children <2 years old, with attack rates of 75 to 100% among those exposed. *G. lamblia* is more common among older children, with somewhat lower attack rates. Other common organisms, often spread by fecal-oral contact, are *Shigella, Campylobacter jejuni,* and *Cryptosporidium.* A characteristic feature of infection among children attending day-care centers is the high rate of secondary cases among family members.

Similarly, hospitals are sites in which enteric infections are concentrated. In medical intensive-care units and pediatric wards, diarrhea is among the most common nosocomial infections. *C. difficile* is the predominant cause of nosocomial diarrhea among adults in the United States; viral pathogens, especially rotavirus, can spread rapidly in pediatric wards. Enteropathogenic *E. coli* has been associated with outbreaks of diarrhea in nurseries for newborns. One-third of elderly patients in chronic-care institutions develop a significant diarrheal illness each year. Surveillance stool cultures suggest that 25% of the residents of these institutions harbor cytotoxin-producing *C. difficile,* which causes more than half of all cases of diarrhea in this population. Antimicrobial therapy can predispose to pseudomembranous colitis by altering the normal colonic flora and allowing the multiplication of *C. difficile* (Chap. 114).

### Age

Most of the morbidity and mortality from enteric pathogens involves children <5 years of age. Breast-fed infants are protected from contaminated food and water and derive some protection from maternal antibodies, but their risk of infection rises dramatically when they begin to eat solid foods. Infants and younger children are more likely than adults to develop rotavirus disease, while older children and adults are more commonly infected with Norwalk-like viruses. Other organisms with higher attack rates among children than among adults include enterotoxigenic, enteropathogenic, and enterohemorrhagic *E. coli,* *C. jejuni,* and *G. lamblia.* In children, the incidence of *Salmonella* infections is highest among those <1 year of age, while the attack rate for *Shigella* infections is greatest among those 6 months to 4 years of age.

### Bacterial Food Poisoning

If the history and the stool examination indicate a noninflammatory etiology of diarrhea and there is evidence of a common-source outbreak, questions concerning the ingestion of specific foods and the time of onset of the diarrhea after a meal can provide clues to the bacterial cause of the illness. Potential causes of bacterial food poisoning are shown in Table 113-3.

Bacterial disease caused by an enterotoxin elaborated outside the host, such as that due to *Staphylococcus aureus* or *B. cereus,* has the shortest incubation period (1 to 6 h) and generally lasts <12 h. Most cases of staphylococcal food poisoning are caused by contamination from infected human carriers. Staphylococci can multiply at a wide range of temperatures; thus, if food is left to cool slowly and remains at room temperature after cooking, the organisms will have the opportunity to form enterotoxin. Outbreaks following picnics where potato salad, mayonnaise, and cream pastries have been served offer classic examples of staphylococcal food poisoning. Diarrhea,
nausea, vomiting, and abdominal cramping are common, while fever is less so.

*B. cereus* can produce either a syndrome with a short incubation period—the *emetic* form, mediated by a staphylococcal type of enterotoxin—or one with a longer incubation period (8 to 16 h)—the *diarrheal* form, caused by an enterotoxin resembling *E. coli* LT, in which diarrhea and abdominal cramps are characteristic but vomiting is uncommon. The emetic form of *B. cereus* food poisoning is associated with contaminated fried rice; the organism is common in uncooked rice, and its heat-resistant spores survive boiling. If cooked rice is not refrigerated, the spores can germinate and produce toxin. Frying before serving may not destroy the preformed, heat-stable toxin.

Food poisoning due to *Clostridium perfringens* also has a slightly longer incubation period (8 to 14 h) and results from the survival of heat-resistant spores in inadequately cooked meat, poultry, or legumes. After ingestion, toxin is produced in the intestinal tract, causing moderately severe abdominal cramps and diarrhea; vomiting is rare, as is fever. The illness is self-limited, rarely lasting for more than 24 h.

Not all food poisoning has a bacterial cause. Diagnostic confusion can result from diarrhea caused by nonbacterial agents of short-incubation food poisoning, including capsaicin, which is found in hot peppers, and a variety of toxins found in fish and shellfish (Chap. 378).

**LABORATORY EVALUATION** Many cases of noninflammatory diarrhea are self-limited or can be treated empirically, and in these instances the clinician may not need to determine a specific etiology. Potentially pathogenic *E. coli* cannot be distinguished from normal fecal flora by routine culture. Special tests to detect LT and ST are not available in most clinical laboratories. In situations in which cholera is a concern, stool should be cultured on thiosulfate–citrate–bile salts–sucrose (TCBS) agar. A latex agglutination test has made the rapid detection of rotavirus in stool practical for many laboratories, while reverse-transcriptase polymerase chain reaction and specific antigen enzyme immunoassays have been developed for the identification of Norwalk-like viruses. At least three stool specimens should be examined for *Giardia* cysts or stained for *Cryptosporidium* to level the clinical suspicion regarding the involvement of these organisms is high.

All patients with fever and evidence of inflammatory disease acquired outside the hospital should have stool cultured for *Salmonella*, *Shigella*, and *Campylobacter*. *Salmonella* and *Shigella* can be selected on MacConkey’s agar as non-lactose-fermenting (colorless) colonies or can be grown on *Salmonella-Shigella* agar or in selenite enrichment broth, both of which inhibit most organisms except these pathogens. Evaluation of nosocomial diarrhea should initially focus on *C. difficile*; stool culture for other pathogens in this setting has an extremely low yield and is not cost-effective. Pathogenic strains of *C. difficile* generally produce two toxins, A and B. Toxin B can be detected with a cytotoxin assay; if the toxin is present, a monolayer culture of fibroblasts will show cytopathic effects within 6 to 24 h. Rapid enzyme immunoassays and latex agglutination tests for both toxin A and toxin B have been developed (Chap. 114). Isolation of *C. jejuni* requires inoculation of fresh stool onto selective growth medium and incubation at 42°C in a microaerophilic atmosphere. In many laboratories in the United States, *E. coli* O157:H7 is among the most common pathogens isolated from visibly bloody stools. Strains of this enterohemorrhagic serotype can be identified in specialized laboratories by serotyping but also can be identified presumptively in hospital laboratories as lactose-fermenting, indole-positive colonies of sorbitol nonfermenters (white colonies) on sorbitol MacConkey plates. Fresh stools should be examined for amebic cysts and trophozoites.

### Treatment

In many cases, a specific diagnosis is not necessary or not available to guide treatment. The clinician can proceed with the information obtained from the history, stool examination, and evaluation of the severity of dehydration. Empirical regimens for the treatment of traveler’s diarrhea are listed in Table 113-4.

The mainstay of treatment is adequate rehydration. The treatment of cholera and other dehydrating diarrheal diseases was revolutionized by the promotion of oral rehydration solutions, the efficacy of which depends on the fact that glucose-facilitated absorption of sodium and water in the small intestine remains intact in the presence of cholera toxin. The use of oral rehydration solutions has reduced mortality due to cholera from >50% (in untreated cases) to <1%. The World Health Organization recommends a solution containing 3.5 g sodium chloride, 2.5 g sodium bicarbonate, 1.5 g potassium chloride, and 20 g glucose (or 40 g sucrose) per liter of water. Oral rehydration solutions containing rice or cereal as the carbohydrate source may be even more effective than glucose-based solutions. Patients who are severely dehydrated or in whom vomiting precludes the use of oral therapy should receive intravenous solutions such as Ringer’s lactate.

Although most secretory forms of traveler’s diarrhea—usually due to enterotoxigenic *E. coli*—can be treated effectively with rehydration, bismuth subsalicylate, or antiperistaltic agents, antimicrobial agents can shorten the duration of illness from between 3 and 4 days to between 24 and 36 h.

The antibiotic treatment of children who present with bloody diarrhea raises special concerns. Laboratory studies of enterohemorrhagic *E. coli* strains have demonstrated that a number of antibiotics induce replication of Shiga toxin—producing lambdoid bacteriophages, significantly increasing toxin production by these strains. Clinical studies have supported these laboratory results, and antibiotics are not recommended for the treatment of enterohemorrhagic *E. coli* infections in children.

**Prophylaxis** Improvements in hygiene to limit fecal-oral spread of enteric pathogens will be necessary if the prevalence of diarrheal diseases is to be significantly reduced in developing countries. Travelers
The recommended antibacterial drugs are as follows:

- Loperamide should not be used by patients with fever or dysentery; its use may prolong the clinical course of treatable infections such as those caused by Campylobacter and non-typhoidal Salmonella. Recent research has shown promising advances in the development of vaccines against rotavirus, *Shigella*, *V. cholerae*, *S. typhi*, and enterotoxigenic *E. coli*.

### Clinical Syndrome

| Watery diarrhea (no blood in stool, no fever), 1 or 2 unformed stools per day without distressing enteric symptoms | Oral fluids (PediaLyte, Lytren, or flavored mineral water) and saltine crackers |
| Watery diarrhea (no blood in stool, no fever), 1 or 2 unformed stools per day with distressing enteric symptoms | Bismuth subsalicylate (for adults): 30 mL or 2 tablets (262 mg/tablet) every 30 min for 8 doses; or loperamide*: 4 mg initially followed by 2 mg after passage of each unformed stool, not to exceed 8 tablets (16 mg) per day (prescription dose) or 4 caplets (8 mg) per day (over-the-counter dose); drugs can be taken for 2 days |
| Watery diarrhea (no blood in stool, no distressing abdominal pain, no fever), >2 unformed stools per day | Antibacterial drug** plus (for adults) loperamide (see dose above) |
| Dysentery (passage of bloody stools) or fever (>37.8°C) | Antibacterial drug** |
| Vomiting, minimal diarrhea | Fluids and electrolytes (PediaLyte, Lytren); continue feeding, especially with breast milk; seek medical attention for moderate dehydration, fever lasting >24 h, bloody stools, or diarrhea lasting more than several days |
| Diarrhea in infants (<2 y old) | Fluids and electrolytes; can consider attapulgite, 0.5 g initially, with dose repeated after passage of each unformed stool or every 2 h (whichever is earlier), for a total dosage of 9 g/d; seek medical attention for persistent or severe symptoms |
| Diarrhea in pregnant women | Travel to Thailand (with risk of fluoroquinolone-resistant *Campylobacter*): Adults: Azithromycin (at above dose for adults). Alternative agent: a fluoroquinolone (at above doses for adults). Children: Same as for children traveling to other areas (see above). All patients should take oral fluids (PediaLyte, Lytren, or flavored mineral water) plus saltine crackers. If diarrhea becomes moderate or severe, if fever persists, or if bloody stools or dehydration develops, the patient should seek medical attention. 

* Source: After Dupont.

** Loperamide should not be used by patients with fever or dysentery; its use may prolong diarrheal disease in patients with infection due to *Shigella* or other invasive organisms.

---

** FURTHER READING: **

**DEFINITION** Clostridium difficile–associated disease (CDAD) is a unique colon infection that is acquired almost exclusively in association with antimicrobial use and the consequent disruption of the normal colonic flora. The most commonly diagnosed diarrheal illness acquired in the hospital, CDAD results from the ingestion of spores of *C. difficile* that vegetate, multiply, and secrete toxins, causing diarrhea and pseudomembranous colitis (PMC).

**ETIOLOGY AND EPIDEMIOLOGY** *C. difficile* is an obligately anaerobic, gram-positive, spore-forming bacillus whose spores are found widely in nature, particularly in the environment of hospitals and chronic care facilities. CDAD occurs most frequently in hospitals and nursing homes where the level of antimicrobial use is high and the environment is contaminated by *C. difficile* spores.

Clindamycin, ampicillin, and cephalosporins were the first antibiotics associated with CDAD; the second- and third-generation cephalosporins, particularly cefotaxime, ceftriaxone, cefuroxime, and ceftazidime, are now the agents most frequently responsible for this condition. Penicillin/β-lactamase-inhibitor combinations such as ticarcillin/clavulanate and piperacillin/tazobactam pose significantly less risk. However, all antibiotics, including vancomycin and metronidazole (the agents most commonly used to treat CDAD), have been found to carry a risk of subsequent CDAD.

*C. difficile* is acquired exogenously, most frequently in the hospital, and is carried in the stool of symptomatic and asymptomatic patients. The rate of fecal colonization is often ≥20% among adult patients hospitalized for >1 week; in contrast, the rate is 1 to 3% among community residents. The risk of *C. difficile* acquisition increases in proportion to length of hospital stay. Asymptomatic fecal carriage of *C. difficile* in healthy neonates is very common, often exceeding 50% during the first 6 months of life. Spores of *C. difficile* are found on environmental surfaces (where the organism can persist for months) and on the hands of hospital personnel who fail to practice good hand hygiene. Hospital epidemics of CDAD have been attributed to a single *C. difficile* strain and to multiple strains present simultaneously. Other identified risk factors for CDAD include older age, greater severity of illness, use of electronic rectal thermometers, enteral tube feeding, antacid treatment, and gastrointestinal surgery.

**PATHOLOGY AND PATHOGENESIS** Spores of toxigenic *C. difficile* are ingested, survive gastric acidity, germinate in the small bowel, and colonize the lower intestinal tract, where they elaborate two large toxins: toxin A, an enterotoxin, and toxin B, a cytotoxin. These toxins initiate processes resulting in the disruption of epithelial-cell barrier function, diarrhea, and pseudomembrane formation. Toxin A is a potent neutrophil chemoattractant, and both toxins glucosylate the GTP-binding proteins of the Rho subfamily that regulate the actin cell cytoskeleton. Disruption of the cell cytoskeleton results in loss of cell shape, adherence, and tight junctions, with resultant fluid leakage. The pseudomembranes of PMC are confined to the colonic mucosa and initially appear as 1- to 2-mm whitish-yellow plaques. The intervening mucosa appears unremarkable, but, as the disease progresses, the pseudomembranes coalesce to form larger plaques and become confluent over the entire colon wall (Fig. 114-1). The whole colon is usually involved, but 10% of patients have rectal sparing. Viewed microscopically, the pseudomembranes have a mucosal attachment point and contain necrotic leukocytes, fibrin, mucus, and cellular debris. The epithelium is eroded and necrotic in focal areas, with neutrophil infiltration of the mucosa.

Patients colonized with *C. difficile* were initially thought to be at high risk for CDAD. However, four prospective studies have shown that colonized patients actually have a decreased risk of subsequent CDAD. At least three events are proposed as essential for the development of CDAD (Fig. 114-2). Exposure to antimicrobial agents is the first event and establishes susceptibility to *C. difficile* infection. The second event is exposure to toxigenic *C. difficile*. Given that the majority of patients do not develop CDAD after the first two events, a third event is clearly essential for its occurrence. Candidate third
CLINICAL MANIFESTATIONS Diarrhea is the most common symptom caused by *C. difficile*. Stools are almost never grossly bloody and range from soft and unformed to watery or mucoid in consistency, with a characteristic odor. Patients may have as many as 20 bowel movements per day. Clinical and laboratory findings include fever in 28% of cases, abdominal pain in 22%, and leukocytosis in 50%. When adynamic ileus (which is seen on x-ray in ~20% of cases) results in cessation of stool passage, the diagnosis of CDAD is frequently overlooked. A clue to the presence of unsuspected CDAD in these patients is unexplained leukocytosis with $\geq 15,000$ cells/mm$^3$. Such patients are at high risk for complications of *C. difficile* infection, particularly toxic megacolon and sepsis.

*C. difficile* diarrhea recurs after treatment in ~20% of cases. Recurrences may represent either relapses due to the same strain or reinfections with a new strain. Recurrence of clinical CDAD is likely to be a result of continued disruption of the normal fecal flora by the antibiotic used to treat CDAD.

DIAGNOSIS The diagnosis of CDAD is based on a combination of clinical criteria: (1) diarrhea ($\geq 3$ unformed stools per 24 h for $\geq 2$ days), with no other recognized cause; plus (2) toxin A or B detected in the stool, toxin-producing *C. difficile* detected by stool culture, or pseudomembranes seen in the colon. PCR is a more advanced form of CDAD and is visualized at endoscopy in only ~50% of patients with diarrhea who have a positive stool culture and toxin assay for *C. difficile* (Table 114-1). Endoscopy is a rapid diagnostic tool in seriously ill patients with suspected PMC and an acute abdomen, but a negative result in this examination does not rule out CDAD.

Despite the array of tests available for *C. difficile* and its toxins (Table 114-1), no single test has high sensitivity, high specificity, and rapid turnaround. The turnaround time for reporting of a positive result in the cell cytotoxicity test can be shortened to <24 h if cell cultures are examined at intervals as short as 4 h. However, this approach is labor intensive, and observation for 48 h is required for a conclusive test result. Most laboratory tests for toxins lack sensitivity; thus, if the first specimen is negative and diarrhea persists, testing of additional stool specimens increases the likelihood of diagnosis. Empirical treatment is appropriate if CDAD is strongly suspected on clinical grounds. Testing of asymptomatic patients is not recommended except for epidemiologic study purposes. In particular, so-called “tests of cure” of asymptomatic treated patients are not recommended because many patients continue to harbor the organism and toxin after diarrhea has ceased and test results do not correlate with recurrence of CDAD. These test results should not be used to restrict placement of patients in long-term-care or nursing home facilities.

* Vancomycin treatment for first episodes of CDAD is discouraged because of possible development of vancomycin resistance in other nosocomial bacteria, such as enterococci.
failed. Diarrhea response rates to oral therapy with vancomycin or metronidazole are ≥94%. The mean interval to resolution of diarrhea is 2 to 4 days. Treatment should not be deemed a failure until a drug has been given for at least 6 days. On the basis of data for shorter courses of vancomycin (Table 114-2), it is recommended that treatment be given for 10 days, although no controlled comparisons are available. Metronidazole, although not approved by the U.S. Food and Drug Administration (FDA) for the treatment of CDAD, is the drug of first choice and the least expensive agent. Metronidazole-resistant isolates have been reported rarely, but treatment failure has not been attributed to resistance. Vancomycin as first-line treatment is discouraged because it may increase the incidence of vancomycin-resistant enterococci in hospitals.

Recurrent CDAD In all, 15 to 25% of patients experience recurrences of CDAD, either as relapses caused by the original organism or as reinfections following treatment (Table 114-2). Re-treatment with metronidazole is recommended for first recurrences of CDAD. There is no standard treatment for multiple recurrences. Approaches include the administration of vancomycin, metronidazole, or bacitracin followed by the yeast Saccharomyces boulardii or Lactobacillus GG; the administration of vancomycin followed by synthetic fecal bacterial enema; and the intentional colonization of the patient with a nontoxigenic strain of *Clostridium difficile*. None of these biotherapeutic agents is available in the United States as an FDA-approved pharmaceutical for treating CDAD. Other approaches include the use of vancomycin in tapering doses over 21 days, with subsequent pulse-dosing every several days for 21 days; the administration of vancomycin followed by that of the anion-exchange binding resin cholestyramine; and combined treatment with vancomycin and rifampin—the approach the authors favor (vancomycin, 125 mg four times daily, and rifampin, 300 mg twice daily, for 10 days). In antibody-deficient children, intravenous immunoglobulin has been used successfully to treat CDAD.

Fulminant CDAD Fulminant CDAD is the most difficult treatment challenge in the rare patients who present with or develop toxic megacolon or ileus. These patients often do not have diarrhea, and their illness mimics an acute surgical abdomen. Sepsis (hypotension, fever, tachycardia, leukocytosis) may result from severe CDAD. An acute abdomen (with or without toxic megacolon) may include signs of cardia, leukocytosis) may result from severe CDAD. An acute abdomen (with or without toxic megacolon) may include signs of cardia, signs of CDAD. Other approaches include the use of vancomycin in tapering doses over 21 days, with subsequent pulse-dosing every several days for 21 days; the administration of vancomycin followed by that of the anion-exchange binding resin cholestyramine; and combined treatment with vancomycin and rifampin—the approach the authors favor (vancomycin, 125 mg four times daily, and rifampin, 300 mg twice daily, for 10 days). In antibody-deficient children, intravenous immunoglobulin has been used successfully to treat CDAD.

Fulminant CDAD Fulminant CDAD is the most difficult treatment challenge in the rare patients who present with or develop toxic megacolon or ileus. These patients often do not have diarrhea, and their illness mimics an acute surgical abdomen. Sepsis (hypotension, fever, tachycardia, leukocytosis) may result from severe CDAD. An acute abdomen (with or without toxic megacolon) may include signs of obstruction, ileus, bowel-wall thickening, and ascites on abdominal computed tomography (CT), often with peripheral-blood leukocytosis (≥25,000 cells/mm³). Whether or not the patient has diarrhea, the differential diagnosis of an acute abdomen, sepsis, or toxic megacolon should include CDAD if the patient has received antibiotics in the past 2 months. Cautious sigmoidoscopy or colonoscopy to visualize PMC and an abdominal CT examination are the best diagnostic tests in patients without diarrhea.

Medical management of fulminant CDAD is suboptimal because of the difficulty of delivering metronidazole or vancomycin to the colon by the oral route in the presence of ileus. Six patients with severe ileus have been successfully treated by the authors with vancomycin—given via nasogastric tube and by retention enema—plus intravenous metronidazole. Surgical intervention is indicated for patients with suspected perforation of the colon or fulminant CDAD that does not respond to medical management. The incidence of fulminant CDAD requiring colectomy may be increasing, and surgical mortality may be >50% in this setting.

PROGNOSIS The mortality rate attributed to CDAD is 0.6 to 3.5%, with the highest figures among the elderly. Most patients recover, but some have recurrences over months or years.

PREVENTION AND CONTROL Strategies for the prevention of CDAD are of two types: those aimed at preventing transmission of the organism to the patient and those aimed at reducing the risk of CDAD if the organism is transmitted. Transmission of *Clostridium difficile* in clinical practice has been prevented by gloving of personnel and elimination of the use of contaminated electronic thermometers. CDAD outbreaks have been most successfully controlled by restricting use of specific antibiotics, such as clindamycin and second- and third-generation cephalosporins. Outbreaks of CDAD due to clindamycin-resistant strains have resolved promptly when clindamycin use was restricted.

SEXUALLY TRANSMITTED DISEASES: OVERVIEW AND CLINICAL APPROACH

KING K. HOLMES

CLASSIFICATION AND EPIDEMIOLOGY

Certain sexually transmitted diseases (STDs), such as syphilis, gonorrhea, HIV infection, hepatitis B, and chancroid, are most concentrated within “core populations” having high rates of partner change, concurrent partners, or “dense” sexual networks—for example, prostitutes and their clients, some homosexual men, and persons involved in the use of illicit drugs, particularly crack cocaine and methamphetamine. Other STDs are distributed more evenly throughout society. For example, chlamydial infections, genital infections with human papillomavirus (HPV), and genital herpes can spread efficiently in relatively low-risk populations.

In general, the product of three factors determines the initial rate of spread of any sexually transmitted infection (STI) within a population: rate of exposure of susceptible to infectious people, efficiency of transmission per exposure, and duration of infectivity of those infected. Efforts to prevent and control STIs attempt to decrease the duration of infectivity (through early diagnosis and curative or suppressive treatment), to decrease the efficiency of transmission (e.g., through promotion of condom use and safer sexual practices), and to decrease the rate of exposure of susceptibles to infected persons (e.g., through individual counseling and efforts to change the norms of sexual behavior).

In all societies, STDs rank among the most common of all infectious diseases, with >30 infections now classified as predominantly sexually transmitted or as frequently sexually transmissible (Table 115-1). In developing countries, with three-quarters of the world’s population and 90% of the world’s STDs, such factors as population growth (especially in adolescent and young-adult age groups), rural-to-urban migration, wars, and poverty create exceptional vulnerability to disease resulting from risky sexual behaviors. During the 1990s, in
China, Russia, the other states of the former Soviet Union, and South Africa, internal social structures changed rapidly as borders opened to the West, unleashing enormous new epidemics of HIV infection and other STDs. HIV has become the leading cause of death in some developing countries, and HPV and hepatitis B virus (HBV) remain important causes of cervical and hepatocellular carcinoma, respectively—two of the most common malignancies in the developing world. Sexually transmitted herpes simplex virus (HSV) infections now cause most genital ulcer disease throughout the world and an increasing proportion of cases of genital herpes in developing countries with generalized HIV epidemics, where the positive feedback loop between HSV and HIV transmission is a growing, intractable problem. Globally, five curable STDs—gonorrhea, chlamydial infections, syphilis, chancre, and trichomoniasis—caused ~350 million new infections annually in the mid-1990s. Up to 50% of women of reproductive age in developing countries have bacterial vaginosis (arguably acquired sexually). All six of these curable infections have been associated with increased risk of HIV transmission or acquisition.

In the industrialized countries, fear of HIV infection since the mid-1980s, coupled with widespread behavioral interventions and better-organized systems of care for the curable STDs, have helped curb the transmission of the latter diseases. Nonetheless, foci of hyperendemic transmission persist in the southeastern United States and in most large U.S. cities. Rates of gonorrhea and syphilis remain higher in the United States than in any other Western industrialized country. The remarkable resurgence of gonorrhea and syphilis among homosexual and bisexual men in many parts of the United States and Europe since the 1990s reflects increased risk-taking since the advent of potent antiretroviral therapy and has been accompanied by increasing HIV transmission in this group. The prevalence of antibody to HSV-2 has begun to fall only recently (since the mid-1990s), and genital HPV infections among men has been associated with increased risk of HIV transmission or acquisition.

**MANAGEMENT OF COMMON STD SYNDROMES**

Although other chapters discuss management of specific STIs, delineating treatment based on diagnosis of a specific infection, most patients are actually managed (at least initially) on the basis of presenting symptoms and signs and associated risk factors, even in industrialized countries. Table 115-2 lists some of the most common clinical STD syndromes and their microbial etiologies. Strategies for their management are outlined below. "Chapters 172 and 173 address the management of infections with human retroviruses."

STD care and management begin with risk assessment and proceed to clinical assessment, diagnostic testing or screening, treatment, and prevention. Indeed, the routine care of any patient begins with risk assessment (e.g., for risk of heart disease, cancer). STD/HIV risk assessment is important in primary care, urgent care, and emergency care settings as well as in specialty clinics providing adolescent, prenatal, and family planning services. STD/HIV risk assessment guides interpretation of symptoms that could reflect an STD; decisions on screening or prophylactic/preventive treatment; risk reduction counseling and intervention (e.g., hepatitis B vaccination); and notification of partners of patients with known infections. Consideration of routine demographic (e.g., gender, age, marital status, area of residence) is a simple first step in STD/HIV risk assessment. For example, national guidelines now recommend routine screening of sexually active females ≤25 years of age for *Chlamydia trachomatis* infection. Table 115-3 provides a set of 10 STD/HIV risk-assessment questions that clinicians can pose verbally or that health care systems can adapt (with yes/no responses) into a routine self-administered questionnaire for use in clinics. The initial framing statement gives permission to discuss taboo topics.

Risk assessment is followed by clinical assessment (elicitation of information on specific current symptoms and signs of STDs). Confirmatory diagnostic tests (for persons with symptoms or signs) or screening tests (for those without symptoms or signs) may involve microscopic examination, culture, antigen detection tests, genetic probe or amplification tests, or serology. Initial syndrome-based treatment should cover the most likely causes. For certain syndromes, results of rapid tests can narrow the spectrum of this initial therapy (e.g., wet mount of vaginal fluid for women with vaginal discharge, Gram's stain of urethral discharge for men with urethral discharge, rapid plasma reagin test for genital ulcer). After the institution of treatment, STD management proceeds to the "4 C's" of prevention and control: contact tracing (see "Prevention and Control of STDs," below), ensuring compliance with therapy, and counseling on risk reduction, including condom promotion and provision.

**URETHRITIS IN MEN**

During the 1990s, the incidence of reported gonorrhea among men in the United States fell to 126 cases per 100,000 population; the incidence figures then leveled off through 2002. The incidence of reported *C. trachomatis* infections among men has been increasing steadily (with increased testing), reaching 130 cases per 100,000 in 2002. Until recently, *C. trachomatis* caused ~30 to 40% of cases of nongonococcal urethritis (NGU); however, the proportion of cases due to this organism may have declined in some populations served by effective chlamydial-control programs. HSV and *Trichomonas vaginalis* each cause a small proportion of NGU cases in the United States. Recently, multiple studies have consistently implicated *Mycoplasma genitalium* as a probable cause of many *Chlamydia*-negative cases, while fewer studies than in the past have implicated *Ureaplasma* gender, age, marital status, area of residence* makes them an essential component of routine screening. For example, *Trichomonas vaginalis* is a common cause of urethritis in men who practice insertive anal intercourse. The initial diagnosis of urethritis in men currently includes specific tests only for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, as well as specific treatments for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* infections. Table 115-4 provides a set of 10 STD/HIV risk-assessment questions that clinicians can pose verbally or that health care systems can adapt (with yes/no responses) into a routine self-administered questionnaire for use in clinics. The initial framing statement gives permission to discuss taboo topics.

Risk assessment is followed by clinical assessment (elicitation of information on specific current symptoms and signs of STDs). Confirmatory diagnostic tests (for persons with symptoms or signs) or screening tests (for those without symptoms or signs) may involve microscopic examination, culture, antigen detection tests, genetic probe or amplification tests, or serology. Initial syndrome-based treatment should cover the most likely causes. For certain syndromes, results of rapid tests can narrow the spectrum of this initial therapy (e.g., wet mount of vaginal fluid for women with vaginal discharge, Gram's stain of urethral discharge for men with urethral discharge, rapid plasma reagin test for genital ulcer). After the institution of treatment, STD management proceeds to the "4 C's" of prevention and control: contact tracing (see "Prevention and Control of STDs," below), ensuring compliance with therapy, and counseling on risk reduction, including condom promotion and provision.

and *C. trachomatis*. The following summarizes the approach to the patient with suspected urethritis:

1. **Establish the presence of urethritis.** If proximal-to-distal “milking” of the urethra does not express a purulent or mucopurulent discharge, even after the patient has not voided for several hours or preferably overnight, a Gram-stained smear of urethral discharge or of an anterior urethral specimen obtained by passage of a small urethroginal swab 2 to 3 cm into the urethra usually reveals ≥5 neutrophils per 1000× field in areas containing cells; in gonococcal infection, such a smear usually reveals gram-negative intracellular diplococci as well. Alternatively, the centrifuged sediment of the first 20 to 30 mL of voided urine can be examined for inflammatory cells, either by microscopy showing ≥10 leukocytes per high-power field or by the leukocyte esterase test. Patients with symptoms who lack objective evidence of urethritis may have functional rather than organic problems and generally do not benefit from repeated courses of antibiotics.

2. **Evaluate for complications or alternative diagnoses.** A brief history and examination will exclude epididymitis and systemic complications, such as disseminated gonococcal infection (DGI) and Reiter’s syndrome. Although digital examination of the prostate gland seldom contributes to the evaluation of sexually active young men with urethritis, men with dysuria who lack evidence of urethritis as well as sexually inactive men with urethritis should undergo prostate palpation, urinalysis, and urine culture to exclude bacterial prostatitis and cystitis.

3. **Evaluate for gonococcal and chlamydial infection.** An absence of typical gram-negative diplococci on Gram’s-stained smear of urethral exudate containing inflammatory cells warrants a preliminary diagnosis of NGU and should lead to testing of the urethral specimen for *C. trachomatis*. Culture or DNA detection tests for *N. gonorrhoeae* may be positive when Gram’s staining is negative; certain strains of *N. gonorrhoeae* can result in negative urethral Gram’s stains in up to 30% of cases of urethritis. Results of tests for gonococcal and chlamydial infection predict the patient’s prognosis (with greater risk for recurrent NGU if neither chlamydiae nor gonococci are found than if either is detected) and can

**TABLE 115-3** Ten-Question STD/HIV Risk Assessment

**Framing Statement:** In order to provide the best care for you today and to understand your risk for certain infections, it is necessary for us to talk about your sexual behavior.

**Screening Questions:**

1. Do you have any reason to think you might have a sexually transmitted disease? If so, what reason?
2. For all adolescents <18 years old: Have you begun having any kind of sex yet?
3. Have you ever had any sexually transmitted diseases or any genital infections? If so, which ones?
4. Have you had sex with men, women, or both?
5. Have you ever injected yourself (“shot up”) with drugs? (If yes, have you ever shared needles or injection equipment?)
6. Have you ever had sex with a gay or bisexual man or with anyone who had ever injected drugs?
7. Has your sex partner(s) had any sexually transmitted infections? If so, which ones?
8. Have you recently developed any of these symptoms?

**STD Symptoms Checklist:**

- (a) Discharge of pus (drip) from the penis
- (b) Genital sores (ulcers) or rash
- (c) Abnormal vaginal discharge
- (d) Genital sores (ulcers), rash, or itching

**Sexual Practices, Past 2 Months** (for patients answering yes to any of the above questions, to guide examination and testing):

1. Breastfeeding
2. Abdominal pain or cramps
3. New papillomas or warts
4. Abnormal vaginal discharge
5. Abnormal uterine bleeding
6. Painful or irregular menses

**Query about Interest in STD Screening Tests** (for patients answering no to all of the above questions):

1. Would you like to be tested for HIV or any other STDs today? (If yes, clinician can explore which STD and why.)

</tr>
</tbody>
</table>

**MANAGEMENT OF RECURRENCE**

Confirm objective evidence of urethritis. If patient was reexposed to untreated or new partner, repeat treatment of patient and partner. If patient was not reexposed, consider infection with *T. vaginalis* or doxycycline-resistant *Ureaplasma*, and consider treatment with metronidazole or azithromycin.

---

4. **Treat urethritis.**

Table 115-4 summarizes the steps in management of sexually active men with symptoms of urethral discharge and/or dysuria.

---

**TREATMENT**

In practice, if Gram’s stain does not reveal gonococci, urethritis is treated with a regimen effective for NGU, such as azithromycin (1.0 g orally in a single dose) or doxycycline (100 mg orally bid for 7 days). If gonococci are demonstrated by Gram’s stain or if no diagnostic tests are performed to definitively exclude gonorrhea, treatment should include a single-dose regimen for gonorrhea (Chap. 128) plus azithromycin or doxycycline treatment for *C. trachomatis*. Sexual partners should be tested for gonorrhea and chlamydial infection and should receive the same regimen given to the male index case. Patients with confirmed persistence or recurrence of urethritis after treatment should be re-treated with the initial regimen if they did not comply with the original treatment or were reexposed to an untreated partner. Otherwise, an intraurethral swab specimen and a first-voided urine sample should be cultured for *T. vaginalis*. If compliance with initial treatment is confirmed and reexposure excluded, treatment with metronidazole (2 g orally in a single dose) plus erythromycin base (500 mg orally qid for 7 days) is recommended.

**EPIDIDYMITS**

Acute epididymitis, almost always unilateral, must be differentiated from testicular torsion, tumor, and trauma. Torsion, a surgical emergency, usually occurs in the second or third decade of life and produces a sudden onset of pain, elevation of the testicle within the scrotal sac, rotation of the epididymis from a posterior to an anterior position, and absence of blood flow on Doppler examination or 99mTc scan. Persistence of symptoms after a course of therapy for epididymitis suggests the possibility of testicular tumor. In sexually active men under age 35, acute epididymitis is caused most frequently by *C. trachomatis* and less commonly by *N. gonorrhoeae* and is usually associated with overt or subclinical urethritis. Acute epididymitis occurring in older men or following urinary tract instrumentation is usually caused by urinary pathogens. Similarly, epididymitis in men who have practiced insertive rectal intercourse is often caused by Enterobacteriaceae. These men usually have no urethritis but do have bacteriuria.

**Ceftriaxone** (250 mg as a single dose IM) followed by doxycycline (100 mg orally bid for 10 days) is effective for epididymitis caused by *N. gonorrhoeae* or *C. trachomatis*. Alternatively, ofloxacin (300 mg orally bid for 10 days) or levofloxacin (500 mg orally once daily for 10 days) is also effective for syndrome-based treatment of epididymitis because of effectiveness against Enterobacteriaceae as well as *N. gonorrhoeae* and *C. trachomatis*; however, emerging gonococcal resistance to fluoroquinolones now limits the use of these drugs in some areas.

**URETHRITIS AND THE URETHRAL SYNDROME IN WOMEN**

*Chlamydia trachomatis*, *N. gonorrhoeae*, and occasionally HSV cause symptomatic urethritis—known as the urethral syndrome in women—characterized by “intestinal” dysuria (usually without urinary urgency or frequency) and pyuria, with *Escherichia coli* or other uropathogens not present in urine at counts of ≥10^5/mL. In contrast, the dysuria associated with vulvar herpes or vulvovaginal candidiasis (and perhaps with trichomoniasis) is often described as “external,” being caused by painful contact of urine with the inflamed or ulcerated labia or introitus. Acute onset, association with urinary urgency or frequency, hematuria, or suprapubic bladder tenderness suggests bacterial cystitis. Among women with symptoms of acute bacterial cystitis, costovertebral pain and tenderness or fever suggests acute pyelonephritis. →The management of bacterial urinary tract infection (UTI) is discussed in Chap. 269.

Signs of vulvovaginitis, coupled with symptoms of external dysuria, suggest vulvar infection (e.g., with HSV or *Candida albicans*). Among dysuric women without signs of vulvovaginitis, bacterial UTI must be differentiated from the urethral syndrome by assessment of risk, evaluation of the pattern of symptoms and signs, and specific microbiologic testing. An STD etiology of the urethral syndrome is suggested by young age, more than one current sexual partner, a new partner within the past month, a partner with urethritis, or coexisting mucopurulent cervicitis (see below). The finding of a single urinary pathogen, such as *E. coli* or *Staphylococcus saprophyticus*, at a concentration of ≥10^5/mL in a properly collected specimen of midstream urine from a dysuric woman with pyuria indicates probable bacterial UTI, whereas pyuria with <10^5 conventional uropathogens per milliliter of urine (“sterile” pyuria) suggests acute urethral syndrome due to *C. trachomatis* or *N. gonorrhoeae*. Gonorrhea and chlamydial infection should be sought by specific tests (e.g., nucleic acid amplification tests on the first 10 mL of voided urine). Among dysuric women with sterile pyuria caused by infection with *N. gonorrhoeae* or *C. trachomatis*, appropriate treatment alleviates dysuria.

**VULVOVAGINAL INFECTIONS**

*Abnormal Vaginal Discharge* If directly questioned about vaginal discharge during routine health checkups, many women acknowledge having nonspecific symptoms of vaginal discharge that do not correlate with objective signs of inflammation or with actual infection. However, unsolicited reporting of abnormal vaginal discharge does suggest bacterial vaginosis or trichomoniasis. Specifically, an abnormally increased amount or an abnormal odor of the discharge is associated with one or both of these conditions. Cervical infection with *N. gonorrhoeae* or *C. trachomatis* does not appear to cause an increased amount or abnormal odor of discharge, but cervicitis, like trichomoniasis, can include the production of an increased number of neutrophils in vaginal fluid, resulting in a yellow color. Vulvar conditions such as genital herpes or vulvovaginal candidiasis can cause vulvar pruritus, burning, irritation, or lesions as well as external dysuria (as urine passes over the inflamed vulva) or vulvar dyspareunia.

Certain vulvovaginal infections may have serious sequelae. Tricho-
of vulvovaginal complaints has documented the inaccuracy of the form-
mer, and comparison of evaluations by nurse-midwives with those by
physician-practitioners showed that the practitioners’ clinical evalua-
tions correlated poorly both with the nurses’ evaluations and with di-
gnostic tests. The diagnosis and treatment of the three most common
types of vaginal infection are summarized in Table 115-5.
Inspection of the vulva and perineum may reveal tender genital ulcer-
cations (typically due to HSV infection, occasionally due to chan-
roid) or fissures (typically due to vulvovaginal candidiasis) or dis-
charge visible at the introitus before insertion of a speculum (sugges-
tive of bacterial vaginosis or trichomoniasis). Speculum examination
permits the clinician to discern whether the discharge in fact looks
abnormal and whether any abnormal discharge in the vagina emanates
from the cervical os (mucoid and, if abnormal, yellow) or from the
vagina (not mucoid, since the vaginal epithelium does not produce
mucus). Symptoms or signs of abnormal vaginal discharge should
prompt testing of vaginal fluid for pH, fishy odor when mixed with
10% KOH, and microscopic features when mixed with saline and with
10% KOH. Additional objective laboratory tests useful for establishing
the cause of abnormal vaginal discharge include Gram’s staining to

* Color of discharge is best determined by examination against the white background of a swab.
† pH determination is not useful if blood is present.
‡ To detect fungal elements, vaginal fluid is digested with 10% KOH prior to microscopic examination; to examine for other features, fluid is mixed (1:1) with physiologic saline.
§ Single-dose regimen is less effective than 7-day metronidazole regimen.
detect alterations in the vaginal flora; card tests for bacterial vaginosis, as described below; and a new DNA probe test (the Affirm test) to detect *T. vaginalis* and *C. albicans* as well as the increased concentrations of *Gardnerella vaginalis* associated with bacterial vaginosis.

**TREATMENT**

Patterns of treatment for vaginal discharge vary widely. In developing countries, where clinics or pharmacies often dispense treatment based on symptoms alone without examination or testing, oral treatment with metronidazole—either as a 2-g single dose or as a 7-day regimen—provides reasonable coverage against both trichomoniasis and bacterial vaginosis, the usual causes of symptoms of vaginal discharge; metronidazole treatment of sex partners prevents reinfection of women with trichomoniasis, even though it does not help prevent the recurrence of bacterial vaginosis. Guidelines promulgated during the 1990s by the World Health Organization suggested treatment for cervical infection and for vulvovaginal candidiasis in women with symptoms of abnormal vaginal discharge; in retrospect, these recommendations were faulty, since these conditions seldom produce such symptoms.

In industrialized countries, clinicians treating symptoms and signs of abnormal vaginal discharge should at least differentiate between bacterial vaginosis and trichomoniasis, because optimal management of patients and partners differs for these two conditions (as discussed briefly below).

**Vaginal Trichomoniasis** (See also Chap. 199) Symptomatic trichomoniasis characteristically produces a profuse, yellow, purulent, homogeneous vaginal discharge and vulvar irritation, often with visible inflammation of the vaginal and vulvar epithelium and petechial lesions on the cervix (the so-called strawberry cervix, usually evident only by colposcopy). The pH of vaginal fluid usually rises to $\geq 5.0$. In women with typical symptoms and signs of trichomoniasis, microscopic examination of vaginal discharge mixed with saline reveals motile trichomonads in most culture-positive cases. However, in the absence of symptoms or signs, culture is often required for detection of the organism. Polymerase chain reaction (PCR) tests for *T. vaginalis* compare favorably with culture, and PCR testing of urine is now disclosing surprisingly high prevalences of this pathogen among men at several STD clinics in the United States. Treatment of asymptomatic cases reduces rates of transmission and prevents later development of symptoms.

Only nitroimidazoles consistently cure trichomoniasis. Tinidazole and ornidazole have longer half-lives than metronidazole but do not give better results than a single 2-g oral dose of metronidazole, which is much less expensive. Treatment of male sexual partners—often facilitated by dispensing metronidazole to the female patient to give to her partner(s), with a warning about avoiding the concurrent use of alcohol—significantly reduces both the risk of reinfection and the reservoir of infection. Treatment with 0.75% metronidazole gel intravaginally, although moderately effective for bacterial vaginosis, is not reliable for vaginal trichomoniasis. Systemic use of metronidazole is not recommended during the first trimester of pregnancy but is considered safe thereafter. In a large randomized trial, metronidazole treatment of trichomoniasis during pregnancy did not reduce the frequency of perinatal morbidity.

**Bacterial Vaginosis** This syndrome (formerly termed nonspecific vaginitis, *Haemophilus vaginitis*, *atactobacter vaginitis*, or *Gardnerella-associated vaginal discharge*) is characterized by symptoms of vaginal malodor and a slightly to moderately increased white discharge, which appears homogeneous, is low in viscosity, and smoothly coats the vaginal mucosa. An interesting observation is that new genital HPV infection in young women is associated with increased subsequent risk of developing bacterial vaginosis. Other risk factors include multiple sexual partners and recent intercourse with a new partner, but metronidazole treatment of male partners has not reduced the rate of recurrence among affected women.

The vaginal fluid of women with bacterial vaginosis is characterized by markedly increased prevalences and concentrations of *G. vaginalis*, *Mycoplasma hominis*, and several anaerobic bacteria [e.g., *Mobiluncus*, *Prevotella* spp. (formerly *Bacteroides* spp.), and some *Peptostreptococcus* spp.]. The vaginal fluid usually lacks hydrogen peroxide–producing *Lactobacillus* spp., which constitute most of the normal vaginal flora and perhaps help protect against certain cervical and vaginal infections. Vaginal douching, use of intravaginal nonoxynol-9 spermicide, and new sexual partners can all result in loss of vaginal colonization by hydrogen peroxide–producing lactobacilli.

Bacterial vaginosis is conventionally diagnosed clinically with the Amsel criteria, which include any three of the following four clinical abnormalities: (1) objective signs of increased white homogeneous vaginal discharge; (2) a vaginal discharge pH of $>4.5$; (3) liberation of a distinct fishy odor (attributable to volatile amines such as trimethylamine) immediately after vaginal secretions are mixed with a 10% solution of KOH; and (4) microscopic demonstration of “clue cells” (vaginal epithelial cells coated with cocc gobacillary organisms giving them a granular appearance and indistinct borders; Fig. 115-1) on a wet mount prepared by mixing vaginal secretions with normal saline in a ratio of $\sim 1:1$. A diagnostic card test facilitates screening of vaginal fluid for pH $> 4.5$ and amines, and a dipstick test detects proline aminopeptidase, an enzyme associated with this syndrome.

![FIGURE 115-1](image-url) A. Vaginal epithelial “clue cells.” Note granular appearance due to adherent *Gardnerella* vaginitis and indistinct cell margins (400×). B. Normal vaginal epithelial cells. The cell margins are distinct and lack granularity.
lower short-term cure rates. Intravaginal treatment with 2% clindamycin cream [one full applicator (5 g containing 100 mg of clindamycin phosphate) each night for 7 nights] or with 0.75% metronidazole gel [one full applicator (5 g containing 37.5 mg of metronidazole) twice daily for 5 days] is also approved for use in the United States and does not elicit systemic adverse reactions. Oral clindamycin (300 mg bid for 7 days) and clindamycin ovlules (100 g intravaginally once at bedtime for 3 days) have also been approved. Unfortunately, long-term recurrence (i.e., several months later) is distressingly common after either oral or intravaginal treatment. Treatment of male partners with metronidazole does not prevent recurrence of bacterial vaginosis. No controlled data support the use of currently available vaginal or oral preparations of lactobacilli for the treatment or prevention of recurrence of bacterial vaginosis. In a randomized trial, repeated intravaginal inoculation of a vaginal peroxide-producing Lactobacillus species following treatment of bacterial vaginosis with metronidazole did not reduce the frequency of recurrence. A meta-analysis of 18 studies concluded that bacterial vaginosis during pregnancy substantially increased the risk of preterm delivery and of spontaneous abortion. Although intravaginal treatment of bacterial vaginosis during pregnancy has not reduced perinatal morbidity, oral clindamycin treatment of this syndrome early in pregnancy significantly reduced the risk of late miscarriage and of preterm delivery. Oral antimicrobial treatment of bacterial vaginosis for ≥7 days early in pregnancy may reduce the risk of preterm delivery for women with a history of this pregnancy outcome.

**Vulvovaginal Pruritus, Burning, or Irritation** Vulvovaginal candidiasis produces vulvar pruritus, burning, or irritation, generally without symptoms of increased vaginal discharge or malodor. Genital herpes can produce similar symptoms, with lesions sometimes difficult to distinguish from the fissures caused by candidiasis. Signs of vulvovaginal candidiasis include vulvar erythema, edema, fissures, and tenderness. With candidiasis, a white scanty vaginal discharge sometimes takes the form of white trash-like plaques or cottage cheese—like curds adhering loosely to the vaginal mucosa. *C. albicans* accounts for nearly all cases of symptomatic vulvovaginal candidiasis, which probably arise from endogenous strains of *C. albicans* that have colonized the vagina or the intestinal tract. Complicated vulvovaginal candidiasis includes cases that recur four or more times per year; are unusually severe; are caused by non-*albicans Candida* spp.; or occur in women with uncontrolled diabetes, debilitation, immunosuppression, or pregnancy.

The diagnosis of vulvovaginal candidiasis usually involves the demonstration of pseudohyphae or hyphae by microscopic examination of vaginal fluid mixed with saline or 10% KOH or subjected to demonstration of pseudohyphae or hyphae by microscopic examination. Although the above criteria for MPC are neither highly specific nor highly predictive of gonococcal or chlamydial infection in many settings, current CDC guidelines call for consideration of empirical treatment for MPC, pending test results, “for a patient who has suspected gonorrhea or chlamydial infection, if (a) the prevalences of these infections are high in the patient population, and (b) the patient might be difficult to locate after treatment.” In this situation, therapy should include a single-dose regimen effective for gonorrhea plus treatment for chlamydial infection, as outlined in Table 115-4 for the treatment of urethritis. In settings where gonorrhea is much less common than chlamydial infection, initial therapy for chlamydial infection alone suffices, pending test results for gonorrhea. The etiology and potential benefit of treatment of endocervicitis not associated with gonorrhea or chlamydial infection remain undefined. Although the antimicrobial susceptibility of *M. genitalium* is not yet well defined, it currently seems reasonable to use azithromycin to treat possible *M. genitalium* infections.
infection in such cases. Sexual partner(s) of a woman with MPC should be examined and given a regimen similar to that chosen for the woman unless results of tests for gonorrhea or chlamydial infection in either partner warrant different therapy or no therapy.

CERVICAL ECOTP Y Cervical ectopy, often mislabeled “cervical erosion,” is easily confused with infectious endocervicitis. Ectopy represents the presence of the one-cell-thick columnar epithelium extending from the endocervix out onto the visible ectocervix. In ectopy, the cervical os may contain clear or slightly cloudy mucus but usually not yellow mucopus. Colposcopy shows intact epithelium. Normally found during adolescence and early adulthood, ectopy gradually recedes through the second and third decades of life, as squamous metaplasia replaces the ectopic columnar epithelium. Oral contraceptive use favors the persistence or reappearance of ectopy, while smoking apparently accelerates squamous metaplasia. Cauterization of ectopy is not warranted. Ectopy may render the cervix more susceptible to infection with *N. gonor rhoeae*, *C. trachomatis*, or HIV.

PELVIC INFLAMMATORY DISEASE The term pelvic inflammatory disease usually refers to infection that ascends from the cervix or vagina to involve the endometrium and/or fallopian tubes. Infection can extend beyond the reproductive tract to cause pelvic peritonitis, generalized peritonitis, pericholangitis, or pelvic abscess. In rare instances, infection extends secondarily to the pelvic organs from adjacent foci of inflammation (e.g., appendicitis, regional ileitis, or diverticulitis), as a result of hematogenous dissemination (e.g., of tuberculosis), or as a rare complication of certain tropical diseases (e.g., schistosomiasis). Intrauterine infection can be primary (spontaneously occurring and usually sexually transmitted) or secondary to invasive intrauterine surgical procedures [e.g., dilatation and curettage, termination of pregnancy, insertion of an intrauterine device (IUD), or hysterosalpingography] or to parturition.

Etiology The agents most often implicated in acute PID include those that are primary causes of endocervicitis (*N. gonorrhoeae* and *C. trachomatis*) and those that can be regarded as components of an altered vaginal flora. In general, PID is most often associated with gonorrhea where there is a high incidence of gonorrhea—e.g., in developing countries and in indigent, inner-city populations in the United States.

In recent case-control studies, detection of *M. genitalium* by PCR in endometrial specimens has also been significantly associated with histopathologic diagnoses of endometritis.

Anaerobic and facultative organisms (especially *Prevotella* species, peptostreptococci, *E. coli*, *Haemophilus influenzae*, and group B streptococci) as well as genital mycoplasmas have been isolated from specimens obtained at laparoscopy from the peritoneal fluid or fallopian tubes in a varying proportion (typically one-fourth to one-third) of women with PID studied in the United States. The difficulty of determining the exact microbial etiology of an individual case of PID has implications for the approach to empirical antimicrobial treatment of this infection.

Epidemiology In the United States in 2002, women 15 to 44 years of age made ~200,000 initial visits to physician’s offices for PID, and an estimated 66,000 women were hospitalized for acute PID. Important risk factors for acute PID include the presence of endocervical infection or bacterial vaginosis, a history of salpingitis or of recent vaginal douching, and the use of an IUD (especially among nulliparous women, during the first few months after IUD insertion, and among women with multiple sex partners). Certain other iatrogenic factors, such as dilatation and curettage or cesarean section, can increase the risk of PID, especially among women with endocervical gonococcal or chlamydial infection or bacterial vaginosis. The onset of symptoms of *N. gonorrhoeae*–associated and *C. trachomatis*–associated PID often occurs during or soon after the menstrual period; this timing suggests that menstruation is a risk factor in women with endocervical infection. Experimental inoculation of the fallopian tubes of lower primates has shown that repeated exposure to *C. trachomatis* leads to the greatest degree of tissue inflammation and damage; thus, immunopathology probably contributes to the pathogenesis of chlamydial salpingitis. Women using oral contraceptives appear to be at decreased risk of symptomatic PID, and tubal sterilization reduces the risk of salpingitis by preventing intraluminal spread of infection into the tubes.

Clinical Manifestations ENDOMETRITIS: A CLINICAL PATHOLOGIC SYNDROME A study of women with clinically suspected PID who were undergoing both endometrial biopsy and laparoscopy showed that those with endometritis alone differed from those who also had salpingitis in that they significantly less often had lower quadrant, adnexal, or cervical motion or abdominal rebound tenderness; fever; or elevated C-reactive protein levels. In addition, women with endometritis alone differed from those with neither endometritis nor salpingitis in that they more often had gonorrhea, chlamydial infection, and risk factors such as douching or IUD use. Thus, women with endometritis alone were intermediate between those with neither endometritis nor salpingitis and those with salpingitis with respect to risk factors, clinical manifestations, cervical infection prevalence, and elevated C-reactive protein.

SALPINGITIS Symptoms of nontuberculous salpingitis classically evolve from a yellow or malodorous vaginal discharge caused by MPC and/or bacterial vaginosis to midline abdominal pain and abnormal vaginal bleeding caused by endometritis and then to bilateral lower abdominal and pelvic pain caused by salpingitis, with nausea, vomiting, and increased abdominal tenderness caused by peritonitis.

The abdominal pain in nontuberculous salpingitis is usually described as dull or aching. In some cases, pain is lacking or is atypical, but active inflammatory changes are found in the course of an unrelated evaluation or procedure, such as a laparoscopic evaluation for infertility. Abnormal uterine bleeding precedes or coincides with the onset of pain in ~40% of women with PID, symptoms of urethritis (dysuria) occur in 20%, and symptoms of proctitis (anorectal pain, tenesmus, and rectal discharge or bleeding) are occasionally seen in women with gonococcal or chlamydial infection.

Speculum examination shows evidence of MPC (yellow endocervical discharge, easily induced endocervical bleeding) in the majority of women with gonococcal or chlamydial PID. Cervical motion ten-
derness is produced by stretching of the adnexal attachments on the side toward which the cervix is pushed. Bimanual examination reveals uterine fundal tenderness due to endometritis and abnormal adnexal tenderness due to salpingitis that is usually, but not necessarily, bilateral. Adnexal swelling is palpable in about one-half of women with acute salpingitis, but evaluation of the adnexae in a patient with marked tenderness is not reliable. The initial temperature is $>38^\circ C$ in only about one-third of patients with acute salpingitis. Laboratory findings include elevation of the erythrocyte sedimentation rate (ESR) in 75% of patients with acute salpingitis and elevation of the peripheral white blood cell count in up to 60%.

Unlike nontuberculous salpingitis, genital tuberculosis often occurs in older women, many of whom are postmenopausal. Presenting symptoms include abnormal vaginal bleeding, pain (including dysmenorrhea), and infertility. About one-quarter of these women have had adnexal masses. Endometrial biopsy shows tuberculous granulomas and provides optimal specimens for culture.

**PERIHEPATITIS AND PERRIAPPENDICITIS**  
Pleural upper abdominal pain and tenderness (usually localized to the right upper quadrant) develop in 3 to 10% of women with acute PID. Symptoms of perihepatitis arise during or after the onset of symptoms of PID and may overshadow lower abdominal symptoms, thereby leading to a mistaken diagnosis of cholecystitis. In perhaps 5% of cases of acute salpingitis, early laparoscopy reveals perihilar inflammation ranging from edema and erythema of the liver capsule to exudate with fibrinous adhesions between the visceral and parietal peritoneum. When treatment is delayed and laparoscopy is performed late, dense “violin-string” adhesions can be seen over the liver; chronic exertional or positional right upper quadrant pain ensues when traction is placed on the adhesions. Although perihepatitis, also known as the Fitz-Hugh–Curtis syndrome, was for many years specifically attributed to gonococcal salpingitis, most cases are now attributed to chlamydial salpingitis. In patients with chlamydial salpingitis, serum titers of microimmunofluorescent antibody to *C. trachomatis* are typically much higher when perihepatitis is present than when it is absent.

Physical findings include right upper quadrant tenderness and usually include adnexal tenderness and cervicitis, even in patients whose symptoms do not suggest salpingitis. Results of liver function tests and right upper quadrant ultrasonography are nearly always normal. The presence of MPC and pelvic tenderness in a young woman with subacute pleuritic right upper quadrant pain and normal ultrasonography of the gallbladder points to a diagnosis of perihepatitis.

Periappendicitis (appendiceal serositis without involvement of the intestinal mucosa) has been found in ~5% of patients undergoing appendectomy for suspected appendicitis and can occur as a complication of gonococcal or chlamydial salpingitis.

Among women with salpingitis, HIV infection is associated with increased severity of salpingitis and with tuboovarian abscess requiring hospitalization and surgical drainage. Nonetheless, among women with HIV infection and salpingitis, the clinical response to conventional antimicrobial therapy (coupled with drainage of tuboovarian abscess, when found) has been satisfactory.

**Diagnosis**  
Treatment appropriate for PID must not be withheld from patients who have an equivocal diagnosis; it is better to err on the side of overdiagnosis and overtreatment. On the other hand, it is essential to differentiate between salpingitis and other pelvic pathology, particularly surgical emergencies such as appendicitis and ectopic pregnancy.

Nothing short of laparoscopy definitively identifies salpingitis, but routine laparoscopy to confirm suspected salpingitis is generally impractical. Most patients with acute PID have lower abdominal pain of <3 weeks’ duration, pelvic tenderness on bimanual pelvic examination, and evidence of lower genital tract infection (e.g., MPC). Approximately 60% of such patients have salpingitis at laparoscopy, and perhaps 10 to 20% have endometritis alone. Among the patients with these findings, a rectal temperature $>38^\circ C$, a palpable adnexal mass, and elevation of the ESR to $>15$ mm/h also raise the probability of salpingitis, which has been found at laparoscopy in 68% of patients with one of these additional findings, 90% of patients with two, and 96% of patients with three. However, only 17% of all patients with laparoscopy-confirmed salpingitis have had all three additional findings.

In a woman with pelvic pain and tenderness, increased numbers of PMNs (30 per $10^6$ microscopic field in strands of cervical mucus) increase the predictive value of a clinical diagnosis of acute PID, as do onset with menses, history of recent abnormal menstrual bleeding, presence of an IUD, history of salpingitis, and sexual exposure to a male with urethritis. Appendicitis or another disorder of the gut is favored by the early onset of anorexia, nausea, or vomiting; the onset of pain later than day 14 of the menstrual cycle; or unilateral pain limited to the right or left lower quadrant. Whenever the diagnosis of PID is being considered, serum assays for human $\beta$-chorionic gonadotropin should be performed; these tests are usually positive with ectopic pregnancy. Ultrasonography and magnetic resonance imaging (MRI) can be useful for the identification of tuboovarian or pelvic abscess. MRI of the tubes can also show increased tubal diameter, intratubal fluid, or tubal wall thickening in cases of salpingitis.

The primary and uncontested value of laparoscopy in women with lower abdominal pain is for the exclusion of other surgical problems. Some of the most common or serious problems that may be confused with salpingitis (e.g., acute appendicitis, ectopic pregnancy, corpus luteum bleeding, ovarian tumor) are unilateral. Unilateral pain or pelvic mass, although not incompatible with PID, is a strong indication for laparoscopy unless the clinical picture warrants laparotomy instead. Atypical clinical findings, such as the absence of lower genital tract infection, a missed menstrual period, a positive pregnancy test, or failure to respond to appropriate therapy, are other common indications for laparoscopy. Endometrial biopsy is relatively sensitive and specific for the diagnosis of endometritis, which correlates well with the presence of salpingitis.

Endocervical swab specimens should be examined by Gram’s staining for PMNs and gram-negative diplococci and by nucleic acid amplification tests for *N. gonorrhoeae* and *C. trachomatis*. The clinical diagnosis of PID made by expert gynecologists is confirmed by laparoscopy or endometrial biopsy in ~90% of women who also have cultures positive for *N. gonorrhoeae* or *C. trachomatis*. Even among women with no symptoms suggestive of acute PID who were attending an STD clinic or gynecology clinic in Pittsburgh, endometritis was significantly associated with endocervical gonorrhea or chlamydial infection or bacterial vaginosis, being detected in 26, 27, and 15% of women with these conditions, respectively.

**TREATMENT**  
Women with PID can be treated as either outpatients or inpatients. In the multicenter Pelvic Inflammatory Disease Evaluation and Clinical Health (PEACH) trial, 831 women with mild to moderately severe symptoms and signs of PID were randomized to receive either inpatient treatment with intravenous (IV) cefoxitin and doxycycline or outpatient treatment with a single intramuscular (IM) dose of cefoxitin plus oral doxycycline. Short-term clinical and microbiologic outcomes and long-term outcomes were equivalent in the two groups. Nonetheless, hospitalization should be considered when (1) the diagnosis is uncertain and surgical emergencies such as appendicitis and ectopic pregnancy cannot be excluded; (2) pelvic abscess is suspected; (3) severe illness or nausea and vomiting preclude outpatient management; (4) the patient has HIV infection; (5) the patient is assessed as unable to follow or tolerate an outpatient regimen, or (6) the patient has failed to respond to outpatient therapy. Some experts also prefer to hospitalize adolescents with PID for initial therapy. Inpatients with PID should be treated with a single intramuscular (IM) dose of cefoxitin and doxycycline, given either concurrently or sequentially. Intravenous therapy or parenteral management of PID are presented in Table 115-6. Women managed as outpatients should receive a combined regimen with broad activity,

such as ceftriaxone followed by doxycycline. Metronidazole can be added, if tolerated, to enhance activity against anaerobes. Alternatively, oral ofloxacin or levofloxacin, each continued for 14 days and given with or without metronidazole, provides good coverage of the major pathogens. Although few methodologically sound clinical trials (especially with prolonged follow-up) have been conducted, one meta-analysis suggested providing good coverage against anaerobes. The following two parenteral regimens have given nearly identical results in a multicenter randomized trial:

1. Doxycycline (100 mg bid, given IV or by mouth) plus cefotetan (2.0 g IV every 12 h) or cefoxitin (2.0 g IV every 6 h). Administration of these drugs should be continued by the IV route for at least 48 h after the patient’s condition improves and then followed with doxycycline (100 mg bid by mouth) to complete 14 days of therapy.

2. Clindamycin (900 mg IV every 8 h) plus gentamicin (2.0 mg/kg IV or IM, followed by 1.5 mg/kg q 8 h) in patients with normal renal function. Once-daily dosing of gentamicin (with combination of the total daily dose into a single daily dose) has not been evaluated in PID but has been efficacious in other serious infections and could be substituted.

Treatment with these drugs should be continued for at least 48 h after the patient’s condition improves and then followed with oral doxycycline (100 mg bid by mouth) or clindamycin (450 mg qid by mouth) to complete 14 days of therapy. In cases with tuboovarian abscess, clindamycin rather than doxycycline for continued therapy may provide better coverage for anaerobic infection.

**FOLLOW-UP** Hospitalized patients should show substantial clinical improvement within 3 to 5 days. Women treated as outpatients should be clinically reevaluated within 72 h. A follow-up telephone survey of women seen in an emergency room and given a prescription for 10 days of oral doxycycline for PID found that 28% never filled the prescription and 41% stopped taking medication early (after an average of 4.1 days), often because of persistent symptoms, lack of symptoms, or side effects. Women not responding favorably to ambulatory therapy should be hospitalized. After completion of treatment, tests for persistent or recurrent infection with *N. gonorrhoeae* or *C. trachomatis* should be performed if symptoms persist or recur or if the patient has not complied with therapy or has been reexposed to an untreated sex partner.

**SURGERY** Surgery is necessary for the treatment of salpingitis only in the face of life-threatening infection (such as rupture or threatened rupture of a tuboovarian abscess) or for drainage of an abscess. Conservative surgical procedures are usually sufficient. Pelvic abscesses can often be drained by posterior colpotomy, and peritoneal lavage can be used if there is generalized peritonitis.

**Prognosis** Among 900 women in Sweden who underwent long-term follow-up for a mean period of 8 years after successful treatment of an acute episode of PID with various regimens (that today would often not be considered to provide optimal broad antimicrobial activity), late sequelae included infertility due to bilateral tubal occlusion, ectopic pregnancy due to tubal scarring without occlusion, chronic pelvic pain, and recurrent salpingitis. The post-salpingitis risk of infertility due to tubal occlusion among sexually active women not using contraceptives was 14% at 15 to 24 years of age and 26% at 25 to 34 years of age; the risk for women of all ages combined was 11% after one episode of salpingitis, 23% after two episodes, and 54% after three or more episodes. A study at the University of Washington found a sevenfold increase in the risk of ectopic pregnancy and an eightfold increase in the rate of hysterectomy after PID.

**Prevention** A randomized controlled trial designed to determine whether selective screening for chlamydial infection reduced the risk of subsequent PID showed that women randomized to undergo screening had a 56% lower rate of PID over the following year than did women receiving the usual care without screening. This report helped to prompt the establishment of U.S. national guidelines for risk-based chlamydial screening of young women as a highly effective way to reduce the incidence of PID and the prevalence of post-PID sequelae, while also reducing sexual transmission of *C. trachomatis*.

**ULCERATIVE GENITAL LESIONS** Genital ulceration reflects a set of important STIs, most of which sharply increase the risk of sexual acquisition and shedding of HIV. In a 1996 study of genital ulcers in 10 of the U.S. cities with the highest rates of primary syphilis, PCR testing of ulcer specimens demonstrated HSV in 62% of patients, *T. pallidum* in 13%, and *H. ducreyi* in 12 to 20%.

In Asia and Africa, chancroid (Fig. 115-3) was once considered the most common type of genital ulcer, followed in frequency by primary...
FIGURE 115-4 Lymphogranuloma venereum: striking tender lymphadenopathy occurring at the femoral and inguinal lymph nodes, separated by a groove made by Poupart's ligament.

syphilis and then genital herpes. With increased efforts to control chancroid and syphilis, together with more frequent recurrences or persistence of genital herpes attributable to HIV infection, PCR testing of genital ulcers now clearly implicates genital herpes as the most common cause of genital ulceration in many developing countries. Lymphogranuloma venereum (LGV; Fig. 115-4) and donovanosis (granuloma inguinale; Fig. 115-5) continue to cause genital ulceration in developing countries but rarely occur today in North America or Europe. Other causes of genital ulcer include (1) candidiasis and traumatized genital warts—both readily recognized; (2) lesions due to genital involvement of more widespread dermatoses; and (3) cutaneous manifestations of systemic diseases, such as genital mucosal ulceration in Stevens-Johnson syndrome or Behçet’s disease.

Diagnosis Although most genital ulcerations cannot be diagnosed confidently on clinical grounds alone, clinical findings plus epidemiologic considerations (Table 115-7) can usually guide initial management (Table 115-8) pending results of further tests. Clinicians should order a rapid serologic test for syphilis in all cases of genital ulcer and a dark-field or direct immunofluorescence test (or PCR test, where available) for T. pallidum in all lesions except those highly characteristic of infection with HSV (i.e., those with herpetic vesicles). All patients presenting with genital ulceration should be asked to undergo serologic testing for HIV infection.

Typical vesicles or pustules or a cluster of painful ulcers preceded by vesiculopustular lesions suggests genital herpes. These typical clinical presentations make detection of the virus optional; however, many patients want confirmation of the diagnosis, and differentiation of HSV-1 from HSV-2 has prognostic implications, since the latter causes more frequent genital recurrences.

Painless, nontender, indurated ulcers with firm, nontender inguinal adenopathy suggest primary syphilis. If dark-field examination and a rapid serologic test for syphilis are initially negative and the patient will comply with follow-up and sexual abstinence, the performance of two more dark-field examinations on successive days before treatment is begun will improve the sensitivity of the diagnosis of syphilis. Repeated serologic testing for syphilis 1 or 2 weeks after treatment of seronegative primary syphilis usually demonstrates seroconversion.

### Usual causes
- Herpes simplex virus (HSV)
- Treponema pallidum (primary syphilis)
- Haemophilus ducreyi (chancroid)

### Usual initial laboratory evaluation
- Dark-field exam, direct FA, or PCR for *T. pallidum*; RPR test (if negative but primary syphilis suspected, repeat RPR in 1 week); culture, direct FA, ELISA, or PCR for HSV. In chancroid-endemic area: PCR or culture for *H. ducreyi*

### Herpes confirmed or suspected (history or sign of vesicles):
- Treat for genital herpes with acyclovir, valacyclovir, or famciclovir
- Syphilis confirmed (dark-field, FA, or PCR showing *T. pallidum*; or RPR reactive):
  - Benzathine penicillin 2.4 million units IM once to patient, recent (e.g., within 3 months) seronegative partner(s), and every seropositive partner
- Chancroid confirmed or suspected (diagnostic test positive, or HSV and syphilis excluded, and lesion persists):
  - Ciprofloxacin 500 mg PO as single dose
  - Ceftriaxone 250 mg IM as single dose
  - Azithromycin 1 g PO as single dose

### TREATMENT
Immediate syndrome-based treatment for acute genital ulcerations (after collection of all necessary diagnostic specimens) is often appropriate before all test results become available, because patients with typical initial or recurrent episodes of genital or anorectal ulcers can benefit from prompt oral antiviral therapy (Chap. 163); because early treatment prevents further transmission; and because some patients do not return for test results and treatment. The patient with nonvesicular ulcerative lesions who may not return for follow-up or may continue sexual activity should receive initial treatment for syphilis, together with empirical therapy for chancroid if there has been an exposure in an area where chancroid occurs or if regional lymph node suppuration is evident. In resource-poor settings lacking ready access to diagnostic tests, this approach to syndromic treatment for syphilis and chancroid has helped bring these two diseases under control. Finally, empirical antimicrobial therapy may be indicated if ulcers persist and the diagnosis remains unclear after a week of observation despite attempts to diagnose herpes, syphilis, and chancroid.

### PROCTITIS, PROCTOCOLITIS, ENTEROCOLITIS, AND ENTERITIS
Sexually acquired proctitis, with inflammation limited to the rectal mucosa (the distal 10 to 12 cm), results from direct rectal inoculation of typical STD pathogens. In contrast, inflammation extending from the rectum to the colon (proctocolitis), involving both the small and the large bowel (enterocolitis), or involving the small bowel alone (enteritis) can result from ingestion of typical intestinal pathogens through oral-anal exposure during sexual contact. Anorectal pain and mucopurulent, bloody rectal discharge suggest proctitis or proctocolitis. Proctitis commonly produces tenesmus (causing frequent attempts to defecate, but not true diarrhea) and constipation, whereas proctocolitis and enterocolitis more often cause true diarrhea. In all three conditions, anoscopy usually shows mucosal exudate and easily induced mucosal bleeding (i.e., a positive “wipe test”), sometimes with petechiae or mucosal ulcers. Exudate should be sampled for Gram’s staining and other microbiologic studies. Sigmoidoscopy or colonoscopy shows inflammation limited to the rectum in proctitis or disease extending at least up into the sigmoid colon in proctocolitis.

The AIDS era brought an extraordinary shift in the clinical and etiologic spectrum of intestinal infections among homosexual men. The number of cases of the acute intestinal STIs described above fell as high-risk sexual behaviors became less common in this group. At the same time, the number of AIDS-related opportunistic intestinal infections increased rapidly, many associated with chronic or recurrent symptoms. The incidence of these infections has since fallen with increasingly effective antiretroviral therapy.

Acquisition of *N. gonorrhoeae*, HSV, or *C. trachomatis* during receptive anorectal intercourse causes most cases of infectious proctitis in women or homosexual men. Primary and secondary syphilis can also produce anal or anorectal lesions, with or without symptoms. Gonococcal or chlamydial proctitis typically involves the most distal rectal mucosa and the anal crypts and is clinically mild, without systemic manifestations. In contrast, primary proctitis due to HSV and proctocolitis due to the strains of *C. trachomatis* that cause LGV usually produce severe anorectal pain and often cause fever. Perianal ulcers and inguinal lymphadenopathy, most commonly due to HSV, can also occur in LGV or syphilis. Sacral nerve root radiculopathies, usually presenting as urinary retention, laxity of the anal sphincter, or constipation, may complicate primary herpetic proctitis. In LGV, rectal biopsy typically shows crypt abscesses, granulomas, and giant cells—findings resembling those in Crohn’s disease; such findings should always prompt rectal culture and serology for LGV, which is a curable infection. Syphilis can also produce rectal granulomas, usually in association with infiltration by plasma cells or other mononuclear cells. Syphilis, LGV, and HSV infection involving the rectum can produce perirectal adenopathy that is sometimes mistaken for malignancy; syphilis, LGV, HSV infection, and chancroid involving the anus can produce inguinal adenopathy, because anal lymphatics drain to inguinal lymph nodes.

Diarrhea and abdominal bloating or cramping pain without anorectal symptoms and with normal findings on anoscopy and sigmoidoscopy occur with inflammation of the small intestine (enteritis) or with proctocolitis. In homosexual men without HIV infection, enteritis is often attributable to *Giardia lamblia*. Sexually acquired proctocolitis is most often due to *Campylobacter* or *Shigella* spp.

TREATMENT

Acute proctitis in persons who have practiced receptive intercourse is usually sexually acquired. Such patients should undergo anoscopy to detect rectal ulcers or vesicles and petechiae after swabbing of the rectal mucosa; to examine rectal exudates for PMNs and gram-negative diplococci; and to obtain rectal swab specimens for testing for rectal gonorrhea, chlamydial infection, herpes, and syphilis. Pending test results, patients with proctitis should receive empirical syndromic treatment—e.g., with ceftriaxone (a single IM dose of 125 mg for gonorrhea) plus doxycycline (100 mg bid by mouth for 7 days for possible chlamydial infection) plus treatment for herpes or syphilis if indicated.

PREVENTION AND CONTROL OF STDs

Prevention and control of STDs require (1) reduction of the average rate of sexual exposure through alteration of behaviors and behavioral norms among both susceptible and infected persons in all population groups; (2) reduction of the efficiency of transmission through the promotion of safer sexual practices, the use of condoms during casual or commercial sex, hepatitis B immunization, and many other approaches (e.g., early detection and treatment of other STIs to reduce the efficiency of sexual transmission of HIV); and (3) shortening of the duration of infectivity of STDs through early detection and curative or suppressive treatment of patients and their sexual partners.

Financial and time constraints imposed by managed-care practice patterns often curtail screening and prevention services. As outlined in Fig. 115-6, the success of clinicians’ efforts to detect and treat STDs depends in part on societal efforts to teach young people how to recognize symptoms of STDs; to motivate those with symptoms to seek care promptly; and to make such care accessible, affordable, and acceptable, especially to the young indigent patients most likely to acquire an STD.

Since many infected individuals develop no symptoms or fail to recognize and report symptoms, clinicians should routinely perform an STI risk assessment for teenagers and young adults as a guide to selective screening. U.S. Preventive Service Task Force Guidelines recommend screening sexually active female patients ≤25 years of age for C. trachomatis whenever they present for health care (at least once a year); older women should be tested if they have more than one sexual partner, have begun a new sexual relationship since the previous test, or have another STD diagnosed. In the United States, widespread selective screening of young women for cervical C. trachomatis infection in some regions has been associated with a 50 to 60% drop in prevalence, and such screening also protects the individual woman from PID. Sensitive urine-based genetic amplification tests permit expansion of screening to men, teenage boys, and girls in settings where examination is not planned or is impractical (e.g., during pre-participation sports examinations).

Although gonorrhea is now substantially less common than chlamydial infection in industrialized countries, screening tests for N. gonorrhoeae are still appropriate for women and teenage girls attending STD clinics and for sexually active teens and young women from areas of high gonorrhea prevalence. However, multiplex nucleic acid amplification tests that combine screening for N. gonorrhoeae and C. trachomatis in a single low-cost assay may facilitate the prevention and control of both infections in populations at high risk.

All patients with newly detected STIs or at high risk for STIs according to routine risk assessment as well as all pregnant women should be encouraged to undergo serologic testing for syphilis and HIV infection, with appropriate HIV counseling before and after testing. Randomized trials have shown that risk-reduction counseling of patients with STIs significantly lowers subsequent risk of acquiring an STD; such counseling should now be considered a standard component of STD management. Preimmunization serologic testing for antibody to HBV is indicated for unvaccinated persons who are known to be at high risk, such as homosexually active men and injection drug users. In most young persons, however, it is more cost-effective to vaccinate against HBV without serologic screening.

Partner notification is the process of identifying and informing partners of infected patients of possible exposure to an STI and of examining, testing, and treating partners as appropriate. In a series of 22 reports concerning partner notification during the 1990s, index patients with gonorrhea or chlamydial infection named a mean of 0.75 to 1.6 partners, of whom one-fourth to one-third were infected; those with syphilis named 1.8 to 6.3 partners, with one-third to one-half infected; and those with HIV infection named 0.76 to 5.31 partners, with up to one-fourth infected. Persons who transmit infection or who have recently been infected and are still in the incubation period usually have no symptoms or only mild symptoms and seek medical attention only when notified of their exposure. Therefore, the clinician must encourage patients to participate in partner notification, must ensure that exposed persons are notified, and must guarantee confidentiality to all involved. In the United States, local health departments often offer assistance in partner notification, treatment, and/or counseling. It seems both feasible and most useful to notify those partners exposed within the patient’s likely period of infectiousness, which is often considered the preceding 1 month for gonorrhea, 1 to 2 months for chlamydial infection, and up to 3 months for early syphilis.

Persons with a new-onset STD always have a source contact who gave them the infection; in addition, they may have a secondary (spread or exposed) contact with whom they had sex after becoming infected. The identification and treatment of these two types of contacts have different objectives. Treatment of the source contact (often a casual contact) benefits the community by preventing further transmission; treatment of the recently exposed secondary contact (typically a spouse or another steady sexual partner) prevents both the development of serious complications (such as PID) in the partner and re-infection of the index patient. A recent survey of a random sample of U.S. physicians found that most instructed patients to abstain from sex during treatment, to use condoms, and to inform their sex partners after being diagnosed with gonorrhea, chlamydial infection, or syphilis; physicians sometimes gave the patients drugs for their partners. However, follow-up of the partners by physicians was infrequent. A recent randomized trial compared patients’ delivery of therapy to partners exposed to gonorrhea or chlamydial infection with conventional notification and advice to partners to seek evaluation for STD; patients’ delivery of therapy to their partners significantly reduced rates of re-

[Adapted from HT Waller and MA Piot: Bull World Health Organ 41:75, 1969 and 42:1, 1970; and from Resource allocation model for public health planning—a case study of tuberculosis control,” Bull World Health Organ 64(Suppl) 1973.]
The costs of nosocomial (hospital-acquired) infections are great. It is estimated that nosocomial infections affect more than 2 million patients, cost $4.5 billion, and contribute to 88,000 deaths in U.S. hospitals annually. Efforts to lower infection risks have been challenged by the growing numbers of immunocompromised patients, antibiotic-resistant bacteria, fungal and viral superinfections, and invasive devices and procedures. Nevertheless, evidence-based guidelines for prevention and control are now available (Table 116-1); according to some estimates, the consistent application of these guidelines may reduce the risk of nosocomial infection by more than one-third. This chapter reviews hospital-acquired and device-related infections and the basic surveillance, prevention, and control and treatment activities that have been developed to deal with these problems.

**Organization and Responsibilities of Infection-Control Programs** The standards of the Joint Commission on Accreditation of Healthcare Organizations require all accredited hospitals to have an active program for surveillance, prevention, and control of nosocomial infections. A multidisciplinary infection-control committee usually oversees the program. The agents of the committee are the chairperson, who is preferably an infectious disease physician, and the infection-control practitioners, who are usually trained in nursing or medical technology and in epidemiology and public health. Education of physicians in infection control and hospital epidemiology is required in infectious disease fellowship programs and is available in courses provided by professional societies, primarily the Society for Healthcare Epidemiology of America.

Diagnosis-related reimbursement has led hospital administrators to place increased emphasis on cost containment and on documentation of the cost-effectiveness of infection control. The quality-improvement movements and the Joint Commission have redirected infection-control attention, in part, beyond the mere writing of policies and procedures to improvement of the actual processes and optimization of outcomes. In many hospitals, epidemiology programs have taken on additional pharmacoepidemiologic and antibiotic-use review responsibilities as well as broader quality-assurance activities under the rubric “patient safety.” All programs must respond to governmental regulation of hospital waste and to standards mandated by the Occupational Safety & Health Administration for protecting health care workers from occupational exposure to bloodborne pathogens and tuberculosis.

**Surveillance** Traditionally, infection-control practitioners have surveyed inpatients for infections acquired in hospitals (defined as those neither present nor incubating at the time of admission). Surveillance involves a review of microbiology laboratory results, "shoe-leather” epidemiology on the nursing wards, application of standardized defi-

Mandatory infections, ongoing dialogue with hospital workers, and common sense. Some innovative infection-control programs have taken advantage of the increased use of computerized pharmacy, microbiology, and other databases in hospitals to create algorithm-driven surveillance.

Most hospitals aim surveillance at infections that (1) are associated with a high level of morbidity [e.g., intensive care unit (ICU)–related infections and nosocomial pneumonia]; (2) are costly (e.g., cardiac surgical wound infections); (3) are difficult to treat (e.g., infections due to antibiotic-resistant bacteria); (4) pose recurrent epidemic problems (e.g., *Clostridium difficile*–related diarrhea); and (5) are potentially preventable (e.g., vascular access–related infections). Quality-assurance activities in infection control have led to increased surveillance of the compliance of personnel with infection-control policies (e.g., monitoring of actual adherence to hand hygiene recommendations).

The results of surveillance are expressed as rates; in general, 5 to 10% of patients develop nosocomial infections. Such overall statistics have little value unless qualified by duration of risk, by site of infection, by patient population, and by exposure to risk factors. Meaningful denominators for infection rates include the number of patients exposed to a specific risk (e.g., rates of pneumonia among patients using mechanical ventilators) and the number of intervention days (e.g., rates of pneumonia per 1000 patient-days on a ventilator).

Temporal trends in rates should be reviewed, and rates should be compared with regional and national norms. However, even comparison rates generated by the ongoing National Nosocomial Infections Surveillance System [a program of the Centers for Disease Control and Prevention (CDC)], which collects data from more than 350 hospitals that use standardized definitions of nosocomial infections, have not been validated independently and represent a nonrandom sample of hospitals. Interhospital comparisons are easily confounded by the wide range in risk factors and in severity of underlying illnesses; unless rates are adjusted for these factors, comparisons may be misleading. Unfortunately, systems for making such adjustments either are rudimentary or have not been well validated.

The ongoing analysis of an individual hospital’s infection rates helps to determine whether control efforts are succeeding and where increased education and control measures should be focused. Knowledge of infection rates is also useful in discussions with the hospital administration regarding areas to which additional resources should be directed.

### Epidemiologic Basis and General Measures for Prevention and Control

Nosocomial infections follow basic epidemiologic patterns that can help to direct prevention and control measures. Nosocomial pathogens have reservoirs, are transmitted by predictable routes, and require susceptible hosts. Reservoirs and sources exist in the inanimate environment (e.g., tap water contaminated with *Legionella*) and in the animate environment (e.g., infected or colonized health care workers, patients, and hospital visitors). The mode of transmission most often is either cross-infection (e.g., indirect spread of pathogens from one patient to another on the inadequately cleaned hands of hospital personnel) or autoinoculation (e.g., aspiration of oropharyngeal flora into the lung along an endotracheal tube). Occasionally, pathogens (e.g., group A streptococci and many respiratory viruses) are spread indirectly from person to person via infectious droplets released by coughing or sneezing. Much less common—but often devastating in terms of epidemic risk—is true airborne spread of droplet nuclei (as in nosocomial chickenpox) or common-source spread by contaminated materials (e.g., iodophors contaminated with *Pseudomonas*). Factors that increase host susceptibility include underlying conditions and the many medical-surgical interventions and procedures that bypass or compromise normal host defenses.

Through its program, the hospital’s infection-control committee must determine the general and specific measures used to control infections and must review and recommend specific antiseptics and disinfectants for hospital use. Given the prominence of cross-infection, hand hygiene is the single most important preventive measure in hospitals (Table 116-2). Health care workers’ rates of adherence to hand-hygiene recommendations are abysmally low (<50%). Reasons cited include inconvenience, time pressures, and skin damage from frequent washing. Sinkless alcohol rubs are quick and highly effective and actually improve hand condition since they contain emollients and allow the retention of natural protective oils that are removed with repeated rinsing. Use of alcohol hand rubs between patient contacts is now recommended for all health care workers except when the hands are visibly soiled, in which case washing with soap and water is still required.

### Nosocomial and Device-Related Infections

The fact that 25 to 50% of nosocomial infections are due to the combined effect of the patient’s own flora and invasive devices highlights the importance of improvements in the use and design of such devices. Intensive educational programs can be associated with at least a temporary reduction in infection rates through improved asepsis in handling and earlier removal of invasive devices, but the maintenance of such gains is often difficult. Of particular note, shortages of trained personnel jeopardize safe and effective patient care and have been associated with increased rates of infection and death among patients.

### Urinary Tract Infections

Urinary tract infections (UTIs) account for as many as 40 to 45% of nosocomial infections; up to 3% of bacteriuria develops without apparent cause. Although UTIs contribute only 10 to 15% to prolongation of hospital stay and to extra costs, these infections are important reservoirs and sources for spread of antibiotic-resistant bacteria in hospitals. Almost all nosocomial UTIs are associated with preceding instrumentation or indwelling bladder catheters, which create a 3 to 10% risk of infection each day. UTIs generally are caused by pathogens that spread up the periurethral space from the patient’s perineum or gastrointestinal tract—the most common pathogenesis in women—or via intraluminal contamination of urinary catheters, usually due to cross-infection by caregivers who are irrigating catheters or emptying drainage bags. Pathogens occasionally come from inadequately disinfected urologic equipment and rarely come from contaminated supplies (e.g., dilute aqueous benzalkonium chloride, an ineffective disinfectant).

The most important measures for preventing nosocomial UTIs are (1) the placement of catheters only when absolutely necessary and not solely for the convenience of caregivers, (2) the use of aseptic technique for catheter insertion and for urinary tract instrumentation, (3) the manipulation and opening of drainage systems as infrequently as possible, and (4) the removal of catheters as soon as feasible.

</table>
should develop criteria for and closely monitor these four performance measures.

Sealed catheter–drainage tube junctions can help to prevent breaks in the system. Approaches to the prevention of UTIs also have included the use of topical metnal antimicrobials, drainage bag disinfectants, and anti-infective catheters. A meta-analysis and more recent studies suggest that silver alloy–coated catheters may reduce the incidence of bacteriuria, at least during short-term catheterization. However, because of conflicting study results, none of the latter three measures is considered routine.

Systemic antimicrobials given for other purposes decrease the risk of UTI during the first 4 days of catheterization, after which resistant bacteria or yeasts emerge as pathogens. Selective decontamination of the gut is also associated with a reduced risk. Again, however, neither approach is routine.

Irrigation of catheters, with or without antimicrobials, may actually increase the risk of infection. A condom catheter for men without bladder obstruction may be more acceptable than an indwelling catheter, but the infection risks with the two types are similar unless the condom catheter is carefully maintained. The role of suprapubic catheters in preventing infection is not well defined.

Treatment of UTIs is based on the results of quantitative cultures of urine (see Chap. 269); the most common pathogens are Escherichia coli, nosocomial gram-negative bacilli, enterococci, and Candida. Several caveats apply in the treatment of institutionally acquired infection. First, in patients with chronic indwelling bladder catheters, especially those in long-term-care facilities, the “catheter flora”—microorganisms living in the biofilm or on encrustations within the catheter lumen—may differ from the actual urinary tract pathogens. Therefore, for suspected infection in the setting of chronic catheterization (especially in women), it is useful to replace the bladder catheter and to obtain a freshly voided urine specimen. Second, as in all nosocomial infections, at the time treatment is initiated on the basis of a positive culture, it is useful to repeat the culture to verify the persistence of infection. Third, the frequency with which UTIs occur may lead to the erroneous assumption that this site alone is the source of infection in a febrile hospitalized patient. Thus, in the treatment of nosocomial UTIs, it is important to assess the patient for symptoms, especially of upper-pole infection (e.g., flank pain in conscious patients), and for signs of abnormal urinary sediment. Since nosocomial UTIs usually occur in the setting of catheterization or recent instrumentation, lower-tract symptoms (e.g., dysuria) may not be reliable. Fourth, recovery of Staphylococcus aureus from urine cultures may result from hema-togenous seeding and may indicate an occult systemic infection. Finally, although Candida is now the most common pathogen in nosocomial UTIs in ICU patients, it is not clear that candiduria in the absence of upper-pole invasion, obstruction, neutropenia, or immunosuppression warrants treatment.

Pneumonia Pneumonia accounts for 15 to 20% of nosocomial infections but has been responsible for 24% of extra hospital days and 39% of extra costs—i.e., 6 days and $6000 (based on 1992 dollars) per episode. Almost all cases of bacterial nosocomial pneumonia are caused by aspiration of endogenous or hospital-acquired oropharyngeal (and occasionally gastric) flora. Nosocomial pneumonias are associated with more deaths than are infections at any other body site. However, attributable mortality for ventilator-associated pneumonia—the most common and lethal form of nosocomial pneumonia—is in the 6 to 14% range; this figure suggests that the risk of dying from nosocomial pneumonia is affected greatly by other factors, including comorbidities, inadequate antibiotic treatment, and the involvement of specific pathogens (particularly Pseudomonas aeruginosa and Acinetobacter). Surveillance and accurate diagnosis of pneumonia are often problematic in hospitals because many patients, especially those in the ICU, have abnormal chest roentgenographs, fever, and leukocytosis potentially attributable to multiple causes. Viral pneumonias, which are particularly important in pediatric and immunocompromised patients, are discussed in the virology section and in Chap. 239.

Risk factors for nosocomial pneumonia, particularly ventilator-associated pneumonia, include those events that increase the risk of colonization by potential pathogens (e.g., prior antimicrobial therapy, contaminated ventilator circuits or equipment, or decreased gastric acidity); those that heighten the possibility of aspiration of oropharyngeal contents into the lower respiratory tract (e.g., intubation, decreased levels of consciousness, or presence of a nasogastric tube); and those that reduce host defense mechanisms in the lung and permit overgrowth of aspirated pathogens (e.g., chronic obstructive pulmonary disease, old age, or upper abdominal surgery).

Control measures for pneumonia are aimed at the remediation of risk factors in general patient care (e.g., minimizing aspiration-prone supine positioning) and at meticulous aseptic care of respirator equipment (e.g., disinfecting or sterilizing all inline reusable components such as nebulizers, replacing tubing circuits at intervals of >48 h—rather than more frequently—to lessen the number of breaks in the system, and teaching aseptic technique for suctioning). In a large multicenter trial, sucralfate, which provides stress-ulcer prophylaxis without altering gastric pH, did not reduce the risk of ventilator-associated pneumonia, despite the theoretical advantage of lessened risk for gastric colonization by gram-negative bacilli. The benefits of selective decontamination of the oropharynx and gut with nonabsorbable antimicrobials and/or use of short-course postintubation systemic antibiotics have been controversial. Among the logical preventive measures that require further investigation are the use of endotracheal tubes that provide channels for subglottic drainage of secretions and the use of noninvasive mechanical ventilation whenever feasible. Of note, even interventions that have reduced the rate of ventilator-associated pneumonia most often have not reduced overall ICU mortality; this fact suggests that this infection is a marker for patients with an otherwise heightened risk of death.

The most likely pathogens for nosocomial pneumonia and treatment options are discussed in Chap. 239. Several considerations regarding diagnosis and treatment are worth emphasizing. Clinical criteria for diagnosis (e.g., fever, leukocytosis, development of purulent secretions, new or changing radiographic infiltrates, change in oxygen requirement or ventilator settings) have high sensitivity but relatively low specificity. These criteria are most useful for selecting patients for bronchoscopic or nonbronchoscopic procedures that yield lower respiratory tract samples protected from upper-tract contamination; quantitative cultures of such specimens have diagnostic sensitivities in the range of 80%. Early-onset nosocomial pneumonia, which manifests within the first 4 days of hospitalization, is most often caused by community-acquired pathogens, such as Streptococcus pneumoniae and Haemophilus species. Late-onset pneumonias most commonly are due to S. aureus, P. aeruginosa, Enterobacter species, Klebsiella pneumoniae, or Acinetobacter—a pathogen of increasing concern in many ICUs. When invasive techniques are used to diagnose ventilator-associated pneumonia, the proportion of isolates accounted for by gram-negative bacilli decreases from 50–70% to 35–45%. Infection is polymicrobial in as many as 20 to 40% of cases. The role of anaerobic bacteria in ventilator-associated pneumonia is not well defined. The appropriate duration of therapy for nosocomial pneumonia, although generally stated to be in the 10- to 21-day range, is not well studied. Finally, in febrile patients (particularly those who have endotracheal and/or nasogastric tubes), more occult sources of respiratory tract infection, especially bacterial sinuses and otitis media, should be considered.

Surgical Wound Infections Wound infections account for up to 20 to 30% of nosocomial infections but contribute up to 57% of extra hospital days and 42% of extra costs. Because the average wound infection has an incubation period of 5 to 7 days, which is longer than many postoperative stays, and because many procedures now are performed on an outpatient basis, the incidence of wound infections has become difficult to assess. These infections usually are caused by the patient’s
Infections Related to Vascular Access and Monitoring

Intravascular devices are common causes of local site infection and cause up to 50% of nosocomial bacteremias; central vascular catheters account for 80 to 90% of these infections. National estimates indicate that as many as 250,000 bloodstream infections associated with central vascular catheters occur each year in the United States, with an attributable mortality of 12 to 25% and an estimated cost of $25,000 per episode; one-third to one-half of these episodes occur in ICUs. With increasing care of seriously ill patients in the community, vascular catheter–associated bloodstream infections acquired by outpatients are receiving more attention than in the past. A recent study of bacteremia patients at three hospitals showed that the numbers of patients being treated for device-associated bacteremia acquired in the hospital or in the community setting (e.g., home or clinic intravascular therapy) were similar. This finding emphasizes the need to broaden surveillance activities.

Vascular device–related infections may be the most preventable of nosocomial infections. Evidence-based control measures include implementing educational programs with didactic and interactive components for persons who insert and maintain catheters, using maximal sterile barrier precautions (e.g., gowns, gloves, masks, and large drapes) during catheter placement, using chlorhexidine for skin antisepsis prior to catheter placement, and ensuring that “idle catheters” are removed. Hospitals should periodically monitor adherence to these performance indicators. Use of antimicrobial- or antiseptic-impregnated central venous catheters is a reasonable control measure for adults whose catheters are expected to remain in place for >5 days if, after implementation of the performance measures just listed, the rates of catheter-related bloodstream infection remain above the goals set by individual institutions based on benchmark national rates and local factors. Additional control measures for infections associated with vascular access include avoiding the femoral site for catheterization because of an unusually high risk of infection (most likely related to the density of the skin flora); moving peripheral catheters to a new site at specified intervals (e.g., every 72 to 96 h), which may be facilitated by use of an intravenous therapy team; and applying disposable transducers for pressure monitoring and aseptic technique for accessing transducers or other vascular ports. Improvements in composition of semitransparent access-site dressings and potential nursing benefits (ease of bathing and site inspection, protection of site from secretions) favor the use of such coverings. Unresolved issues include the best frequency for rotation of central vascular catheter sites (given that guidewire-assisted catheter changes at the same site do not lessen infection risk); the appropriate role of mupirocin ointment, a topical antibiotic with excellent antistaphylococcal activity, in site care; the relative degrees of risk posed by peripherally inserted central catheters (PICC lines); and the risk-benefit of prophylactic use of heparin to avoid catheter thrombi, which may be associated with increased risk of infection.

Vascular device–related infection is suspected on the basis of the appearance of the catheter site or the presence of fever or bacteremia without another source in patients with vascular catheters. The diagnosis is confirmed by the recovery of the same species of microorganism from peripheral-blood cultures (preferably two cultures drawn from peripheral veins by separate venipunctures) and from semiquantitative or quantitative cultures of the vascular catheter tip. Less commonly used diagnostic measures include differential time to positivity (>2 h) for blood drawn through the vascular access device compared with a sample from a peripheral vein or differences in quantitative cultures (a 5- to 10-fold or greater “step-up”) for blood samples drawn simultaneously from a peripheral vein and from a central vascular catheter. When infusion-related sepsis is considered (e.g., because of the abrupt onset of fever or shock temporally related to infusion therapy), a sample of the infusate or blood product should be retained for culture.
Therapy for vascular access–related infection is directed at the pathogen recovered from the blood and/or infected site. Important considerations in treatment are the need for an echocardiogram (to evaluate the patient for bacterial endocarditis), the duration of therapy, and the need to remove potentially infected catheters. In one report, approximately one-fourth of patients with intravascular catheter–associated *S. aureus* bacteremia studied by transesophageal echocardiography had evidence of endocarditis; the implication is that this test may be useful in determining the appropriate duration of treatment. Detailed consensus guidelines for the management of intravascular catheter–related infections have been published and recommend catheter removal in most cases of bacteremia or fungemia due to nontunneled central venous catheters. When attempting to salvage a potentially infected catheter, some clinicians use the “antibiotic lock” technique (instillation of concentrated antibiotic solution into the catheter lumen) in addition to systemic antimicrobial therapy. In one study of hemodialysis catheters, only about one-third of salvage attempts were successful, although delayed removal did not appear to increase the risk of complications. When feasible, a potentially infected central vascular catheter may be exchanged over a guidewire. If cultures of the removed catheter tip are positive, the replacement catheter will be moved to a new site; if the tip cultures are negative, the replacement catheter can remain in the original site. For patients with track-site infection, successful therapy without catheter removal is unusual. For patients with suppurative venous thrombophlebitis, excision of the affected vein is required. The authors of the consensus guidelines advise that the decision to remove a tunneled catheter or implanted device suspected to be the source of bacteremia or fungemia should be based on the severity of the patient’s illness, the strength of the evidence that the device is infected, an assessment of the specific pathogens, and the presence of local or systemic complications.

**ISOLATION TECHNIQUES** Written policies for the isolation of infectious patients are a standard component of infection-control programs. In 1996, the CDC revised its isolation guidelines to make them simpler; to recognize the importance of all body fluids, secretions, and excretions in the transmission of nosocomial pathogens; and to focus precautions on the major routes of infection transmission.

The revised guidelines contain two tiers of precautions. **Standard precautions** are designed for the care of all patients in hospitals to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection. These precautions include gloving as well as hand cleansing for potential contact with (1) blood; (2) all other body fluids, secretions, and excretions, whether or not they contain visible blood; (3) nonintact skin; and (4) mucous membranes. Depending on exposure risks, standard precautions also include use of masks, eye protection, and gowns.

In the second tier are precautions for the care of patients with suspected or diagnosed colonization or infection with transmissible pathogens. These transmission-based guidelines collapse the older category- and disease-specific isolation guidelines into three sets of precautions based on probable routes of transmission: *airborne precautions*, *droplet precautions*, and *contact precautions*. Sets of precautions may be combined for diseases that have more than one route of transmission (e.g., varicella). Potentially contagious clinical syndromes, such as acute diarrhea, are included in the revised guidelines.

Because some prevalent antibiotic-resistant pathogens, particularly vancomycin-resistant enterococci (VRE), may be present on intact skin of patients in hospitals, some experts recommend gloving for all contact with patients who are acutely ill and/or from high-risk units, such as ICUs. In recent trials, wearing gloves did not replace the need for hand hygiene because hands occasionally became contaminated during wearing or removal of gloves. Some studies have suggested that use of gowns and gloves compared with routine care of patients (i.e., using neither of these barriers) decreases the risk of nosocomial infection. However, more recent evaluations suggest that gowning by personnel does not add benefit beyond that conferred by gloving and hand hygiene. Nevertheless, requiring increased precaution levels can improve the compliance of health care workers with isolation recommendations by 30%.

**EPIDEMIC AND EMERGING PROBLEMS** Outbreaks and emerging pathogens are always big news but probably account for fewer than 5% of nosocomial infections. Concerns about emerging pathogens often prompt authorities to require hospitals to develop contingency and response plans. The investigation and control of nosocomial epidemics require that infection-control personnel develop a case definition, confirm that an outbreak really exists (since many apparent epidemics are actually pseudo-outbreaks due to surveillance or laboratory artifacts), review aseptic practices and disinfectant use, determine the extent of the outbreak, perform an epidemiologic investigation to determine modes of transmission, work closely with microbiology personnel to culture for common sources or personnel carriers as appropriate and to type epidemiologically important isolates, and heighten surveillance to judge the effect of control measures. Control measures generally include the early reinforcement of routine aseptic practices and hand hygiene during a search for compliance problems that may have fostered the outbreak, the ensuring of the appropriate isolation of cases (and the institution of cohort isolation and nursing if needed), and the implementation of further controls on the basis of the investigation’s findings. Examples of some emerging and potential epidemic problems follow.

**Chickenpox** When health care workers are exposed to chickenpox in the community or through patients with initially unrecognized infections, or when these employees work during the 24 h before developing chickenpox, infection-control practitioners institute a varicella exposure investigation and control plan. The names of exposed workers and patients are obtained; medical histories are reviewed, and (if necessary) serologic tests for immunity are conducted; physicians are notified of susceptible exposed patients; postexposure prophylaxis with varicella-zoster immune globulin (VZIG) is considered for immunocompromised or pregnant contacts (see Table 164-1); preemptive use of acyclovir is considered as an alternative strategy in some susceptible persons; and susceptible exposed employees are furloughed during the at-risk period for disease (8 to 21 days, or 28 days if VZIG has been administered). Routine varicella vaccination of children and susceptible employees can markedly decrease risk and frequency of exposures.

**Tuberculosis** The resurgence of pulmonary tuberculosis in the United States since 1987 and a series of nosocomial outbreaks of infection with multidrug-resistant strains—primarily involving patients with AIDS and their caregivers—led to a successful revamping of tuberculosis control. Important control measures include prompt recognition, isolation, and treatment of cases; recognition of atypical presentations (e.g., lower-lobe infiltrates without cavitation); use of negative-pressure, 100% exhaust, private isolation rooms with closed doors and 6 to 12 or more air changes per hour; use of face masks (“respirators” approved by the National Institute for Occupational Safety and Health) by caregivers entering isolation rooms; possible use of high-efficiency particulate air filter units and/or ultraviolet lights for disinfecting air when other engineering controls are not feasible or reliable; and follow-up skin-testing of susceptible personnel who have been exposed to infectious patients before isolation.

**Group A Streptococci** The potential for a group A streptococcal outbreak should be considered when even a single nosocomial case occurs. Most outbreaks involve surgical wounds and are due to the presence of an asymptomatic carrier in the operating room. Investigation can be confounded by carriage at extrahospital sites such as the rectum and vagina. Health care workers in whom carriage has been linked to nosocomial recent evaluation of group A streptococci are removed from the patient-care setting and are not permitted to return until carriage has been eliminated by antimicrobial therapy.
**Aspergillus** Fungal spores are common in the environment, particularly on dusty surfaces. When hospital ceiling tiles are removed to provide access for repairs or when dusty areas are disturbed during hospital renovation, the spores become airborne. Inhalation of spores by immunosuppressed (especially neutropenic) patients creates a risk of pulmonary and/or paranasal sinus infection and disseminated aspergillosis. Routine surveillance among neutropenic patients for infections with filamentous fungi, such as *Aspergillus* and *Fusarium*, helps hospitals to determine whether they have unduly large environmental risks. As a matter of routine, hospitals should inspect and clean air-handling equipment, review all planned renovations with infection-control personnel and subsequently construct appropriate barriers, remove immunosuppressed patients from renovation sites, and consider the use of high-efficiency particulate air intake filters for rooms housing immunosuppressed patients.

**Legionella** Sporadic and epidemic cases of nosocomial *Legionella* pneumonia are most often due to the contamination of potable water and predominantly affect immunosuppressed patients, particularly those receiving glucocorticoid medication. The risk varies greatly within and among geographic regions, depending on the extent of hospital hot-water contamination, on the presence or absence of high-risk patient populations, and on specific hospital practices (e.g., inappropriate use of nonsterile water in respiratory therapy equipment). Laboratory-based surveillance for nosocomial *Legionella* should be performed, and a diagnosis of legionellosis should probably be considered more often than it is. If cases are detected, environmental samples (e.g., tap water) should be cultured. If cultures yield *Legionella* and if typing of clinical and environmental isolates reveals a correlation, eradication measures should be pursued (Chap. 132). An alternative approach is to periodically culture tap water in wards housing high-risk patients. If *Legionella* is found, a concerted effort should be made to culture samples from all patients with nosocomial pneumonia for *Legionella*.

**Antibiotic-Resistant Bacteria** Outbreaks of antibiotic resistance can depend on any of the following events: Darwinian selection of bacterial chromosomal mutations, spread of plasmid- and/or transposon-borne resistance among bacterial species, and (re)admission to the hospital of patients chronically infected with resistant bacteria. After the introduction of resistant strains, dissemination occurs by cross-infection on contaminated hands of caregivers or, occasionally, via personnel carriage and/or environmental contamination. Outbreak control (Table 116-3) depends on close laboratory surveillance, with early detection of problems; on the reinforcement of routine asepsis (e.g., hand hygiene); on the implementation of barrier precautions for all colonized and/or infected patients; on the use of patient-surveillance cultures to more fully ascertain the extent of patient colonization; and on the timely initiation of an epidemiologic investigation when rates increase. Colonized personnel who are implicated in nosocomial transmission and patients who pose a threat may be decontaminated; for example, colonization with methicillin-resistant *S. aureus* may be controlled with oral antibiotics, including trimethoprim-sulfamethoxazole and rifampin, and with topical agents, including hexachlorophene or chlorhexidine and mupirocin. In a few ICUs, selective decontamination has been used successfully as a temporary emergency control measure for outbreaks of infection due to gram-negative bacilli.

An emerging bacterial-resistance problem to plague hospitals is the presence of VRE. Initially an ICU problem, VRE have now spread onto general wards in many hospitals. VRE are particularly problematic because of a substantial "iceberg" effect (i.e., the fact that, for each individual with a clinical infection, many other patients are colonized); the occurrence of both gastrointestinal and skin colonization (reflecting fecal contamination on the skin of ill, hospitalized patients); and the propensity for these organisms to contaminate the patient’s environment, which may increase the risk of cross-infection. Control of VRE requires strict attention to hand hygiene by personnel, concerted use of barrier precautions or cohort nursing for patients known to be colonized or infected, and emphasis on thorough cleaning of the rooms of these patients.

Spread of vancomycin resistance to *S. aureus* is a major concern. Clinical infections with methicillin-resistant *S. aureus* strains that exhibit high-level vancomycin resistance due to VRE-derived plasmids have now been reported in the setting of prolonged or repeated treatment with vancomycin and/or VRE colonization. The detection of these strains appears to be readily accomplished in clinical microbiology laboratories and should trigger an aggressive epidemiologic investigation and infection-control measures.

Because the excessive use of broad-spectrum antibiotics underlies many resistance problems, aggressive antibiotic-control policies must be considered a cornerstone of resistance-control efforts. Although the efficacy of antibiotic-control measures in reducing rates of antimicrobial resistance has not been proved in prospective controlled trials, it seems worthwhile to restrict the use of particular agents to narrowly defined indications or possibly to cycle the use of antibiotic classes to limit selective pressure on the nosocomial flora.

**Bioterrorism Preparedness** The terrorist attack on the World Trade Center in New York City; other horrific events of September 11, 2001; and the subsequent mailings of anthrax spores in the United States have made bioterrorism a prominent source of concern to hospital

### TABLE 116-4 Highlights of Hospital Preparedness for Bioterrorism

- **Emergency Department:** Educate staff regarding bioterrorism diagnoses, case definitions, and appropriate syndrome-based isolation precautions.
- **Laboratory:** Identify protocols and laboratory safety procedures for agents of bioterrorism.
- **Pharmacy:** Develop medication and vaccine par stock, allocation, and delivery plans.
- **Nursing:** Assess bed and isolation surge capacity; help develop contingency plans to free bed space by early discharges and deferred admissions.
- **Hospital Police:** Plan for responsibilities as first responders and providers of risk assessment.
- **Mailroom:** Plan for risk assessment and need/indicators-for-use of personal protective equipment as appropriate.
- **Engineering/Buildings and Grounds:** Evaluate air-handling systems and ensure familiarity with shutoffs and controls; educate staff about environmental decontamination.
- **Outpatient Areas:** Develop plans for family and community evaluation and staging for delivery of prophylactic medications and/or vaccines.
- **Public Health:** Ascertain local public health resources and open lines of communication, education, and surveillance.
- **The Community:** Plan for infection-control practitioners to serve as liaisons/links/facilitators for emergency departments, laboratories, and community providers.
- **Administration:** Perform resource assessment for medical supplies, transportation capabilities, potable water, sanitation facilities, provider backup, bed-space backup, etc. Overseer development of an incident command system.

"**Morale Officer:**" Establish this position to help survey and keep staff functioning.

The evaluation of infections in transplant recipients involves consideration of both the donor and the recipient of the transplanted organ. Infections following transplantation are complicated by the use of drugs that are necessary to enhance the likelihood of survival of the transplanted organ but that also cause the host to be immunocompromised. Thus what might have been a latent or asymptomatic infection in an immunocompetent donor or in the recipient prior to therapy becomes a life-threatening problem when the recipient becomes immunosuppressed.

A variety of organisms have been transmitted by organ transplantation (Table 117-1). Careful attention to the sterility of the medium used to process the organ combined with meticulous microbiologic evaluation reduces rates of transmission of bacteria that may be present or grow in the organ culture medium. From 2% to >20% of donor kidneys are estimated to be contaminated with bacteria—in most cases, with the organisms that colonize the skin or grow in the tissue culture medium used to bathe the donor kidney while it awaits implantation. The reported rate of bacterial contamination of transplanted bone marrow is as high as 17% but is most commonly ~1%. The use of enrichment columns and monoclonal-antibody depletion procedures results in a higher incidence of contamination. Approximately 2% of cryopreserved marrow and peripheral-blood stem cells transfused as part of treatment for cancer are contaminated. In one series of patients receiving contaminated products, 14% had fever or bacteremia, but none died. Results of cultures performed at the time of cryopreservation and at the time of thawing were helpful in guiding therapy for the recipient.

In many transplantation centers, transmission of infections that may be latent or clinically inapparent in the donor organ has resulted in the development of specific donor-screening protocols. In addition to ordering serologic studies focusing on viruses such as herpes-group viruses [herpes simplex virus (HSV) 1, HSV-2], varicella-zoster virus (VZV), cytomegalovirus (CMV), human herpesvirus (HHV) type 6, Epstein-Barr virus (EBV), HHV-8, hepatitis B and C viruses, HIV, and human T-cell lymphotropic virus (HTLV) type I and on parasites such as Toxoplasma gondii, clinicians caring for organ donors should consider assessing stool (for parasites) and should perform skin testing for Mycobacterium tuberculosis. An investigation of the patient’s dietary habits (e.g., consumption of raw meat or fish or of unpasteurized dairy products), occupations or avocations (e.g., gardening or spelunking), and travel history (e.g., travel to areas with endemic fungi) is mandatory. It is expected that the recipient will have been likewise assessed. This chapter considers aspects of infection unique to various transplantation settings.

**INFECTIONS IN BONE MARROW AND HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS**

Bone marrow or hematopoietic stem cell transplantation for either immunodeficiency or cancer results in a transient state of complete immune incompetence. Immediately after transplantation, both phagocytes and immune cells (T and B cells) are absent, and the host is extremely susceptible to infection. The reconstitution that follows transplantation has been likened to maturation of the immune system in neonates. The analogy does not entirely predict infections seen in bone marrow transplant (BMT) and hematopoietic stem cell transplant (HSCT) recipients because the new marrow matures in an old host who has several latent infections already. Nevertheless, infections occur in a predictable time frame after transplantation (Table 117-2).

**BACTERIAL INFECTIONS** In the first month after bone marrow or hematopoietic stem cell transplantation, infectious complications are similar to those in granulocytopenic patients receiving chemotherapy for acute leukemia (Chap. 72). Because of the anticipated 1- to 4-week duration...
are common in the first few days after bone marrow transplantation. Gram-negative bacteremia among these patients. Bacterial infections due to encapsulated organisms mark the late posttransplantation period (>6 months after bone marrow reconstitution).

**Fungal Infections** Beyond the first week after transplantation, fungal infections become increasingly common. As in most granulocytopenic patients, Candida infections are most commonly seen in this setting. With increased use of prophylactic fluconazole, infections with resistant fungi, such as Candida glabrata and Aspergillus, have become more common. In patients with graft-versus-host disease (GVHD) who require prolonged or indefinite courses of glucocorticoids and other immunosuppressive agents [e.g., cyclosporine, tacrolimus, mycophenolate mofetil, rapamycin, alemtuzumab (an antilymphocyte and antimonocyte antibody)], there is a high risk of fungal infection (usually with *Candida* or *Aspergillus*), even after engraftment and resolution of neutropenia. These patients are also at high risk of reactivation of fungal infection (histoplasmosis, coccidioidomycosis, blastomycosis) in areas where endemic fungi reside and if they are involved in activities such as spelunking or gardening. Because of the high and prolonged risk of *Pneumocystis* pneumonia (especially among patients being treated for hematologic malignancies), most patients should receive maintenance prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) starting 1 month after engraftment and continuing for at least 1 year.

**Parasitic Infections** The regimen just described for *Pneumocystis* pneumonia may also protect patients seropositive for *T. gondii*, which may cause pneumonia as well as central nervous system (CNS) lesions. The advantages of maintaining patients on daily TMP-SMX for 1 year after transplantation include protection against *Listeria monocytogenes* and nocardial disease as well as late infections with *Streptococcus pneumoniae* and *Haemophilus influenzae*, which are a consequence of the inability of the immature bone marrow to respond to polysaccharide antigens.

**Viral Infections** BMT/HSCT recipients are susceptible to infection with a variety of viruses, including reactivation syndromes caused by most HHVs (Table 117-3) and infections caused by viruses that circulate in the community.

**Herpes Simplex Virus** Within the first 2 weeks after transplantation, most patients who are seropositive for HSV-1 excrete the virus from the oropharynx. The ability to isolate HSV declines with time. Administration of prophylactic acyclovir (or valacyclovir) to seropositive BMT/HSCT recipients has been shown to reduce mucositis and prevent HSV pneumonia (a rare condition reported almost exclusively in BMT recipients). Both esophagitis (usually due to HSV-1) and anogenital disease (commonly induced by HSV-2) may be prevented with acyclovir prophylaxis. For further discussion, see Chap. 163.

**Varicella-Zoster Virus** Reactivation of herpes zoster may occur within the first month but more commonly occurs several months after transplantation. Reactivation rates are ~40% for allogeneic recipients and 25% for autologous recipients. Localized zoster can spread locally on an immunosuppressed patient. Fortunately, disseminated disease can usually be controlled with high doses of acyclovir. Because of the high incidence of disseminated *Herpes simplex* virus (HSV) infections in BMT recipients, both esophagitis (usually due to HSV-1) and anogenital disease (commonly induced by HSV-2) may be prevented with acyclovir prophylaxis. For further discussion, see Chap. 163.

The organisms involved are predominantly aerobic bacteria found in the bowels (*Escherichia coli, Klebsiella, Pseudomonas*) and those found on the skin or in intravenous catheters (*Staphylococcus aureus, coagulase-negative staphylococci*). Beyond the first few days of neutropenia, infections with filamentous bacteria (*Nocardia* and the organisms that cause actinomycosis) become more common. Episodes of bacteremia due to encapsulated organisms mark the late posttransplantation period (>6 months after bone marrow reconstitution).

infection of herpes zoster among patients with skin lesions, acyclovir is given prophylactically in some centers to prevent severe disease. Low doses of acyclovir (400 mg orally, three times daily) appear to be effective in preventing reactivation of VZV. However, acyclovir also inhibits the development of VZV-specific immunity. Thus, its administration for only 6 months after transplantation does not prevent zoster from occurring when treatment is stopped. Some data suggest that administration of low doses of acyclovir for an entire year after transplantation is effective and may eliminate most cases of posttransplantation zoster. →For further discussion, see Chap. 164.

Cytomegalovirus The onset of CMV disease (interstitial pneumonia, bone marrow suppression, or graft failure) usually comes between 30 and 90 days after transplantation, when the granulocyte count is adequate but immunologic reconstitution has not occurred. CMV disease rarely develops earlier than 14 days after transplantation and may become evident as late as 4 months after the procedure. It is of great concern in the second month after transplantation, particularly in allogeneic BMT/HSCT recipients. In cases in which the donor marrow is depleted of T cells (to prevent GVHD or eliminate a T cell tumor), the disease may be manifested earlier. The use of cCD52 antibody (alemtuzumab) to prevent GVHD in nonmyeloablative transplantation has been associated with an increase in CMV disease. Patients who receive ganciclovir (for prophylaxis, preemptive treatment, or treatment; see below) may develop CMV infection even later than 4 months after transplantation; treatment appears to delay the development of the normal immune response to CMV infection. Although CMV disease may present as isolated fever, granulocytopenia, or gastrointestinal disease, the foremost cause of death from CMV infection in this setting is pneumonia.

With the standard use of CMV-negative or filtered blood products, primary CMV infection should be a risk in allogeneic transplantation only when the donor is CMV-seronegative and the recipient is CMV-seropositive. Reactivation disease or superinfection with another strain from the donor is also common in CMV-positive recipients, and most seropositive patients who undergo bone marrow transplantation excrete CMV, with or without clinical findings. Serious CMV disease is much more common among allogeneic than autologous recipients and is often associated with GVHD. In addition to pneumonia and marrow suppression, CMV ulcers and oropharyngitis occur in both the lower and the upper gastrointestinal tract, and it may be difficult to distinguish diarrhea due to GVHD from that due to CMV infection.

The finding of CMV in the liver of a patient with GVHD does not necessarily mean that CMV is responsible for hepatic enzyme abnormalities.

Management of CMV disease in BMT/HSCT recipients includes strategies directed at prophylaxis, suppression, preemptive therapy, or treatment. Prophylaxis results in a lower incidence of disease at the cost of treating many patients who otherwise would not require therapy. Because of the high fatality rate associated with CMV pneumonia in these patients and the difficulty of early diagnosis of CMV infection, prophylactic intravenous ganciclovir (or oral valganciclovir) has been used in some centers and has been shown to abort CMV disease during the period of maximal vulnerability (from engraftment to day 120 after transplantation). The foremost problem with the administration of ganciclovir relates to adverse effects, which include dose-related bone marrow suppression (thrombocytopenia, leukopenia, anemia, and pan-cytopenia). Because the frequency of CMV pneumonia is lower among autologous BMT recipients (2 to 7%) than among allogeneic BMT recipients (10 to 40%), prophylaxis in the former group will not become the rule until a less toxic antiviral agent becomes available.

Like prophylaxis, suppressive treatment, which targets patients with polymerase chain reaction evidence of CMV or urine cultures positive for CMV, entails the unnecessary treatment of many individuals (on the basis of a laboratory test that is not highly predictive of disease) with drugs that have adverse effects. Currently, because of the neutropenia associated with ganciclovir in BMT/HSCT recipients, a preemptive approach—treatment of those patients in whose blood CMV is detected by an antigen or DNA test—is used at most centers. This approach is almost as effective as prophylaxis or suppression and causes less toxicity. Quantitative viral load assays, which are not dependent on circulating polymorphonuclear leukocytes, have supplanted antigen-based assays and are used by most centers. A positive test (or increase in titer) prompts the initiation of preemptive therapy.

Treatment of CMV pneumonia in BMT/HSCT recipients requires both intravenous immune globulin (IVIg) and ganciclovir. In patients who cannot tolerate ganciclovir, foscarnet is a useful alternative, although it may produce nephrotoxicity and electrolyte imbalance. Transfusion of CMV-specific T cells from the donor decreased viral load in a small series of patients; this result suggests that immunotherapy may play a role in the treatment of this disease in the future. →For further discussion, see Chap. 166.

Human Herpesviruses 6 and 7 HHV-6, the cause of roseola in children, is a ubiquitous herpesvirus that reactivates (as determined by culture of the virus from the blood) in ~50% of transplant recipients between 2 and 4 weeks after surgery. In some cases, reactivation of HHV-6 appears to be associated with neutropenia; since, like CMV, this virus can be found in marrow cells, it is possible that HHV-6 reactivation is responsible for some of the neutropenia that follows bone marrow transplantation. Although encephalitis developing after transplantation has been associated with HHV-6 in cerebrospinal fluid (CSF), the causality of the association is not well defined. HHV-6 DNA is sometimes found in lung samples after transplantation. However, its role in pneumonitis is unclear. While HHV-6 has been shown to be susceptible to foscarnet (and possibly to ganciclovir) in vitro, the efficacy of antiviral treatment has not been well studied. Little is known about the related herpesvirus HHV-7 or its role in postransplantation infection. →For further discussion, see Chap. 166.

Epstein-Barr Virus Primary EBV infection can be fatal to transplant recipients; EBV reactivation can cause EBV–B cell lymphoproliferative disease (LPD), which may also be fatal to patients taking immunosuppressive drugs. The localization of EBV to B cells leads to several interesting phenomena in BMT/HSCT recipients. The marrow aplasia that occurs as part of the BMT/HSCT procedure may eliminate latent EBV from the host. Infection can then be reacquired immediately after transplantation by transfer of infected donor B cells.

*Note: BMT, bone marrow transplant.*
The diagnosis of pneumonitis in BMT/HSCT recipients is more likely to result in severe infection. The recipient is then at risk for a secondary bacterial infection.

EBV-LPD can develop in the recipient’s B cells (if any should survive marrow ablation) but is more likely to be a consequence of outgrowth of infected donor cells. Both lytic and latent EBV replication are more likely during immunsuppression (e.g., they are associated with GVHD and the use of antibodies to T cells). Although less likely in autologous transplantation, reactivation can occur in T-cell-depleted autologous recipients (e.g., patients being given antibodies to T cells for the treatment of a T cell lymphoma with marrow depletion). EBV-LPD, which can become apparent as soon as 1 to 3 months after engraftment, causes high fevers and cervical adenopathy resembling the symptoms of infectious mononucleosis but more commonly presents as an extranodal mass. The incidence of 0.6% among allogeneic BMT/HSCT recipients contrasts with figures of ~5% for renal transplant recipients and up to 20% for cardiac transplant patients. In all cases, EBV-LPD is more likely to occur with continued immunsuppression (especially that caused by the use of antibodies to T cells and cyclosporine or other T-cell–suppressive agents).

EBV-specific T cells generated from the donor have been used experimentally to prevent and to treat EBV-LPD in the allogeneic recipient. Administration of a monoclonal antibody to CD20 (rituximab) for the treatment of B cell lymphomas that express this surface protein has elicited dramatic responses and currently constitutes first-line therapy for EBV-LPD, although long-term suppression of new antibody responses accompanies therapy. The role of antivirals is uncertain because no available agents have been documented to have activity against latent EBV infection. Ganciclovir has been postulated to have activity on the basis of its ability to inhibit proliferation of B cells, but this activity is associated with toxicity. High-dose zidovudine shows promise for the treatment of EBV-positive CNS lymphomas—another EBV-associated complication of transplantation. Both interferon α and retinoic acid have been used in the treatment of EBV-LPD, as has IV Ig, but no large studies have assessed the efficacy of these agents. Chemotherapeutic regimens have been used as a last resort, even though patients’ tolerance and long-term results have been disappointing in this setting. →For further discussion, see Chap. 165.

Human Herpesvirus 8 The EBV-related gamma herpesvirus HHV-8, which is causally associated with Kaposi’s sarcoma, with primary effusion lymphoma, and sometimes with multicentric Castleman’s disease, has rarely resulted in disease in BMT/HSCT recipients. The reasons may be a relatively low seroprevalence in the population and ease, has rarely resulted in disease in BMT/HSCT recipients. The roleplay between increased CMV replication and enhanced graft rejection is well established: Increasing immunosuppression leads to increased CMV replication and may present as severe systemic disease or as infection of the transplanted organ. HHV-6 reactivation (assessed by HHV-6 DNAemia) was associated with fever and granulocytopenia. In subsequent weeks, the consequences of the administration of agents that suppress cell-mediated immunity and of the acquisition or reactivation (from the transplanted organ) of viruses and parasites become apparent. CMV infection is often a problem in the first 6 months after transplantation and may present as severe systemic disease or as infection of the transplanted organ. HHV-6 reactivation (assessed by blood culture) occurs within the first 2 to 4 weeks after transplantation and may be associated with fever and granulocytopenia. Data suggest that HHV-6 and HHV-7 may exacerbate CMV-induced disease. CMV is associated not only with generalized immunosuppression but also with organ-specific, rejection-related syndromes: glomerulopathy in kidney transplant recipients, bronchiolitis obliterans in lung transplant recipients, vasculopathy in heart transplant recipients, and the vanishing bile duct syndrome in liver transplant recipients. A complex interplay between increased CMV replication and enhanced graft rejection is well established: Increasing immunosuppression leads to increased CMV replication, which is associated with graft rejection. For this reason, considerable attention has been focused on the diagnosis, treatment, and prophylaxis of CMV infection in organ transplant recipients. Early transplantation of West Nile virus to transplant recipients from an organ donor has been reported.

Beyond 6 months after transplantation, infections characteristic of...
patients with defects in cell-mediated immunity—e.g., infections with *Listeria, Nocardia,* various fungi, and other intracellular pathogens—may be a problem. Elimination of these late infections will not be possible until specific tolerance to the transplanted organ can be achieved without the administration of drugs that lead to generalized immunosuppression. Meanwhile, vigilance, prophylaxis/preemptive therapy (when indicated), and rapid diagnosis and treatment of infections can be lifesaving in solid organ transplant recipients, who, unlike most BMT recipients, continue to be immunosuppressed.

Solid organ transplant recipients are susceptible to EBV-LPD from as early as 2 months to many years after transplantation. The prevalence of this complication is increased by potent and prolonged use of T cell-suppressive drugs. The condition may be reversed (in some cases) by decreasing the degree of immunosuppression. Among organ transplant patients, those with heart and lung transplants—who receive the most intensive immunosuppressive regimens—are most likely to develop EBV-LPD, particularly in the lungs. Although the disease usually originates in recipient B cells, several cases of donor origin have been reported. There is a notable tendency for EBV-LPD to develop in the transplanted organ. High organ-specific content of B lymphoid tissues (i.e., bronchial-associated lymphoid tissue in the lung), anatomical factors (i.e., lack of access of host T cells to the transplanted organ because of disturbed lymphatics), and differences in major histocompatibility loci between the host T cells and the organ (i.e., lack of cell migration or lack of effective T cell/macrophage cooperation) may result in defective elimination of EBV-infected B cells. Solid organ transplant recipients are also highly susceptible to the development of Kaposi’s sarcoma, and B cell proliferative disorders associated with Kaposi’s sarcoma—associated herpesvirus (KSHV, primary effusion lymphoma, multicentric Castleman’s disease). Kaposi’s sarcoma, however, develops very rapidly after transplantation and may occur in the allograft. However, because the seroprevalence of KSHV is very low in Western countries, Kaposi’s sarcoma is infrequent in these areas.

**KIDNEY TRANSPLANTATION** (See Table 117-4) Early Infections Infections developing soon after kidney transplantation are often caused by bacteria associated with skin or wound infections. There is a role for perioperative antibiotic prophylaxis, and many centers give cephalosporins to decrease the risk of postoperative complications. Urinary tract infections developing soon after transplantation are often caused by bacteria associated with skin or wound infections. There is a role for perioperative antibiotic prophylaxis, and many centers give cephalosporins to decrease the risk of postoperative complications. **Note:** CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; PPD, purified protein derivative; VZV, varicella-zoster virus.
seropositive kidneys). Ganciclovir is useful for prophylaxis and the treatment of serious CMV disease. One study showed a significant (50%) reduction in CMV disease and rejection at 6 months in patients who received prophylactic valacyclovir (an acyclovir congener) for the first 90 days after renal transplantation. The availability of ganciclovir and valacyclovir has allowed most centers to move to oral prophylaxis for transplant recipients.

Infection with the other herpes-group viruses may become evident within 6 months after transplantation or later. Early after transplantation, HSV may cause either oral or anogenital lesions that are usually responsive to acyclovir. Large ulcerating lesions in the anogenital area may lead to bladder and rectal dysfunction as well as predisposing to bacterial infection. VZV may cause fatal disseminated infection in nonimmune kidney transplant recipients, but in immune patients reactivation zoster usually does not disseminate outside the dermatome; thus disseminated VZV infection is a less fearsome complication in kidney transplantation than in bone marrow transplantation. HHV-6 may reactivate and (although usually asymptomatic) may be associated with fever, rash, marrow suppression, or encephalitis.

EBV reactivation disease is more serious; it may present as an extranodal proliferation of B cells that invade the CNS, nasopharynx, liver, small bowel, heart, and transplanted kidney. The disease is diagnosed by the finding of a proliferation of EBV-positive B cells. The incidence of EBV-LPD is highest among patients given high doses of cyclosporine, tacrolimus, or other immunosuppressive agents (including anti–T-cell antibodies). Disease may regress once immunocompetence is restored. HHV-8 infection can be transmitted with the donor kidney and is associated with the development of Kaposi’s sarcoma in the recipient. Kaposi’s sarcoma (primary vs. reactivation of HHV-8) often appears within 1 year after transplantation, although the range of onset times is wide (1 month to 20 years).

The papovaviruses BK and JC (polyomavirus hominis types 1 and 2) have been cultured from the urine of kidney transplant recipients (as they have from that of BMT recipients). The excretion of BK virus is associated with ureteral strictures, BK nephropathy, and—in rare instances—vascularopathy. JC virus is associated with progressive multifocal leukoencephalopathy (rare). Adenoviruses may persist with continued immunosuppression in these patients.

Kidney transplant recipients are also subject to infections with other intracellular organisms. These patients may develop pulmonary infections with Nocardia, Aspergillus, and Mucor as well as infections with other pathogens in which the T cell/macrophage axis plays an important role. In patients without intravenous catheters, L. monocytogenes is a common cause of bacteremia ≥1 month after renal transplantation and should be seriously considered in renal transplant recipients presenting with fever and headache. Kidney transplant recipients may develop Salmonella bacteremia, which can lead to endovascular infections and require prolonged therapy. Pulmonary infections with Pneumocystis are common unless the patient is maintained on TMP-SMX prophylaxis. Nocardia infection (Chap. 146) may present in the skin, bones, and lungs or in the CNS, where it usually takes the form of single or multiple brain abscesses. Nocardia infection generally occurs ≥1 month after transplantation and may follow immunosuppressive treatment for an episode of rejection. Pulmonary findings are nonspecific: localized disease with or without cavities is most common, but the disease may disseminate. The diagnosis is made by culture of the organism from sputum or from the involved nodule. As with Pneumocystis, prophylaxis with TMP-SMX is often efficacious in the prevention of disease. The occurrence of Nocardia infections >2 years after transplantation suggests that a long-term prophylactic regimen may be justified.

Toxoplasmosis can occur in seropositive patients but is less common than in other transplant settings, usually developing in the first few months after kidney transplantation. Again, TMP-SMX is helpful in prevention. In endemic areas, histoplasmosis, coccidioidomycosis, and blastomycosis may cause pulmonary infiltrates or disseminated disease.

Late Infections Late infections (>6 months after kidney transplantation) include CMV retinitis and a variety of CNS complications. Patients (particularly those whose immunosuppression has been increased) are at risk for subacute meningitis due to Cryptococcus neoformans. Cryptococcal disease may present in an insidious manner (sometimes as a skin infection before the development of clear CNS findings). Listeria meningitis may have an acute presentation and requires prompt therapy to avoid a fatal outcome.

Patients who continue to take glucocorticoids are predisposed to infection. “Transplant elbow” is a recurrent bacterial infection in and around the elbow that is thought to result from a combination of poor tensile strength of the skin of steroid-treated patients and steroid-induced proximal myopathy that requires patients to push themselves up with their elbows to get out of chairs. Bouts of cellulitis (usually caused by S. aureus) recur until patients are provided with elbow protection.

Kidney transplant recipients are susceptible to invasive fungal infections—such as those due to Aspergillus and Rhizopus, which may present as superficial lesions before dissemination. Mycobacterial infection (particularly that with Mycobacterium marinum) can be diagnosed by skin examination. Infection with Prototheca wickerhamii (an achlorophyllic alga) has been diagnosed by skin biopsy. Warts caused by human papillomaviruses (HPVs) are a late consequence of persistent immunosuppression; imiquimod or other forms of local therapy are usually satisfactory.

HEART TRANSPLANTATION ⊲ Early Infections Sternal wound infection and mediastinitis are early complications of heart transplantation. An in-dwelling catheter is common, with fever or a mildly elevated white blood cell count preceding the development of site tenderness or drainage. Clinical suspicion based on evidence of sternal instability and failure to heal may lead to the diagnosis. Although common microbial residents of the skin (e.g., S. aureus and Staphylococcus epidermidis) as well as gram-negative organisms (e.g., Pseudomonas aeruginosa) and fungi (e.g., Candida) are often involved, mediastinitis in heart transplant recipients (in rare cases) can also be due to Mycoplasma hominis (Chap. 159). Since this organism requires an anaerobic environment for growth and may be difficult to see on conventional medium, the laboratory should be alerted that M. hominis infection is suspected. M. hominis mediastinitis has been cured with a combination of surgical debridement (sometimes requiring muscle-flap placement) plus clindamycin and tetracycline. Organisms associated with mediastinitis may be cultured from accompanying pericardial fluid.

Middle-Period Infections T. gondii (Chap. 198) resident in the heart of a seropositive donor may be transmitted to a seronegative recipient. Thus serologic screening for T. gondii infection is important before and in the months after cardiac transplantation. Rarely, active disease can be introduced at the time of transplantation. The overall incidence of toxoplasmosis is so high in this setting that some prophylaxis is always warranted. Although alternatives are available, the most frequently used agent is TMP-SMX, which prevents infection with Pneumocystis as well as with Nocardia and other bacterial pathogens. CMV has also been transmitted by heart transplantation. CNS infections can be caused by Toxoplasma, Nocardia, and Aspergillus. L. monocytogenes meningitis should be considered in heart transplant recipients with fever and headache.

CMV infection is associated with poor outcomes after heart transplantation. The virus is usually cultivable 1 to 2 months after transplantation, causes early signs and laboratory abnormalities (usually fever and atypical lymphocytosis or leukopenia and thrombocytopenia) at 2 to 3 months, and produces severe disease (e.g., pneumonia) at 3 to 4 months. Seropositive recipients usually develop cultivable virus faster than patients whose primary CMV infection is a consequence of transplantation. Between 40 and 70% of patients develop symptomatic CMV disease in the form of (1) CMV pneumonia, the
most likely form of CMV disease to be fatal; (2) CMV esophagitis and gastritis, sometimes accompanied by abdominal pain with or without ulcerations and bleeding; and (3) the CMV syndrome, consisting of CMV in the blood along with fever, leukopenia, thrombocytopenia, and hepatic enzyme abnormalities. Ganciclovir is efficacious in the treatment of CMV infection; prophylaxis with ganciclovir or possibly with other antivirals, as described for renal transplantation, may reduce the incidence of CMV-related disease.

Late Infections

EBV infection usually presents as a lymphoma-like proliferation of B cells late after heart transplantation, particularly in patients maintained on heavy immunosuppression. A subset of heart and heart-lung transplant recipients may develop early (within 2 months) fulminant EBV-LPD. Treatment includes the reduction of immunosuppression if possible and the consideration of B cell antibodies (rituximab), immunomodulatory agents, or chemotherapy, as discussed earlier under bone marrow/hematopoietic stem cell transplantation. HHV-8-associated disease, including primary effusion lymphoma, has been reported in heart transplant recipients. Prophylaxis for Pneumocystis infection is required for these patients (see below).

LUNG TRANSPLANTATION Early Infections

It is not surprising that lung transplant recipients are predisposed to the development of pneumonia. The combination of ischemia and the resulting mucosal damage together with accompanying denervation and lack of lymph drainage probably contributes to the high rate of pneumonia (66% in one series). The prophylactic use of high doses of broad-spectrum antibiotics for the first 3 or 4 days after surgery decreases the incidence of pneumonia. Gram-negative pathogens (Enterobacteriaceae and Pseudomonas species) are troublesome in the first 2 weeks after surgery (the period of maximal vulnerability). Pneumonia can also be caused by Candida (possibly as a result of colonization of the donor lung), Aspergillus, and Cryptococcus.

Mediastinitis may occur at an even higher rate among lung transplant recipients than among heart transplant recipients and most commonly develops within 2 weeks of surgery. Pneumonisus due to CMV (which may be transmitted as a consequence of transplantation) usually presents between 2 weeks and 3 months after surgery, with primary disease occurring later than reactivation disease.

Middle-Period Infections

The development of postsurgical biliary stricture predisposes patients to cholangitis. These patients may lack the characteristic signs and symptoms of cholangitis: fever, abdominal pain, and jaundice. Alternatively, these findings may be present but may suggest graft rejection. The diagnosis of cholangitis in liver transplant recipients therefore requires documentation of bacteremia or demonstration of aggregated neutrophils in bile duct biopsy specimens. Unfortunately, invasive studies of the biliary tract (either T-tube cholangiography or endoscopic retrograde cholangiopancreatography) may themselves lead to cholangitis. For this reason, many clinicians recommend prophylaxis with antibiotics covering gram-negative organisms and anaerobes when these procedures are performed in liver transplant recipients.

Viral hepatitis is a common complication of liver transplantation (Chap. 285). Reactivation of hepatitis B and C infections, for which transplantation may be performed, is problematic. To prevent hepatitis B infection, high-dose intravenous hepatitis B immune globulin is administered. The long-term efficacy of lamivudine (3TC) and adefovir in inhibiting hepatitis B viral replication after transplantation is being studied. A combination of interferon α and ribavirin is being tested for treatment/prophylaxis of hepatitis C infection.

As in other transplantation settings, reactivation disease with herpes-group viruses is common (Table 117-3). Herpesviruses can be transmitted in donor organs. Although CMV hepatitis occurs in ~4% of liver transplant recipients, it is usually not so severe as to require retransplantation. CMV disease develops in the majority of seronegative recipients of organs from CMV-positive donors, but fatality rates are lower among liver transplant recipients than among lung or heart/lung transplant recipients. Disease due to CMV is associated with the vanishing bile duct syndrome after liver transplantation. Patients respond to treatment with ganciclovir; prophylaxis with CMV immune globulin and acyclovir or oral ganciclovir may modify disease.

LIVER TRANSPLANTATION Early Infections

As in other types of transplantation, early bacterial infections are a major problem after liver transplantation. Many centers administer systemic broad-spectrum antibiotics for the first 5 days after surgery, even in the absence of documented infection. However, despite prophylaxis, infectious complications are common and are correlated with the duration of the surgical procedure and the type of biliary drainage. An operation lasting >12 h is associated with an increased likelihood of infection. Patients who have a choledochojejunostomy with drainage of the biliary duct to a Roux-en-Y jejunal bowel loop have more fungal infections than those whose bile is drained via a choledochocholedochostomy with anastomosis of the donor common bile duct to the recipient common bile duct.

Peritonitis and intraabdominal abscesses are common complications of liver transplantation. Bacterial peritonitis may result from biliary leaks and primary or secondary infection after leakage of bile. Peritonitis in liver transplant recipients is often polymicrobial, commonly involving enterococci, aerobic gram-negative bacteria, staphylococci, anaerobes, or Candida. Only one-third of patients with intraabdominal abscesses have bacteremia. Abscesses within the first month after surgery may occur not only over the liver but also in the spleen, pericolic area, and pelvis. Treatment includes antibiotic administration and drainage as necessary.

Middle-Period Infections

The development of postsurgical biliary stricture predisposes patients to cholangitis. These patients may lack the characteristic signs and symptoms of cholangitis: fever, abdominal pain, and jaundice. Alternatively, these findings may be present but may suggest graft rejection. The diagnosis of cholangitis in liver transplant recipients therefore requires documentation of bacteremia or demonstration of aggregated neutrophils in bile duct biopsy specimens. Unfortunately, invasive studies of the biliary tract (either T-tube cholangiography or endoscopic retrograde cholangiopancreatography) may themselves lead to cholangitis. For this reason, many clinicians recommend prophylaxis with antibiotics covering gram-negative organisms and anaerobes when these procedures are performed in liver transplant recipients.
for HHV-6 in posttransplantation fever and leukopenia has been proposed. HHV-6 and HHV-7 appear to exacerbate CMV disease in this setting. EBV-LPD after liver transplantation shows a propensity for involvement of the liver, and such disease may be of donor origin.

**PANCREAS TRANSPLANTATION** Transplantation of the pancreas can be complicated by early abdominal infection. To prevent contamination of the allograft with enteric bacteria and yeasts, some surgeons, instead of draining the pancreas through the bowel, drain secretions into the urinary tract or bladder. A cuff of duodenum is used in the anastomosis between the pancreatic graft and either the bladder or the gut. In addition to bicarbonate loss, bladder drainage causes a high rate of urinary tract infection and sterile cystitis. Prophylactic antimicrobials are commonly used at the time of surgery. An alternative method—the transplacement of islet cells only—may eliminate the problems characteristically posed by wound and urinary tract sepsis in pancreas transplant recipients.

Issues related to the development of CMV infection, EBV-LPD, and infections with opportunistic pathogens in patients receiving a pancreas are similar to those in other solid organ transplant recipients.

**MISCELLANEOUS INFECTIONS IN SOLID ORGAN TRANSPLANTATION**

### Indwelling Intravenous Catheter Infections

The prolonged use of indwelling intravenous catheters for administration of medications, blood products, and nutrition is common in diverse transplantation settings and poses a risk of local and bloodstream infection. Significant insertion-site infection is most commonly caused by *S. aureus*. Bloodstream infection most frequently develops within a week of catheter placement or in patients who become neutropenic. Coagulase-negative staphylococci are the most common isolates from the blood. —*For further discussion of differential diagnosis and therapeutic options, see Chap. 72.*

### Tuberculosis

The incidence of tuberculosis occurring within 12 months after solid organ transplantation ranges broadly worldwide (0.35 to 15%), reflecting prevalences in local populations. Nonrenal transplantation, GVHD within 6 months, and intensity of immunosuppression are predictive of tuberculosis reactivation and development of disseminated disease in a host with latent disease. The use of antibodies to tumor necrosis factor is associated with the development of active tuberculosis. Tuberculosis has rarely been transmitted from the donor organ. In contrast to the low mortality in BMT/HSCT recipients, mortality in solid organ transplant patients is reported to be 29%. Isoniazid toxicity has not been a significant problem except in the liver transplant setting.

### Virus-Associated Malignancies

In addition to malignancy associated with gammaherpesvirus infection (EBV, HHV-8) and simple warts (HPV), other tumors that are virus-associated or suspected of being virus-associated are more likely to develop in transplant recipients, particularly those who require long-term immunosuppression, than in the general population. The interval to tumor development is usually >1 year. Transplant recipients develop nonmelanoma skin or lip cancers that, in contrast to de novo skin cancers, have a high ratio of squamous cells to basal cells. HPV appears to play a major role in these lesions. Cervical and vulvar carcinomas, quite clearly associated with HPV, develop with increased frequency in female transplant recipients. Among renal transplant recipients, rates of melanoma are modestly increased and rates of cancers of the kidney and bladder are increased.

### VACCINATION OF TRANSPLANT RECIPIENTS

In addition to receiving antibiotic prophylaxis, transplant recipients should be vaccinated against likely pathogens (Table 117-6). In the case of BMT recipients, optimal responses cannot be achieved until after immune reconstitution, despite previous immunization of both donor and recipient. Recipients of allogeneic BMTs must be reimmunized if they are to be protected against pathogens. The situation is less clear-cut in the case of autologous transplantation. T and B cells in the peripheral blood may reconstitute the immune response if they are transferred in adequate numbers. However, cancer patients (particularly those with Hodgkin’s disease, in whom vaccination has been extensively studied) who are undergoing chemotherapy do not respond normally to immunization, and titers of antibodies to infectious agents fall more rapidly than in healthy individuals. Therefore, even immunosuppressed patients who have not had marrow transplants may need booster vaccine injections. If memory cells are specifically eliminated as part of a marrow “cleanup” procedure, it will be necessary to reimmunize the recipient with a new primary series. Optimal times for immunizations of different transplant populations are being evaluated. Immunization of household and other contacts (including health care personnel) against influenza every season is likely to benefit the patient by preventing local spread.

In the absence of compelling data as to optimal timing, it is reasonable to administer the pneumococcal and *H. influenzae* type b conjugate vaccines to both autologous and allogeneic BMT recipients 12 months after transplantation and again 12 months later (since the response to the initial vaccine dose is weak in the early posttransplantation period). Recent studies indicate that the use of the pneumococcal conjugate vaccines will be more effective than previous products. The pneumococcal and *H. influenzae* type b vaccines are particularly important for patients who have undergone splenectomy. In addition, *Neisseria meningitidis* polysaccharide vaccine, diphtheria vaccine, tetanus vaccine, and inactivated polio vaccine can all be given at these same intervals (12 and 24 months after transplantation). Some authorities recommend a new primary series for tetanus/diphtheria and inactivated polio vaccine (vaccination 12, 14, and 16 months after transplantation). Because of the risk of spread, household contacts of BMT recipients (or of patients immunosuppressed as a result of chemotherapy) should receive only inactivated polio vaccine. Live-virus measles/mumps/rubella (MMR) vaccine can be given to autologous BMT recipients 24 months after transplantation and to most allogeneic BMT recipients at the same point if they are not receiving maintenance therapy with immunosuppressive drugs and do not have ongoing GVHD. The risk of spread from a household contact is lower for MMR vaccine than for polio vaccine. Neither patients nor household contacts of patients should be vaccinated with vaccinia unless they have been exposed to the smallpox virus. In patients who have active GVHD and/or are taking high maintenance doses of glucocorticoids, it may be prudent to avoid all live-virus vaccines. In the absence of detectable antibody titers, vaccination to prevent hepatitis B and hepatitis A also seems advisable.

</tbody>
</table>

* Studies indicate that it is possible to “immunize the graft” before transplantation.
In the case of solid organ transplant recipients, administration of all the usual vaccines and of the indicated booster doses should be completed before immunosuppression, if possible, to maximize responses. For patients taking immunosuppressive agents, the administration of pneumococcal vaccine should be repeated every 5 years. No data are available for meningococcal polysaccharide vaccine, but it is probably reasonable to administer it along with the pneumococcal vaccine or more frequently (every 3 years for persons with significant exposure risk). *H. influenzae* conjugate vaccine is safe and should be efficacious in this population; therefore, its administration before transplantation is recommended. Booster doses of this vaccine are not recommended for adults. Solid organ transplant recipients who continue to receive immunosuppressive drugs (glucocorticoids, cyclosporine) should not receive live-virus vaccines. A person in this group exposed to measles should be given immune globulin. Similarly, an immunocompromised patient who is seronegative for varicella and who comes into contact with a person who has chickenpox should be given varicella-zoster immune globulin as soon as possible (and certainly within 96 h) or, if this is not possible, should be started immediately on a 10- to 14-day course of acyclovir therapy. Susceptible household contacts of transplant recipients should receive live attenuated ZEV vaccine, but vaccinees should avoid direct contact with the patient if a rash develops.

Immunocompromised patients who travel may benefit from some but not all vaccines. In general, they should receive any killed or inactivated vaccine preparation appropriate to the area they are visiting; this recommendation includes the vaccines for Japanese encephalitis, hepatitis A and B, poliomyelitis, meningococcal infection, and typhoid. The live typhoid vaccines are not recommended for use in most immunocompromised patients, but inactivated typhoid or the purified polysaccharide vaccine can be used. Live yellow fever vaccine should not be administered. Phenol-inactivated cholera vaccine is probably of little use in this setting. On the other hand, immunization with the purified-protein hepatitis B vaccine is indicated if patients are likely to be exposed. Patients who will reside for >6 months in areas where hepatitis B is common (Africa, Southeast Asia, the Middle East, Eastern Europe, parts of South America, and the Caribbean) should receive hepatitis B vaccine. Inactivated hepatitis A vaccine should be used in the appropriate setting (Chap. 107). If hepatitis A vaccine is not administered, travelers should consider receiving passive protection with immune globulin (the dose depending on the duration of travel in the high-risk area).

**Section 4 Approach to Therapy for Bacterial Diseases**

The development of vaccines and drugs that prevent and cure bacterial infections was one of the twentieth century’s major contributions to human longevity and quality of life. Antibacterial agents are among the most commonly prescribed drugs of any kind worldwide. Used appropriately, these drugs are lifesaving. However, their indiscriminate use drives up the cost of health care, leads to a plethora of side effects and drug interactions; bacterial strategies for resistance; and bacterial susceptibility in vitro. In addition, patient-associated parameters, such as the site of infection and the immune and excretory status of the host, are critically important to appropriate therapeutic decisions. This chapter provides specific data required for making an informed choice of antibacterial agent.

**MECHANISMS OF ACTION**

Antibacterial agents, like all antimicrobial drugs, are directed against unique targets not present in mammalian cells. The goal is to limit toxicity to the host and maximize chemotherapeutic activity affecting invading microbes only. **Bactericidal drugs** kill the bacteria that are within their spectrum of activity; **bacteriostatic drugs** only inhibit bacterial growth. While bacteriostatic activity is adequate for the treatment of most infections, bactericidal activity may be necessary for cure in patients with altered immune systems (e.g., neutropenia), protected infectious foci (e.g., endocarditis or meningitis), or specific infections (e.g., complicated *Staphylococcus aureus* bacteremia). The mechanisms of action of the antibacterial agents to be discussed in this section are summarized in Table 118-1 and are depicted in Fig. 118-1.

**INHIBITION OF CELL-WALL SYNTHESIS**

One major difference between bacterial and mammalian cells is the presence in bacteria of a rigid cell wall external to the cell membrane. The wall protects bacterial cells from osmotic rupture, which would result from the cell’s usual marked hyperosmolarity (by up to 20 atm) relative to the host environment. The structure conferring cell-wall rigidity and resistance to osmotic lysis in both gram-positive and gram-negative bacteria is peptidoglycan, a large, covalently linked sacculus that surrounds the bacterium. In gram-positive bacteria, peptidoglycan is the only layered structure external to the cell membrane and is thick (20 to 80 nm); in gram-negative bacteria, there is an outer membrane external to a very thin (1-nm) peptidoglycan layer.

Chemotherapeutic agents directed at any stage of the synthesis, export, assembly, or cross-linking of peptidoglycan lead to inhibition of bacterial cell growth and, in most cases, to cell death. Peptidoglycan is composed of (1) a backbone of two alternating sugars, N-acetylglucosamine and N-acetylmuramic acid; (2) a chain of four amino acids that extends down from the backbone (stem peptides); and (3) a peptide bridge that cross-links the peptide chains. Peptidoglycan is formed by the addition of subunits (a sugar with its five attached amino acids) that are assembled in the cytoplasm and transported through the cytoplasmic membrane to the cell surface. Subsequent cross-linking is...

* Compounds in parentheses are major representatives for the class.

driven by cleavage of the terminal stem-peptide amino acid. Antibacterial agents act to inhibit cell-wall synthesis in several ways, as described below.

**Bacitracin**  Bacitracin, a cyclic peptide antibiotic, inhibits the conversion to its active form of the lipid carrier that moves the water-soluble cytoplasmic peptidoglycan subunits through the cell membrane to the cell exterior. Cell-wall subunits accumulate in the cytoplasm and cannot be added to the growing peptidoglycan chain.

**Glycopeptides**  Glycopeptides (vancomycin and teicoplanin) are high-molecular-weight antibiotics that bind to the terminal D-alanine–D-alanine component of the stem peptide while the subunits are external to the cell membrane but still linked to the lipid carrier. This binding sterically inhibits the addition of subunits to the peptidoglycan backbone.

**β-Lactam Antibiotics**  β-Lactam antibiotics (penicillins, cephalosporins, carbapenems, and monobactams; Table 118-2) are characterized by a four-membered β-lactam ring and prevent the cross-linking reaction called transpeptidation. The energy for attaching a peptide cross-bridge from the stem peptide of one peptidoglycan subunit to another is derived from the cleavage of a terminal D-alanine residue from the subunit stem peptide. The cross-bridge amino acid is then attached to the penultimate D-alanine by transpeptidase enzymes. The β-lactam ring of the antibiotic forms an irreversible covalent acyl bond with the transpeptidase enzyme (probably because of the antibiotic’s steric similarity to the enzyme’s D-alanine–D-alanine target), preventing the cross-linking reaction. Transpeptidases and similar enzymes involved in cross-linking are called penicillin-binding proteins (PBPs) because they all have active sites that bind β-lactam antibiotics.

Virtually all the antibiotics that inhibit bacterial cell-wall synthesis are bactericidal. That is, they eventually result in the cell’s death due to osmotic lysis. However, much of the loss of cell-wall integrity following treatment with cell-wall-active agents is due to the bacteria’s own cell-wall remodeling enzymes (autolysins) that cleave peptido-
INHIBITION OF PROTEIN SYNTHESIS

Most of the antibacterial agents that inhibit protein synthesis interact with the bacterial ribosome. The difference between the composition of bacterial and mammalian ribosomes gives these compounds their selectivity.

Aminoglycosides

Aminoglycosides (gentamicin, kanamycin, tobramycin, streptomycin, netilmicin, neomycin, and amikacin) are a group of structurally related compounds containing three linked hexose sugars. They exert a bactericidal effect by binding irreversibly to the 30S subunit of the bacterial ribosome and blocking initiation of protein synthesis. The reason for the lethal effect of aminoglycosides, as opposed to the largely bacteriostatic effect of other protein synthesis-inhibiting antibacterial drugs, is not completely understood. Uptake of aminoglycosides and their penetration through the cell membrane constitute an aerobic, energy-dependent process. Thus, aminoglycoside activity is markedly reduced in anaerobic environments. Spectinomycin, an aminocyclitol antibiotic, also acts on the 30S ribosomal subunit but has a different mechanism of action from the aminoglycosides and is bacteriostatic rather than bactericidal.

Macrolide Antibiotics

Macrolide antibiotics (erythromycin, clarithromycin, and azithromycin) consist of a large lactone ring to which sugars are attached. Ketolide antibiotics, including telithromycin, replace the cladinose sugar on the macrolactone ring with a ketone group. These drugs bind specifically to the 50S portion of the bacterial ribosome. After attachment of tRNA to the initiation site of the 30S ribosomal subunit (the process blocked by aminoglycosides), the 50S subunit becomes bound to the 30S component to form the 70S ribosomal complex.
plex, and protein chain elongation proceeds. When these drugs bind to the 50S ribosomal subunit, protein chain elongation is inhibited. Although structurally unrelated to the macrolides, *lincomamides* (clindamycin and lincomycin) bind to a site on the 50S ribosome nearly identical to the binding site for macrolides. Although the mechanism and site of action of macrolides and lincosamides are similar, the number and types of bacteria against which these two groups of agents are active differ.

**Streptogramins** Streptogramins [quinupristin (streptogramin B) and dalfopristin (streptogramin A)], which are supplied as a combination in Synercid, are peptide macrolactones that also bind to the 50S ribosome and block protein synthesis. Streptogramin B binds to a ribosomal site similar to the binding site for macrolides and lincosamides, whereas streptogramin A binds to a different ribosomal site, blocking the late phase of protein synthesis. The two streptogramins act synergistically to kill bacteria if the strain is susceptible to both components.

**Chloramphenical** Chloramphenicol consists of a single aromatic ring and a short side chain. This antibiotic binds reversibly to the 50S portion of the bacterial ribosome at a site close to but not identical with the binding sites for the macrolides and lincosamides. The ribosomal binding of chloramphenicol inhibits peptide bond formation.

**Linezolid** Linezolid is the first drug in a new, completely synthetic class of antimicrobial agents, the oxazolidinones. Linezolid binds to the 50S ribosomal subunit and blocks the initiation of protein synthesis.

**Tetracyclines** Tetracyclines (tetracycline, doxycycline, and minocycline) consist of four aromatic rings with various substituent groups. They interact reversibly with the bacterial 30S ribosomal subunit, blocking the binding of aminoacyl tRNA to the mRNA-ribosome complex. This mechanism is markedly different from that of the aminoglycosides, which also bind to the 30S subunit. The specificity of tetracyclines for bacteria depends both on their selectivity for bacterial ribosomes and on their requirement for active, energy-dependent transport into the bacterial cell by a system not found in mammalian cell membranes.

**Sulfonamides** Sulfonamides are structural analogues of p-aminobenzoic acid (PABA), one of the three structural components of folic acid (the other two being pteridine and glutamate). The first step in the synthesis of folic acid is the addition of PABA to pteridine by the enzyme dihydropteroic acid synthetase. Sulfonamides compete with PABA as substrates for the enzyme. The selective effect of sulfonamides is due to the fact that bacteria synthesize folic acid, while mammalian cells cannot and must have exogenous supplies. However, the activity of sulfonamides can be greatly reduced by the presence of excess PABA or by the exogenous addition of end products of one-carbon transfer reactions (e.g., thymidine and purines). High concentrations of the latter substances may be present in some infections as a result of tissue and white cell breakdown, compromising sulfonamide activity.

**Trimethoprim** Trimethoprim is a diaminopyrimidine, a structural analogue of the pteridine moiety of folic acid. Trimethoprim is a competitive inhibitor of dihydrofolate reductase; this enzyme is responsible for reduction of dihydrofolic acid to tetrahydrofolic acid—the essential final component in the folic acid synthesis pathway that is necessary for all one-carbon transfer reactions. Like the sulfonamides, trimethoprim is bactericidal in the absence of thymine but is only bacteriostatic when this pyrimidine is present in high concentration. The selective antibacterial activity of trimethoprim is based on the much (~50,000-fold) greater sensitivity of bacterial dihydrofolate reductase than of the mammalian enzyme to inhibition by this drug.

**INHIBITION OF NUCLEIC ACID SYNTHESIS OR ACTIVITY** Numerous antibacterial compounds have disparate effects on nucleic acids. The *quinolones*, including nalidixic acid and its fluorinated derivatives (ciprofloxacin, levofloxacin, gatifloxacin, and moxifloxacin), are synthetic compounds that inhibit the activity of the A subunit of the bacterial enzyme DNA gyrase as well as topoisomerase IV. DNA gyrase and topoisomerases are responsible for negative supercoiling of DNA—an essential conformation for DNA replication in the intact cell. Inhibition of the activity of DNA gyrase and topoisomerase IV is lethal to bacterial cells. The antibiotic *novobiocin* also interferes with the activity of DNA gyrase, but it interferes with the B subunit.
Rifampin  Rifampin, used primarily against *Mycobacterium tuberculosis*, is also active against a variety of other bacteria. Rifampin binds tightly to the B subunit of bacterial DNA-dependent RNA polymerase, thus inhibiting transcription of DNA into RNA. Mammalian-cell RNA polymerase is not sensitive to this compound.

Norfloxacin  Norfloxacin, a synthetic compound, causes DNA damage. The nitrofurans, compounds containing a single five-membered ring, are reduced by a bacterial enzyme to highly reactive, short-lived intermediates that are thought to cause DNA strand breakage, either directly or indirectly.

Metronidazole  Metronidazole, a synthetic imidazole, is active against a wide range of anaerobic bacteria and protozoa. Its activity is totally dependent on its anaerobic electron-transport system for energy production. In the presence of this system, the nitro group of metronidazole is reduced to a series of transiently produced, reactive intermediates that are thought to cause DNA damage. The unique re- dox system of anaerobes accounts for the selective antibacterial activity of metronidazole. This compound is also a mutagen and a radiosensitizer of hypoxic mammalian cells.

**MECHANISMS OF RESISTANCE**

Some bacteria exhibit intrinsic resistance to certain classes of antibacterial agents (e.g., obligate anaerobic bacteria to aminoglycosides and gram-negative bacteria to vancomycin). In addition, bacteria that are ordinarily susceptible to antibacterial agents can acquire resistance. Acquired resistance is one of the major limitations to effective antibacterial chemotherapy. Resistance can develop by mutation of existing genes, the acquisition of new genes encoding resistance, or by lateral transfer of resistance genes. Resistance is mediated by enzymes that destroy the antibiotic or inactivate it, thus preventing the drug from reaching its target.

**ALTERATION OF CELL-MEMBRANE PERMEABILITY**

The polypeptides (polymyxin B and colistin, or polymyxin E) are cyclic, basic polypeptides. They behave as cationic, surface-active compounds that disrupt the permeability of both the outer and the cytoplasmic membranes of gram-negative bacteria.

**Gramicidin A** is a polypeptide of 15 amino acids that acts as an ionophore, forming pores or channels in lipid bilayers.

**β-LACTAMS**  Bacteria develop resistance to β-lactam antibiotics by a variety of mechanisms. Most common is the destruction of the drug by β-lactamases. The β-lactamases of gram-negative bacteria are confined to the periplasm, between the inner and outer membranes, while gram-positive bacteria secrete their β-lactamases into the surrounding medium. These enzymes have a higher affinity for the antibiotic than the antibiotic has for its target. Binding results in hydrolysis of the β-lactam ring. Genes encoding β-lactamases have been found in both chromosomal and extrachromosomal locations and in both gram-positive and gram-negative bacteria; these genes are often on mobile genetic elements. Many “advanced-generation” β-lactam antibiotics, such as ceftriaxone and ceftazidime, are stable in the presence of plasmid-mediated β-lactamases and are active against bacteria resistant to earlier-generation β-lactam antibiotics. However, some β-lactamases either acquired by gram-negative bacteria (e.g., *Klebsiella pneumoniae* and *Escherichia coli*) on mobile genetic elements or present as stable chromosomal genes in other gram-negative species (e.g., *Enterobacter* spp.) have a broad substrate specificity, hydrolyzing virtually all penicillins and cephalosporins. One strategy that has been devised for circumventing resistance mediated by β-lactamases is to combine the β-lactam agent with an inhibitor that avidly binds the inactivating enzyme, preventing its attack on the antibiotic. Unfortunately, the inhibitors (e.g., clavulanic acid, sulbactam, and tazobactam) do not bind all chromosomal β-lactamases (e.g., *Enterobacter* chromosomal β-lactamase) and thus cannot be depended on to prevent the inactivation of β-lactam antibiotics by such enzymes. No β-lactam antibiotic or inhibitor has been produced that can resist all of the many β-lactamases that have been identified.

A second mechanism of bacterial resistance to β-lactam antibiotics is an alteration in PBP targets so that the PBPs have a markedly decreased affinity for the drug. While this alteration may occur by mutation of existing genes, the acquisition of new PBP genes (as in staphylococcal resistance to methicillin) or of new pieces of PBP genes (as in streptococcal, gonococcal, and meningococcal resistance to penicillin) is more important.

A final resistance mechanism is the coupling, in gram-negative bacteria, of a decrease in outer-membrane permeability with rapid efflux of the antibiotic from the periplasm to the cell exterior. Mutations of genes encoding outer-membrane protein channels called porins decrease the entry of β-lactam antibiotics into the cell, while additional proteins form channels that actively pump β-lactams out of the cell. Resistance of *Enterobacteriaceae* to some cephalosporins and resistance of *Pseudomonas* spp. to cephalosporins and uredopenicillins are the best examples of this mechanism.

**VANCOMYCIN**  Clinically important resistance to vancomycin was first described among enterococci in France in 1988. Vancomycin-resistant enterococci have subsequently become disseminated worldwide. The genes encoding resistance are carried on plasmids that can transfer from cell to cell and on transposons that can jump from plasmids to chromosomes. Resistance is mediated by enzymes that substitute D-lactate for D-alanine on the peptidoglycan stem peptide so that there is no longer an appropriate target for vancomycin binding. This alteration does not appear to affect cell-wall integrity, however. This type of acquired vancomycin resistance was confined for 14 years to enterococci—more specifically, to *Enterococcus faecalis* rather than the more common pathogen *E. faecalis*. However, in 2002, *S. aureus* isolates that were highly resistant to vancomycin were recovered from two patients in the United States. Both isolates contained the gene that mediated vancomycin resistance in enterococci. In addition, since 1996, a few isolates of both *S. aureus* and *S. epidermidis* that display a four- to eightfold reduction in susceptibility to vancomycin have been found worldwide, and many more isolates may contain subpopulations with reduced vancomycin susceptibility. These isolates have not acquired the genes that mediate vancomycin resistance in enterococci but are mutant bacteria with markedly thickened cell walls. These mutants were apparently selected in patients who were undergoing prolonged vancomycin therapy. The failure of vancomycin therapy in some patients infected with *S. aureus* or *S. epidermidis* strains exhibiting only intermediate susceptibility to this drug is thought to have been a result of this resistance.

**AMINOGLYCOSIDES**  The most common aminoglycoside resistance mechanism is inactivation of the antibiotic. Aminoglycoside-modifying enzymes, usually encoded on plasmids, transfer phosphate, adenyl, or acetyl residues from intracellular molecules to hydroxyl or amino side groups on the antibiotic. The modified antibiotic is less active because of diminished binding to its ribosomal target. Modifying enzymes that can inactivate any of the available aminoglycosides have been found in both gram-positive and gram-negative bacteria.

A second aminoglycoside resistance mechanism, which has been identified in clinical isolates of *Pseudomonas aerugi- nosa*, is decreased antibiotic uptake, presumably due to alterations in the bacterial outer membrane.

---

**118 Treatment, Prophylaxis of Bacterial Infections**
MACROLIDES, KETOLIDES, LINCOLSAMIDES, AND STREPTOPRAMINS Resistance in gram-positive bacteria, which are the usual target organisms for macrolides, lincosamides, and streptogramins, can be due to the production of an enzyme—most commonly plasmid-encoded—that methylates ribosomal RNA, interfering with binding of the antibiotics to their target. Methyltion mediates resistance to erythromycin, clari-thromycin, azithromycin, clindamycin, and streptogramin B. Resistance to streptogramin B converts quinupristin/dalfopristin from a bactericidal to a bacteriostatic antibiotic. Streptococci can also actively cause the efflux of macrolides, and staphylocci can cause the efflux of clindamycin and streptogramin A. In addition, staphylocci can inactivate streptogramin A by acetylation and streptogramin B by either acetylation or hydrolysis. Finally, mutations in 23S ribosomal RNA that alter macrolide binding to their targets have been found in both staphylo cocci and streptococci. Ketolides retain activity against most isolates of Streptococcus pneumoniae resistant to macrolides.

CHLORAMPHENICOL Most bacteria resistant to chloramphenicol produce a plasmid-encoded enzyme, chloramphenicol acetyltransferase, that inactivates the compound by acetylation.

TETRACYCLINES The most common mechanism of tetracycline resistance in gram-negative bacteria is a plasmid-encoded active-efflux pump that is inserted into the cytoplasmic membrane and extrudes antibiotic from the cell. Resistance in gram-positive bacteria is due either to active efflux or to ribosomal alterations that diminish binding of the antibiotic to its target. Genes involved in ribosomal protection are found on mobile genetic elements.

MUPIROCIN Although the topical compound mupirocin was introduced into clinical use relatively recently, resistance is already becoming widespread in some areas. The mechanism appears to be either mutation of the target isoleucine tRNA synthetase so that it is no longer inhibited by the antibiotic or plasmid-encoded production of a form of the target enzyme that binds mupirocin poorly.

TRIMETHOPRIM AND SULFONAMIDES The most prevalent mechanism of resistance to trimethoprim and the sulfonamides in both gram-positive and gram-negative bacteria is the acquisition of plasmid-encoded genes that produce a new, drug-insensitive target—specifically, an insensitive dihydrofolate reductase for trimethoprim and an altered dihydropteroate synthetase for sulfonamides.

QUINOLONES Resistance to the newer fluoroquinolones emerged rapidly among Staphylococcus and Pseudomonas spp. after the introduction of these agents. Widespread use of fluoroquinolones in the community has resulted in increasing rates of resistance in S. pneumoniae. The most common mechanism is the development of one or more mutations in target DNA gyrase and topoisomerase IV that prevent the antibacterial agent from interfering with the activity of the enzyme. Some gram-negative bacteria develop mutations that both decrease outer-membrane porin permeability and cause active drug efflux from the cytoplasm. Mutations that result in active quinolone efflux are also found in gram-positive bacteria.

RIFAMPIN Bacteria rapidly become resistant to rifampin by developing mutations in the B subunit of RNA polymerase that render the enzyme unable to bind the antibiotic. The rapid selection of resistant mutants is the major limitation to the use of this antibiotic against otherwise-susceptible staphylococci and requires that the drug be used in combination with another antibacterial agent.

LINEZOLID Enterococci, streptococci, and staphylococci become resistant to linezolid in vitro by mutation of the 23S rRNA binding site. Clinical isolates of E. faecium and E. faecalis acquire resistance to linezolid readily by this mechanism, often during therapy, but linezolid-resistant staphyloccocal and streptococcal isolates are rare.

MULTIPLE ANTIBIOTIC RESISTANCE The acquisition by one bacterium of resistance to multiple antibacterial agents is becoming increasingly common. The two major mechanisms are the acquisition of multiple unrelated resistance genes and the development of mutations in a single gene or gene complex that mediate resistance to a series of unrelated compounds. The construction of multiresistant strains by acquisition of multiple genes occurs by sequential steps of gene transfer and environmental selection in areas of high-level antimicrobial use. In contrast, mutations in a single gene can conceivably be selected in a single step. Bacteria that are multiresistant by virtue of the acquisition of new genes include hospital-associated gram-negative bacteria, enterococci, and staphylocci and community-acquired strains of salmonellae, gonococci, and pneumococci. Mutations that confer resistance to multiple unrelated antimicrobial agents occur in the genes encoding outer-membrane porins and efflux proteins of gram-negative bacteria. These mutations increase bacterial intracellular and periplasmic accumulation of β-lactams, quinolones, tetracyclines, chloramphenicol, and aminoglycosides. Multiresistant bacterial isolates pose increasing problems in U.S. hospitals; strains resistant to all available antibacterial chemotherapy have already been identified.

PHARMACOKINETICS OF ANTIBIOTICS The pharmacokinetic profile of an antibacterial agent refers to concentrations in serum and tissue versus time and reflects the processes of absorption, distribution, metabolism, and excretion. Important characteristics include peak and trough serum concentrations and mathematically derived parameters such as half-life, clearance, and distribution volume. Pharmacokinetic information is useful for estimating the appropriate antibacterial dose and frequency of administration, for adjusting dosages in patients with impaired excretory capacity, and for comparing one drug with another. In contrast, the pharmacodynamic profile of an antibiotic refers to the relationship between serum and tissue concentrations of the antibiotic and its minimal inhibitory concentrations (MICs) for bacteria. For further discussion of basic pharmacokinetic principles, see Chap. 3.

ABSORPTION Antibiotic absorption refers to the rate and extent of a drug’s systemic bioavailability after oral, intramuscular, or intravenous administration.

Oral Administration Most patients with infection are treated with oral antibacterial agents in the outpatient setting. Advantages of oral therapy over parenteral therapy include lower cost, generally fewer adverse effects (including complications of indwelling lines), and greater acceptance by patients. The percentage of an orally administered antibacterial agent that is absorbed (i.e., its bioavailability) ranges from as little as 10 to 20% (erythromycin and penicillin G) to nearly 100% [amoxicillin, clindamycin, metronidazole, doxycycline, trimethoprim-sulfamethoxazole (TMP-SMX), linezolid, and most fluoroquinolones]. These differences in bioavailability are not clinically important as long as drug concentrations at the site of infection are sufficient to inhibit or kill the pathogen. However, therapeutic efficacy may be compromised when absorption is reduced as a result of physiologic or pathologic conditions (such as the presence of food for some drugs or the shunting of blood away from the gastrointestinal tract in patients with hypotension), drug interactions (such as that of quinolones and metal cations), or noncompliance. The oral route is usually used for patients with relatively mild infections in whom absorption is not thought to be compromised by the preceding conditions. In addition, the oral route can often be used in more severely ill patients after they have responded to parenteral therapy (“switch” therapy).

Intramuscular Administration Although the intramuscular route of administration usually results in 100% bioavailability, it is not as widely used in the United States as the oral and intravenous routes, in part because of the pain often associated with intramuscular injections and the relative ease of intravenous access in the hospitalized patient. Intramuscular injection may be suitable for specific indications requiring an “immediate” and reliable effect (e.g., with long-acting forms of penicillin, including benzathine and procaine, and with single doses of ceftriaxone for acute otitis media or uncomplicated gonococcal infection).

Part VI Infectious Diseases
Intravenous Administration  The intravenous route is appropriate when oral antibacterial agents are not effective against a particular pathogen, when bioavailability is uncertain, or when larger doses are required than are feasible with the oral route. After intravenous administration, bioavailability is 100%; serum concentrations are maximal at the end of the infusion. For many patients in whom long-term antimicrobial therapy is required and oral therapy is not feasible, outpatient parenteral antibiotic therapy, including the use of convenient portable pumps, may be cost-effective and safe. Alternatively, some oral antibacterial drugs (e.g., fluoroquinolones) are sufficiently active against Enterobacteriaceae to provide potency equal to that of parenteral therapy; their use may allow the patient to return home from the hospital earlier or to avoid hospitalization entirely.

DISTRIBUTION To be effective, an antibacterial agent must exceed the pathogen’s MIC. Serum concentrations usually exceed the MIC for susceptible bacteria, but since most infections are extravascular, the antibiotic must also distribute to the site of the infection. Concentrations of most antibacterial agents in interstitial fluid are similar to free-drug concentrations in serum. However, when the infection is located in a “protected” site where penetration is poor, such as cerebrospinal fluid (CSF), the eye, the prostate, or infected cardiac vegetation, higher parenteral doses or local administration for prolonged periods may be required for cure. In addition, even though an antibacterial agent may penetrate to the site of infection, its activity may be antagonized by factors in the local environment, such as an unfavorable pH or inactivation by cellular degradation products. For example, since the activity of aminoglycosides is reduced at acidic pH, the acidic environment in many infected tissues may be partly responsible for the relatively poor efficacy of aminoglycoside monotherapy. In addition, the abscess milieu reduces the penetration and local activity of many antibacterial compounds, so that surgical drainage may be required for cure.

Most bacteria that cause human infections are located extracellularly. Intracellular pathogens such as Legionella, Chlamydia, Brucella, and Salmonella may persist or cause relapse if the antibacterial agent does not enter the cell. In general, β-lactams, vancomycin, and aminoglycosides penetrate cells poorly, whereas macrolides, ketolides, tetracyclines, metronidazole, chloramphenicol, rifampin, TMP-SMX, and quinolones penetrate cells well.

METABOLISM AND ELIMINATION Like other drugs, antibacterial agents are disposed of by hepatic elimination (metabolism or biliary elimination), by renal excretion of the unchanged or metabolized form, or by a combination of the two processes. For most antibacterial drugs, metabolism leads to loss of in vitro activity, although some agents, such as cefotaxime, rifampin, rifabutin, and clarithromycin, have bioactive metabolites that may contribute to their overall efficacy.

The most practical application of knowing the mode of excretion of an antibacterial agent is adjustment of the dosage when elimination capability is impaired (Table 118-3). Direct, nonidiosyncratic toxicity from antibacterial drugs may result from failure to reduce the dosage in a patient with impaired elimination. For agents that are primarily cleared intact by glomerular filtration, drug clearance is linearly correlated with creatinine clearance. Unfortunately, for drugs whose elimination is primarily hepatic, no simple marker (such as serum creatinine) is useful for dosage adjustment in patients with liver disease. Even in patients with severe hepatic disease, residual metabolic capability is usually sufficient to preclude accumulation and toxic effects.

PRINCIPLES OF ANTIBACTERIAL CHEMOTHERAPY

The choice of an antibacterial compound for a particular patient and a specific infection involves more than just a knowledge of the agent’s pharmacokinetic profile and in vitro activity. The basic tenets of chemotherapy, to be elaborated below, include the following: When appropriate, material containing the infecting organism(s) should be obtained before the start of treatment so that presumptive identification can be made by microscopic examination of stained specimens and the organism can be grown for definitive identification and susceptibility testing. Awareness of local susceptibility patterns is useful when the patient is treated empirically. Once the organism is identified and its susceptibility to antibacterial agents is determined, the regimen with the narrowest effective spectrum should be chosen. The choice of antibacterial agent is guided by the pharmacokinetic and adverse-reaction profile of active compounds, the site of infection, the immune status of the host, and evidence of efficacy from well-performed clinical trials. If all other factors are equal, the least expensive antibacterial regimen should be chosen.

**SUSCEPTIBILITY OF BACTERIA TO ANTIBACTERIAL DRUGS IN VITRO** Determination of the susceptibility of the patient’s infecting organism to a panel of appropriate antibacterial agents is an essential first step in devising a chemotherapeutic regimen. Standard susceptibility testing is designed to estimate the susceptibility of a bacterial isolate to an antibacterial drug under standardized conditions. These conditions favor rapidly growing aerobic or facultative organisms and assess bacteriostasis only. Specialized testing is required for the assessment of bactericidal antimicrobial activity; for the detection of resistance among such fastidious organisms as obligate anaerobes, Haemophilus spp., and pneumococci; and for the determination of resistance phenotypes with variable expression, such as resistance to mexitilin or oxacillin among staphylococci. Antimicrobial susceptibility testing is important when susceptibility is unpredictable, most often as a result of increasing acquired resistance among hospitalized patients.

**PHARMACODYNAMICS: RELATIONSHIP OF PHARMACOKINETICS AND IN VITRO SUSCEPTIBILITY TO CLINICAL RESPONSE** Bacteria are often considered to be susceptible to a drug if the achievable peak serum concentration exceeds the MIC by approximately fourfold. The breakpoint is the concentration of the antibiotic that separates susceptible from resistant bacteria (Fig. 118-2). When a majority of the isolates of a given bacterial species are inhibited at concentrations below the breakpoint, the species is considered to be within the spectrum of the antibiotic (see “Choice of Antibacterial Therapy,” below).

The pharmacodynamic profile of an antibiotic refers to the quantitative relationships between the time course of antibiotic concentrations in serum and tissue, in vitro susceptibility, and microbial response (inhibition of growth or rate of killing). Three pharmacodynamic parameters quantify these relationships: the ratio of the area...

under the curve for the plasma concentration vs. time curve to MIC (AUC/MIC), the ratio of the maximal serum concentration to the MIC (Cmax/MIC), and the time during a dosing interval that plasma concentrations exceed the MIC (t > MIC). The pharmacodynamic profile of an antibiotic class is characterized as either concentration dependent (fluoroquinolones, aminoglycosides), such that the increase in antibiotic concentration leads to a more rapid rate of bacterial death, or time dependent (β-lactams), such that the reduction in bacterial density is proportional to the time that concentrations exceed the MIC. For concentration-dependent antibiotics, the Cmax/MIC or AUC/MIC ratio correlates best with the reduction in microbial density in vitro and in animal investigations. Dosing strategies attempt to maximize these ratios by the administration of a large dose relative to the MIC for anticipated pathogens, often at long intervals (relative to the serum half-life). Once-daily dosing of aminoglycoside antibiotics is the most practical consequence of these relationships. In contrast, dosage strategies for time-dependent antibiotics emphasize the administration of doses sufficient to maintain serum concentrations above the MIC for a critical portion of the dose interval. Response to β-lactam antibiotics, measured as the decline in bacterial density at the site of infection, appears to be maximal when serum and tissue concentrations are maintained above the MIC for 30 to 50% of the dose interval. For example, the use of high-dose amoxicillin (90 to 100 mg/kg per day) in the treatment of acute otitis media increases not only the penetration of amoxicillin into the inner ear but also the duration of time that concentrations exceed the MIC for pneumococci. This approach provides effective therapy in most patients, including those whose pneumococcal isolates are penicillin resistant. The clinical implications of these pharmacodynamic relationships are in the early stages of investigation; their elucidation should eventually result in more rational antibacterial dosage regimens. Table 118-4 summarizes the pharmacodynamic properties of the major antibiotic classes.

**STATUS OF THE HOST** Various host factors must be considered in the devising of antibacterial chemotherapy. The host’s antibacterial immune function is of importance, particularly as it relates to opsonophagocytic function. Since the major host defense against acute, overwhelming bacterial infection is the polymorphonuclear leukocyte, patients with neutropenia must be treated aggressively and empirically with bactericidal drugs for suspected infection (Chap. 72). Likewise, patients who have deficient humoral immunity (e.g., those with chronic lymphocytic leukemia and multiple myeloma) and individuals with surgical or functional asplenia (e.g., those with sickle cell disease) should be treated empirically for infections with encapsulated organisms, especially the pneumococcus.

**Pregnancy** increases the risk of toxicity of certain antibacterial drugs for the mother (e.g., hepatic toxicity of tetracycline), affects drug disposition and pharmacokinetics, and—because of the risk of fetal toxicity—severely limits the choice of agents for treating infections. Certain antibacterial agents are contraindicated in pregnancy either because their safety has not been established or because they are known to be toxic. These agents include all fluoroquinolones, clarithromycin, erythromycin estolate (but not erythromycin base), and tetracyclines (Table 118-5). Data on the safety of many other antibacterial drugs are limited, but these drugs may be used cautiously when there is no suitable alternative and the perceived benefit outweighs the risk. These agents include the aminoglycosides, azithromycin, clindamycin, imipenem, metronidazole, trimethoprim, and vancomycin. Nitrofurantoin and the sulfonamides are contraindicated in the third trimester but can be used cautiously in the first two trimesters.

In patients with concomitant viral infections, the incidence of adverse reactions to antibacterial drugs may be unusually high. For example, persons with infectious mononucleosis and those infected with HIV react more often to ampicillin and folic acid synthesis inhibitors, respectively.

In addition, the patient’s age, sex, racial heritage, genetic background, and excretory status all determine the incidence and type of side effects that can be expected with certain antibacterial agents.

**SITE OF INFECTION** The location of the infected site may play a major role in the choice and dose of antimicrobial drug. Patients with suspected meningitis should receive drugs that can cross the blood-CSF barrier; in addition, because of the relative paucity of phagocytes and opsonins at the site of infection, the agents should be bactericidal. Chloramphenicol, an older drug but occasionally useful in the treatment of meningitis, is bactericidal for common organisms causing meningitis (i.e., meningococci, pneumococci, and Haemophilus influenzae, but not enteric gram-negative bacilli), is highly lipid-soluble, and enters the CSF well. However, β-lactam drugs, the mainstay of therapy for most of these infections, do not normally reach high levels in CSF. Their efficacy is based on the increased permeability of the blood-brain and blood-CSF barriers to hydrophilic molecules during inflammation and the extreme susceptibility of most infectious organisms to even small amounts of β-lactam drug.

The vegetation, which is the major site of infection in bacterial endocarditis, is also a focus that is protected from normal host-defense mechanisms. Antibacterial therapy needs to be bactericidal, with the selected agent administered parenterally over a long period and at a dose that produces serum levels at least eight times higher than the minimal bactericidal concentration (MBC) for the infecting organism. Likewise, osteomyelitis involves a site that is somewhat resistant to opsonophagocytic removal of infecting bacteria; furthermore, avascular bone (sequestrum) represents a foreign body that thwarts normal host-defense mechanisms. Chronic prostatitis is exceedingly difficult to cure because most antibiotics do not penetrate through the capillaries serving the prostate, especially when acute inflammation is absent. Intraocular infections, especially endophthalmitis, are difficult to treat because retinal capillaries lacking fenestration hinder drug penetration into the vitreous from blood. Inflammation does little to disrupt this barrier. Thus, direct injection into the vitreous is necessary in many cases. Antibiotic penetration into abscesses is usually poor, and local conditions (e.g., low pH or the presence of enzymes that hydrolyze the drug) may further antagonize antibacterial activity.

| TABLE 118-4 Pharmacodynamic Parameters of Major Antimicrobial Classes |
|------------------------|-----------------|
| Parameter Predicting Response | Drug or Drug Class |
| Time above the MIC | Penicillins, cephalosporins, carbapenems, aztreonam |
| 24-h AUC/MIC | Aminoglycosides, fluoroquinolones, tetracyclines, vancomycin, macrolides, clindamycin, quinupristin/dalfopristin |
| Peak to MIC | Aminoglycosides, fluoroquinolones |

*Abbreviations*: MIC, minimal inhibitory concentration; AUC, area under the concentration curve.
In contrast, urinary tract infections, when confined to the bladder, are relatively easy to cure, in part because of the higher concentration of most antibiotics in urine than in blood. Since blood is the usual reference fluid in defining susceptibility (Fig. 118-2), even organisms found to be resistant to achievable serum concentrations may be susceptible to achievable urine concentrations. For drugs that are used only for the treatment of urinary tract infections, such as nitrofurantoin and methenamine salts, achievable urine concentrations are used to determine susceptibility.

COMBINATION CHEMOTHERAPY One of the tenets of antibacterial chemotherapy is that if the infecting bacterium has been identified, the most specific chemotherapy possible should be used. The use of a single agent with a narrow spectrum of activity against the pathogen diminishes the alteration of normal flora and thus limits the overgrowth of resistant nosocomial organisms (e.g., Candida albicans, enterococci, Clostridium difficile, or methicillin-resistant staphylococci), avoids the potential toxicity of multiple-drug regimens, and reduces cost. However, certain circumstances call for the use of more than one antibacterial agent. These are summarized below.

1. Prevention of the emergence of resistant mutants. Spontaneous mutations occur at a detectable frequency in certain genes encoding the target proteins for some antibacterial agents. The use of these agents can eliminate the susceptible population, select out resistant mutants at the site of infection, and result in the failure of chemotherapy. Resistant mutants are usually selected when the MIC of the antibacterial agent for the infecting bacterium is close to achievable levels in serum or tissues and/or when the site of infection limits the access or activity of the agent. Among the most common examples are rifampin for staphylococci, imipenem for Pseudomonas, and fluoroquinolones for staphylococci and Pseudomonas. Small-colony variants of staphylococci resistant to aminoglycosides also emerge during monotherapy with these antibiotics. A second antibacterial agent with a mechanism of action different from that of the first is added to prevent the emergence of these resistant mutants (e.g., imipenem plus an aminoglycoside for systemic Pseudomonas infections). However, since resistant mutants have emerged following combination chemotherapy, this approach clearly is not uniformly successful.

2. Synergistic or additive activity. Synergistic or additive activity involves a lowering of the MIC or MBC of each or all of the drugs tested in combination against a specific bacterium. In synergy, each agent is more active when combined with a second drug than it would be alone, and the drugs’ combined activity is therefore greater than the sum of the individual activities of each drug. In an additive relationship, the combined activity of the drugs is equal to the sum of their individual activities. Among the best examples of a synergistic or additive effect, confirmed both in vitro and by animal studies, are the enhanced bactericidal activities of certain β-lactam/aminoglycoside combinations against enterococci, viridans streptococci, and P. aeruginosa. The synergistic or additive activity of these combinations has also been demonstrated against selected isolates of enteric gram-negative bacteria and staphylococci. The combination of trimethoprim and sulfamethoxazole has synergistic or additive activity against many enteric gram-negative bacteria. Most other antibacterial combinations display indifferent activity (i.e., the combination is no better than the more active of the two agents alone), and some combinations (e.g., penicillin plus tetracycline against pneumococci) may be antagonistic (i.e., the combination is worse than either drug alone).

3. Therapy directed against multiple potential pathogens. For certain infections, either a mixture of pathogens is suspected or the patient is desperately ill with an as-yet-unidentified infection (see “Empirical Therapy,” below). In these situations, the most important of the likely infecting bacteria must be covered by therapy until culture and susceptibility results become available. Examples of the former infections are intraabdominal or brain abscesses and infections of limbs in diabetic patients with microvascular disease. The latter situations include fevers in neutropenic patients, acute pneumonia from aspiration of oral flora by hospitalized patients, and septic shock or sepsis syndrome.

EMPIRICAL THERAPY In many situations, antibacterial therapy is begun before a specific bacterial pathogen has been identified. The choice of agent is guided by the results of studies identifying the usual pathogens at that site or in that clinical setting, by pharmacodynamic considerations, and by the resistance profile of the expected pathogens in a particular hospital or geographic area. Situations in which empirical therapy is appropriate include the following:

1. Life-threatening infection. Any suspected bacterial infection in a patient with a life-threatening illness should be treated presumptively. Therapy is usually begun with more than one agent and is later tailored to a specific pathogen if one is eventually identified.

2. Treatment of community-acquired infections. In many situations, it is appropriate to treat non-life-threatening infections without obtaining cultures. These situations include outpatient infections such as community-acquired upper and lower respiratory tract infections, cystitis, cellulitis or local wound infection, urethritis, and prostatitis. However, if any of these infections recurs or fails to respond to initial therapy, every effort should be made to obtain cultures to guide retreatment.

CHOICE OF ANTIBACTERIAL THERAPY

The antibacterial spectrum of specific agents and the infections for which they represent the treatment of choice are detailed below. No attempt has been made to include all the potential situations in which antibacterial agents may be used. A more detailed discussion of specific bacteria and infections that they cause can be found elsewhere in this volume.

**β-LACTAMS** (Table 118-2) All penicillins (except for the semisynthetic, penicillinase-resistant antistaphylococcal agents) are hydrolyzed by β-lactamases and are ineffective against isolates that produce these enzymes. Penicillin G has a spectrum that includes spirochetes and G6PD, glucose-6-phosphate dehydrogenase.

* Use only for strong clinical indication in the absence of a suitable alternative.

a G6PD, glucose-6-phosphate dehydrogenase.

Prevotella coccemia, viridans streptococcal endocarditis, clostridial myonecrosis, and periodontal infections, meningococcal meningitis and meningo-coccemia, viridans streptococcal endocarditis, clostridial myonecrosis, tetanus, anthrax, rat-bite fever, *P. multocida* infections, and erysipelas (*E. rhusiopathiae*).

Ampicillin extends the spectrum of penicillin G to some gram-negative rods. It is active against some isolates of *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, *Shigella*, and *H. influenzae* and is one of the drugs of choice for susceptible organisms causing salmonellosis, acute otitis media, *H. influenzae* meningitis and epiglottitis, and *Listeria monocytogenes* meningitis. *E. faecalis* is usually susceptible, and amoxicillin is the drug of choice for urinary tract infections caused by this organism. High rates of resistance have lessened the value of ampicillin and amoxicillin as empirical therapy in some situations. For example, >80% of isolates of *E. coli* and *P. mirabilis* are resistant in many hospitals, as are ~30% of isolates of *H. influenzae*; moreover, in some outbreaks of infection due to salmonellae, all isolates are resistant to ampicillin.

The penicillinase-resistant penicillins are used solely for the treatment of staphylococcal infections and are the drugs of choice for systemic or deep staphylococcal infections caused by susceptible organisms. Unfortunately, on average, ~40% of *S. aureus* isolates and >70% of coagulase-negative staphylococcal isolates acquired in U.S. hospitals are resistant to these agents (i.e., methicillin-resistant). The spectrum of these agents also includes most of the same gram-positive bacteria that are susceptible to penicillin G.

The spectrum of the antipseudomonal penicillins includes the bacteria covered by ampicillin as well as some nonpseudomonal enteric gram-negative bacilli. For example, piperacillin is active against many indole-positive *Proteus*, *Enterobacter*, *Klebsiella*, *Providencia*, and *Serratia* spp. However, the susceptibility of these penicillins to *β*-lactamase markedly limits their utility as empirical therapy when infections caused by gram-negative enteric organisms are suspected. The “antipseudomonal penicillins” are no longer commercially available or have been formulated in combination with *β*-lactamase inhibitors.

The addition of a *β*-lactamase inhibitor (clavulanic acid, sulbactam, or tazobactam) to ampicillin, amoxicillin, ticarcillin, or piperacillin extends the spectrum of the *β*-lactam agent to include many organisms that are resistant by virtue of *β*-lactamase production. These organisms include many strains of *E. coli*, *Klebsiella* spp., *Salmonella* spp., *P. mirabilis*, *Listeria monocytogenes*, *Moraxella catarrhalis*, *Providencia* spp., and anaerobes (including *Bacteroides* spp.). Such combinations are also active against staphylococci that produce *β*-lactamase but are not resistant to methicillin. However, the efficacy of these combinations in serious staphylococcal infections has not been adequately proven. Furthermore, *Serratia*, indole-positive *Proteus*, *Citrobacter*, *Enterobacter*, *Providencia*, *Acinetobacter*, and various enteric gram-negative isolates either produce chromosomal *β*-lactamases that are not inhibited by these compounds or develop resistance attributable to non-*β*-lactamase-mediated mechanisms.

The first-generation cephalosporins have a spectrum that includes penicillinase-producing, methicillin-susceptible staphylococci and pseudomonas. *Streptococcus pneumoniae*, *E. coli*, *Klebsiella*, and *Proteus* spp. When these drugs may be used when infections with gram-positive bacteria are suspected, they are not the drugs of choice for such infections. They have excellent activity against many isolates of *E. coli*, *Klebsiella pneumoniae*, and *P. mirabilis* and are among the drugs of choice in presumptive therapy for community-acquired urinary tract infections. They have no activity against *Bacteroides fragilis*, enterococci, methicillin-resistant staphylococci, *Pseudomonas*, *Acinetobacter*, *Enterobacter*, indole-positive *Proteus*, and *Serratia* and only poor activity against *H. influenzae*.

The parenteral second-generation cephalosporins extend the gram-negative spectrum of first-generation compounds. The various second-generation agents have differing activities. Cefuroxime retains activity against gram-positive cocci and is also active against *H. influenzae*, *Neisseria*, and indole-positive *Proteus* but exhibits poor activity against *B. fragilis*. Cefoxitin and cefotetan have reasonably good activity against *B. fragilis*, but cefotetan is less effective against some other *Bacteroides* spp. (e.g., *B. thetaiotaomicron*). Both of the latter drugs display poor activity against gram-positive cocci and *Enterobacter*. No second-generation cephalosporin is active against *Pseudomonas* or *Acinetobacter*.

Oral second- and third-generation cephalosporins have fair activity against gram-positive cocci and *H. influenzae* and are widely used in outpatient therapy for otitis media, sinusitis, and lower respiratory tract infections, although cheaper agents that are equally effective are preferable. Cefditoren, cefdinir, and cefpodoxime have good activity against most respiratory pathogens and methicillin-susceptible *S. aureus*.

Third-generation parenteral cephalosporins all have a broad spectrum of activity against enteric gram-negative rods and are especially useful for treating hospital-acquired infections caused by multiresistant organisms. In addition, ceftriaxone and cefepime have good antipseudomonal activity; the other drugs have poor activity. Since resistance to third-generation cephalosporins is increasing among all nosocomial gram-negative rods, the use of these agents should be guided by susceptibility testing. The gram-positive spectrum of the third-generation cephalosporins is variable. All are less active than first-generation cephalosporins against methicillin-susceptible staphylococci; ceftriaxone and cefotaxime have excellent activity against streptococci, especially *S. pneumoniae*. Cefazidime is not recommended for treatment of streptococcal infections.

Ceftriaxone has an excellent gram-negative spectrum; is active against *Haemophilus*, most *S. pneumoniae* strains, and penicillin-resistant *Neisseria*; has a long serum half-life; and reaches high serum and CSF levels (with inflammation). Thus it has become one of the drugs of choice for empirical therapy for bacterial meningitis (except that caused by *Listeria* and by highly penicillin-resistant pneumococcal strains), all gonococcal infections, salmonellosis, and typhoid fever. The third-generation cephalosporins are among the drugs of choice for nosocomial hospital-acquired pneumonia. Cefepime is more resistant to chromosomal *β*-lactamase produced by *Enterobacter* spp. than are other third-generation cephalosporins and is more active against methicillin-susceptible *S. aureus*. Third-generation cephalosporins have poor activity against *Bacteroides* and no activity against methicillin-resistant staphylococci, *Enterococcus*, *Acinetobacter*, or *Stenotrophomonas*.

The *carbapenems* currently available in the United States are imipenem, meropenem, and ertapenem. Imipenem is marketed in combination with the renal dipeptidase inhibitor cilastatin, which enables imipenem to escape renal inactivation and thus to reach higher urinary levels. Imipenem and meropenem have excellent activity in vitro against virtually all bacterial pathogens except *Stenotrophomonas*, methicillin-resistant staphylococci, and *E. faecium*. Imipenem has dose-related central nervous system side effects that are less frequent with meropenem. Resistance to imipenem and meropenem is a problem among nosocomial isolates of *P. aeruginosa*, ~20% of which are resistant. Ertapenem has poor activity against enterococci, *P. aerugi-nosa*, and *Acinetobacter* but exhibits activity similar to that of meropenem against streptococci. Because of their broad spectrum, imipenem and meropenem can be used as empirical therapy for serious nosocomial infections thought to be caused by multiple bacterial spe-
cies or multiresistant organisms. Imipenem and meropenem are often used to treat hospital-acquired infections caused by Enterobacter spp. because these organisms produce inducible β-lactamas that inactivate third-generation cephalosporins but not the carbapenems. The latter antibiotics are often held in reserve as therapy for nosocomial infections due to gram-negative pathogens that are resistant to third-generation cephalosporins.

The only monobactam currently available is aztreonam. This antibiotic has a spectrum limited to gram-negative enteric bacilli. It has no activity against any gram-positive or anaerobic bacterium. Its gram-negative spectrum is similar to that of cefazidime, with equally good activity against many tobramycin-resistant pseudomonas. Aztreonam’s primary advantages are its theoretical ability to preserve the normal gram-positive and anaerobic flora and the lack of cross-reactive immediate hypersensitivity in patients who have had this type of reaction to other β-lactam antibiotics.

VANCYMYCIN The spectrum of vancomycin is limited to gram-positive cocci, especially enterococci, streptococci, and staphylococci. Vancomycin serves as second-line therapy for most gram-positive bacterial infections but is the drug of choice for infections caused by methicillin-resistant staphylococci or Corynebacterium jeikeium and for serious infections in penicillin-allergic patients. Given orally (a route by which it is not absorbed), vancomycin can be used to treat antibiotic-associated pseudomembranous colitis caused by C. difficile in patients who have failed to respond to metronidazole—the drug of choice. Vancomycin has also been recommended as initial empirical therapy for presumed pneumococcal meningitis because of increasing pneumococcal resistance to penicillins and cephalosporins. Resistance to vancomycin is increasing rapidly among isolates of E. faecium in large hospitals, particularly in areas of high vancomycin use. In addition, S. aureus isolates with both high-level resistance and reduced susceptibility to vancomycin have now been detected. Because of the growing threat of vancomycin-resistant enterococci and the potential for increasing resistance among staphylococci, a national advisory committee has established guidelines for appropriate and limited use of this antibiotic (Table 118-6).

AMINOLYPOSIDES The aminoglycosides are rapidly bactericidal in vitro at low concentrations, with activity limited to gram-negative bacteria and staphylococci. They have no activity against anaerobic bacteria and are not effective in environments that are acidic or have a low oxygen tension. However, their spectrum includes virtually all gram-negative bacteria that are not strict anaerobes, and they are among the drugs of choice for any suspected gram-negative bacteremic infection, particularly in neutropenic patients. Aminoglycosides are synergistically bactericidal in combination with a penicillin for the treatment of staphylococcal, enterococcal, or viridans streptococcal endocarditis and are usually combined with a β-lactam antibiotic for the treatment of gram-negative bacteremia. Aminoglycosides are also among the drugs of choice for severe infections of the upper urinary tract. The major limitations to use of aminoglycosides are their renal and otic toxicity, their diminished activity at certain sites of infection (e.g., abscesses and the central nervous system), and the resistance of target bacteria. Among the available agents, gentamicin and tobramycin are generally preferred because of their low cost. Tobramycin has slightly greater activity against P. aeruginosa, and amikacin retains activity against many tobramycin- and gentamicin-resistant gram-negative bacteria because it is inactivated by fewer aminoglycoside-modifying enzymes. Streptomycin is still one of the drugs of choice in initial therapy for tularemia, plague, glanders, and brucellosis and is a second-line agent for the treatment of tuberculosis.

MACROLIDES AND KETOLIDES Erythromycin has broad-spectrum activity against gram-positive bacteria, with additional activity against Legionella, Mycoplasma, Campylobacter, Bordetella pertussis, and some Chlamydia isolates. It is the drug of choice for infections due to Legionella, Campylobacter, and Mycoplasma and is among the drugs of choice for community-acquired pneumococcal pneumonia and group A streptococcal pharyngitis in penicillin-allergic patients. However, resistance to erythromycin among group A streptococci and especially pneumococci is increasing dramatically in some areas. Erythromycin also appears to be one of the drugs of choice for infections caused by the agent of bacillary angiomatosis (Bartonella henselae) in immunocompromised patients. Clarithromycin and azithromycin have an antibiotic spectrum similar to that of erythromycin in vitro. However, azithromycin has greater activity against Chlamydia. Clarithromycin, in combination with a proton pump inhibitor, has been designated a drug of choice for the treatment of gastric infections due to Helicobacter pylori (gastritis, gastric and duodenal ulcers). Both azithromycin and clarithromycin are active against non-tuberculous mycobacteria, and both appear to have fewer gastrointestinal side effects than does erythromycin. Bacteria that are resistant to erythromycin are also resistant to clarithromycin and azithromycin. Telithromycin is a ketole antibiotic that is similar to erythromycin in structure, spectrum of activity, and mechanism of action. However, telithromycin is active against most macrolide-resistant strains of S. pneumoniae.

LINCOSAMIDES The only lincosamide used in the United States is clindamycin. It shares the gram-positive coccal spectrum of erythromycin but is more active (in some cases showing bactericidal activity) against susceptible staphylococci. However, resistance among staphylococci and some streptococci, mediated by the same genes responsible for macrolide resistance, limits clindamycin’s usefulness against gram-positive cocci. In general, all staphylococci resistant to erythromycin should be considered resistant to clindamycin regardless of the results of in vitro susceptibility testing. However, at least half of the streptococci resistant to erythromycin are truly susceptible to clindamycin. In these bacteria, resistance is mediated by a drug-efflux pump that removes macrolides but not lincosamides. Despite increasing resistance, clindamycin remains useful for most anaerobic infections because of its broad spectrum of activity against most gram-positive and gram-negative strict anaerobes. It is also a drug of choice for the treatment of severe, invasive group A streptococcal infections. In contrast, clindamycin, like erythromycin, has no clinically significant activity against facultative gram-negative enteric bacilli. The appropriate use of clindamycin is limited only by resistance or the development of pseudomembranous colitis, the major serious side effect of this drug.

CHLORAMPHENICOL Chloramphenicol has a broad spectrum of activity against gram-positive and gram-negative bacteria, although plasmid-mediated resistance has diminished its effective spectrum. This antibiotic is rarely used in adult infections because of the rare idiosyncratic side effect of irreversible bone-marrow aplasia and the availability of other agents with similar activity. It remains one of the drugs of choice for the treatment of typhoid fever and plague and is still useful for the treatment of brucellosis and both pneumococcal and meningococcal meningitis in patients with severe penicillin allergy.

TETRACYCLINES  Tetracyclines have a broad spectrum of bacteriostatic activity against gram-positive and gram-negative bacteria and are widely used in a variety of community-acquired infections. These agents are among the drugs of choice for acute bacterial exacerbations of chronic bronchitis, granuloma inguinale, brucellosis (with streptomycin), tularemia, glanders, melioidosis, spirochetal infections caused by Borrelia (Lyme disease and relapsing fever; doxycycline), infections caused by Vibrio vulnificus, some Aeromonas infections, infections due to Stenotrophomonas (minoclycine), plague, ehrlichiosis, chlamydial infections (doxycycline), and granulomatous skin infections due to Mycobacterium marinum (minocycline). The tetracyclines are also used in penicillin-allergic patients for the treatment of leptospirosis, syphilis, actinomycosis, and skin and soft tissue infections caused by gram-positive cocci. Doxycycline is also among the drugs recommended for the treatment of community-acquired pneumonia, although clinical data are few and resistance in S. pneumoniae is increasing.

SULFONAMIDES AND TRIMETHOPRIM  The folic acid synthesis inhibitors have a broad spectrum of bacteriostatic activity individually; in combination, they can be bactericidal against facultative gram-negative bacteria and staphylococci. The fixed combination of sulfamethoxazole and trimethoprim, the major folic acid synthesis inhibitors used in therapy for bacterial infections, has modest activity against some streptococci and no activity against strict anaerobes. However, resistance to TMP-SMX is common among methicillin-resistant staphylococci. Doxycycline is also among the drugs recommended for the treatment of community-acquired pneumonia, although clinical data are few and resistance in S. pneumoniae is increasing.

COLOSTRUM AND TRIMETHOPRIM  The folic acid synthesis inhibitors have a broad spectrum of bacteriostatic activity individually; in combination, they can be bactericidal against facultative gram-negative bacteria and staphylococci. The fixed combination of sulfamethoxazole and trimethoprim, the major folic acid synthesis inhibitors used in therapy for bacterial infections, has modest activity against some streptococci and no activity against strict anaerobes. However, resistance to TMP-SMX is common among methicillin-resistant staphylococci. Doxycycline is also among the drugs recommended for the treatment of community-acquired pneumonia, although clinical data are few and resistance in S. pneumoniae is increasing.

FLUOROQUINOLONES  The fluoroquinolones have excellent activity against most facultative gram-negative rods and variable activity against gram-positive cocci. The quinolones are the oral agents with greatest activity against P. aeruginosa; ciprofloxacin is the most active against this species, although a high rate of acquired resistance limits its utility in many hospitals. All the quinolones except norfloxacin are well absorbed orally; ciprofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are also administered as intravenous formulations. The quinolones are among the drugs of choice for urinary tract infections, bacterial gastroenteritis, community-acquired pneumonia, and enteric fever and are useful for serious hospital-acquired infections caused by gram-negative organisms. While older quinolones (such as ciprofloxacin) have limited activity against gram-positive bacteria, the newer quinolones have an expanded spectrum of activity against gram-positive cocci, including staphylococci (methicillin-susceptible) and streptococci (especially S. pneumoniae). Quinolones can also be used as prophylaxis for persons at risk for meningococcal meningitis. However, use of quinolones should be coupled with the realization that, in conjunction with rapidly expanding usage, resistance is being reported increasingly among all bacteria targeted by these drugs, including S. pneumoniae, Neisseria gonorrhoeae, E. coli, and P. aeruginosa.

RIFAMPIN  Rifampin has been used in combinations for the treatment of serious infections due to methicillin-resistant staphylococci (e.g., coagulase-negative staphylococcal foreign-body infections). Because the spontaneous selection of rifampin-resistant mutants occurs rapidly, rifampin should never be used alone in the treatment of staphylococcal infections. Rifampin is also used for chemoprophylaxis in persons at risk of meningococcal meningitis and for the treatment of Legionella pneumonia.

METRONIDAZOLE  Metronidazole has a spectrum limited to anaerobic bacteria, especially gram-negative species (e.g., Bacteroides spp.). It is less active against anaerobic gram-positive cocci (e.g., Peptostreptococcus and Peptococcus spp.). Because of its spectrum and its ability to penetrate into the area of infection, metronidazole is one of the drugs of choice for the treatment of any abscess in which the involvement of obligate anaerobes is suspected (e.g., lung, brain, or intraabdominal abscesses). Other antibacterial agents should be used in combination with metronidazole if facultative and aerobic pathogens are also thought to be involved. Metronidazole is the drug of choice for the treatment of bacterial vaginosis and antibiotic-associated pseudomembranous colitis.

LINEZOLID  This antibacterial agent has a spectrum limited to gram-positive bacteria and is indicated for the treatment of infections caused by streptococci, staphylococci, and enterococci. Because there is very little preexisting resistance to linezolid, the drug is active against gram-positive bacteria that are resistant to other antibacterial agents. In particular, it is active against vancomycin-resistant enterococci (both E. faecium and E. faecalis) and is one of the drugs of choice for treating infections due to these organisms. However, since this drug has only bacteriostatic activity, it has limited utility in treating complicated S. aureus infections.

POLYMYXINS  Polymyxins B and E have a broad spectrum of activity that includes virtually all gram-negative bacteria. However, while polymyxin B is still used as a component of topical preparations (see “Topical Antibacterial Agents,” below), polymyxin E (colistin) has been used little since the early 1980s because of the high incidence of severe renal toxicity associated with its systemic use. The occurrence in recent years of nosocomial infections caused by strains of bacteria such as P. aeruginosa, Acinetobacter baumannii, and Stenotrophomonas maltophilia that are resistant to all available therapy but susceptible to colistin has prompted a reexamination of its use in certain patients for whom there are no other options. Recent data suggest that colistin is reasonably safe and effective when used with caution.

STREPTOGRAINMS  The combination of streptogramin B (quinupristin) and streptogramin A (dalfopristin) has a spectrum that is limited to gram-positive bacteria and is indicated for the treatment of infections caused by staphylococci, streptococci, and enterococci. When the combination, they can be bactericidal against facultative gram-negative bacteria and staphylococci. The fixed combination of sulfamethoxazole and trimethoprim, the major folic acid synthesis inhibitors used in therapy for bacterial infections, has modest activity against some streptococci and no activity against strict anaerobes. However, resistance to TMP-SMX is common among methicillin-resistant staphylococci. Doxycycline is also among the drugs recommended for the treatment of community-acquired pneumonia, although clinical data are few and resistance in S. pneumoniae is increasing.

URINARY TRACT ANTISEPTICS  Urinary tract antiseptics are active only in the lower urinary tract and cannot be used for the treatment of upper urinary tract or systemic infections. The available agents in this category include nitrofurantoin and methenamine salts, which are most active against susceptible gram-negative enteric bacteria. Nitrofurantoin is often active against vancomycin-resistant enterococci and is a less expensive alternative to linezolid for the treatment of lower urinary tract infections.

TOPICAL ANTIBACTERIAL AGENTS  Mupirocin is available only as a topical preparation for use against staphylococci and streptococci. Its major
applications are for impetigo and eradication of the staphylococcal carrier state. It is the drug of choice for the elimination of nasal carriage of both methicillin-susceptible and methicillin-resistant staphylococci. Unfortunately, the emergence of resistance is limiting its usefulness in some hospitals.

Although their efficacy has never been well documented, topical preparations that include sulfonamides, polymyxin B, neomycin, bacitracin, gramicidin, and novobiocin in a variety of combinations are widely used as eye drops, irrigation solutions, and ointments for superficial skin infections.

**ADVERSE REACTIONS**

Adverse drug reactions are frequently classified by mechanism as either dose-related ("toxic") effects or unpredictable reactions. Unpredictable reactions are either idiosyncratic or allergic. Dose-related reactions include aminoglycoside-induced nephrotoxicity, linezolid-induced thrombocytopenia, penicillin-induced seizures, and vancomycin-induced anaphylactoid reactions. Many of these reactions can be avoided by reducing dosage, limiting the duration of therapy, or reducing the frequency or rate of administration. Adverse reactions to antibacterial agents are a common cause of morbidity, requiring alteration in therapy and additional expense, and they occasionally result in death. The elderly, those with the more severe infections, may be especially prone to certain adverse reactions. —For further discussion of adverse drug reactions, see Chap. 3.

**β-LACTAMS** The therapeutic index for β-lactam antibiotics is broad, and dose-related adverse reactions are uncommon and largely preventable. The greatest concern is allergic reactions. All types can occur, including anaphylaxis (type 1, immediate-hypersensitivity reactions), nephritis and Coombs-positive hemolytic anemia (type 2, cytotoxic reactions), drug fever and serum sickness (type 3, immune-complex formation), contact dermatitis (type 4, cell-mediated effects), and maculopapular eruption (type 5, idiopathic reactions). Approximately 1 to 4% of treatment courses result in an allergic reaction, and 0.004 to 0.015% of treatment courses result in anaphylaxis. Only 10 to 20% of the patients who claim an allergy to penicillin react to skin testing with the major and minor determinants (penicilloyl-polylysine and benzylpenicillin degradation products, respectively); those with negative skin tests only rarely react adversely to subsequent therapeutic doses. Generally, a suitable alternative to β-lactams is available for patients who have a severe allergy, and penicillin desensitization can be carefully undertaken if there is no suitable alternative. A small proportion (<2%) of persons who are allergic to penicillin react similarly when a cephalosporin is administered; thus, cephalosporins are contraindicated in patients with a history of an immediate reaction to penicillin, although they are often used in patients with a history of mild reactions. The same precaution applies to carbapenems, but aztreonam is antigenically distinct and can be administered safely to the penicillin-allergic patient.

Other reactions thought to have an allergic basis include nephritis (associated with methicillin and occasionally nafcillin), hepatitis (related to oxacillin), leukopenia (following high doses of most β-lactams administered for prolonged periods), and severe skin rashes (toxic epidermal necrolysis and Stevens-Johnson syndrome). These reactions are not IgE-mediated, and skin testing is not predictive of their occurrence. For unclear reasons, most patients who have infectious mononucleosis or cytomegalovirus infection develop a rash when given ampicillin or amoxicillin.

Miscellaneous reactions to β-lactams include gastrointestinal side effects ranging in severity from mild diarrhea (5 to 10%) to pseudo-membranous colitis (<1%). Although the probability of antibiotic-associated colitis is low, a large number of cases occur because β-lactams are so commonly prescribed. Drugs excreted to a large extent through the bile, such as ampicillin and ceftriaxone, may be expected to cause diarrhea. The addition of clavulanic acid to amoxicillin further increases the frequency of diarrhea. Ceftriaxone, because of extremely high concentrations in bile, can cause "sludging" in the gallbladder and occasionally produces symptoms compatible with acute cholecystitis.

In high doses—and most often in patients with renal impairment who receive an excessive dose—penicillins (especially ticarcillin and penicillin G) can cause bleeding from impaired platelet aggregation. Seizures are occasionally observed with β-lactams, especially penicillin G and imipenem. This reaction is most common when excessive doses relative to renal function are administered or when the patient has a history of seizures.

**VANCOMYCIN** When vancomycin was first used clinically in 1956, local intolerance at the infusion site was common, as were systemic reactions, including ototoxicity and nephrotoxicity. Current formulations are of higher purity and, when proper dosage guidelines are followed, are very safe, although phlebitis can still be troublesome. The most common adverse reaction is called red man syndrome and is characterized by pruritus, flushing, and erythema of the head and upper torso. This anaphylactoid reaction usually follows the first dose, is dependent on dose size and infusion time, and results from vancomycin-induced release of histamine. The reaction is usually mild in adult patients who receive 1 g over 60 min and diminishes with repeated doses. If vancomycin is mistakenly given as a bolus, severe hypotension may result. In unusually sensitive patients, extending the infusion time or administering H1 receptor antagonists is usually effective in preventing this reaction or reducing its severity. Patients with this reaction must not be mislabeled as having an allergy to vancomycin, since vancomycin may be the only effective treatment for certain infections (e.g., those due to methicillin-resistant staphylococci).

Nephrotoxicity from vancomycin is mild and uncommon. Although some data suggest that aminoglycosides and vancomycin are synergistically nephrotoxic, this point is difficult to prove, and the simultaneous use of these agents should not be avoided if clinically indicated, as in the treatment of enterococcal endocarditis in penicillin-allergic patients.

Otoxicity from vancomycin is rare as long as doses are appropriately reduced in patients with renal insufficiency. Other uncommon adverse reactions include leukopenia, skin rashes, and true allergy. Serum concentrations of vancomycin are of little use in predicting toxicity but may be of value in selecting dosages for patients with unstable renal function.

**AMINOGLYCOSIDES** Aminoglycoside antibiotics have a narrow therapeutic index. The two most common adverse reactions are nephrotoxicity and ototoxicity. Rarely, respiratory depression is observed. Nephrotoxicity results from accumulation of the aminoglycoside in the peritubular space, with damage to the proximal tubule and a corresponding reduction in the glomerular filtration rate. The incidence of nephrotoxicity, defined as an increase of >0.5 mg/dL over baseline in the serum creatinine level, is ~5 to 10% among adult patients who receive therapy for 10 to 14 days. However, many cofactors also influence the frequency of toxicity, such as extremes of age (toxicity is uncommon among children, more common among the elderly), concomitant drug therapy, and hydration status. Nephrotoxicity is manifested clinically by a gradual rise in serum creatinine levels after a few days of therapy and is reversible if the dosage is reduced or treatment is discontinued. Serum creatinine levels should be monitored every 3 to 5 days or more often if changes are seen. There is not an important difference among the most useful agents (gentamicin, tobramycin, and amikacin) in terms of the frequency of nephrotoxicity; streptomycin is a rare cause of nephrotoxicity. Some data suggest that once-daily administration of aminoglycosides may cause less nephrotoxicity than more frequent administration.

Otoxicity from aminoglycoside therapy presents as either auditory or vestibular damage. Since the aminoglycosides can destroy hair cells in the inner ear, ototoxicity may be permanent. The risk of ototoxicity increases with prolonged therapy, higher serum concentrations (especially in patients with renal impairment), hypovolemia, and con-
current treatment with other otoxins, especially ethacrynic acid. There is evidence of a genetic predisposition to ototoxicity in some persons. Clinically apparent ototoxicity, manifested by diminished acuity or vestibular imbalance, is uncommon (probably occurring in <1% of cases) when the duration of therapy is kept to a minimum. With more sensitive monitoring (e.g., audiograms), asymptomatic high-tone hearing loss is more commonly noted. There are no clinically important differences among the aminoglycosides in the overall frequency of ototoxicity.

Neuromuscular depression from aminoglycosides is caused by reduced acetylcholine activity at post synaptic membranes and can result in rare but severe respiratory depression. Risk factors include hypocalcemia, peritoneal administration, use of neuromuscular blockers, and preexisting respiratory depression. This complication can be largely avoided if the aminoglycoside is administered intravenously over 30 min or by intramuscular injection; if respiratory depression occurs, it is reversed by the administration of calcium.

Fear of toxicity should not prevent the use of aminoglycosides for a legitimate indication, since toxicity is usually mild and reversible. The value of measuring serum concentrations is controversial; these measurements are usually unnecessary when the patient is receiving once-daily therapy, especially when the duration is <7 to 10 days.

MACROLIDES Serious adverse reactions to the macrolide antibiotics are very rare. Gastrointestinal effects, such as burning, nausea, and vomiting, are the most common adverse reactions to the macrolides; depending on dosage, these reactions may occur in up to 50% of patients, occasionally requiring early discontinuation of therapy. The mechanism is thought to be the binding of erythromycin to motilin receptors, with a consequent increase in gastrointestinal motility. Gastrointestinal side effects appear equally common for all the oral formulations and also occur with intravenous administration. Clarithromycin and azithromycin are better tolerated than erythromycin, although gastrointestinal distress is still their most common adverse effect.

Less common reactions include hepatotoxicity and ototoxicity. Hepatotoxicity is a rare, nonfatal complication that is usually associated with erythromycin estolate and presents as an allergic cholestatic jaundice. Ototoxicity is rare after oral administration but may occur in a dose-dependent pattern in up to 20% of adults who receive intravenous erythromycin (4 g/d) and have audiograms performed. Ototoxicity is usually reversible and mild. Allergic cutaneous reactions are observed in rare cases. Macrolides are among the many drugs that can prolong the QT interval in some patients. The clinical significance of this effect continues to be investigated. The limited data suggest that the ketolide telithromycin has adverse effects similar to those of erythromycin.

LINCOSAMIDES The most common adverse effect of clindamycin is gastrointestinal distress. Diarrhea has been reported in up to 20% of patients and pseudomembranous colitis in 0.01 to 10%. The mechanism of pseudomembranous colitis is production of a toxin by C. difficile (Chap. 114). C. difficile colonizes the gastrointestinal tract and may produce a toxin when the normal flora is suppressed by clindamycin and other antibiotics, especially β-lactams. This toxin causes mucosal damage that results in cramps, pain, and diarrhea that may be bloody. Pseudomembranous colitis may follow both intravenous and oral administration and may not become manifest until after completion of therapy. Oral metronidazole or oral vancomycin is effective in treating symptomatic patients with toxin-positive stools, but some spores may survive, and relapse is frequent. Metronidazole is the drug of choice since oral treatment with vancomycin can select for vancomycin-resistant enterococci. Although diarrhea and pseudomembranous colitis can be caused by most antibacterial agents, the incidence in relation to the drug used may be highest for clindamycin. Allergic reactions (such as rashes and fever), hepatotoxicity, and neutropenia are observed only rarely.

CHLORAMPHENICOL Chloramphenicol causes two types of bone marrow suppression: a dose-related, reversible suppression of all elements, which occurs commonly during therapy at the maximal recommended doses (4 g/d in adults), and an idiosyncratic, irreversible aplastic anemia, which occurs in ~1 of every 25,000 to 40,000 exposures. The irreversible form has been reported to follow all types of chloramphenicol treatment, including ocular administration, and often develops months after therapy is discontinued.

In premature neonates and infants, chloramphenicol can cause a dose-related “gray syndrome” that is characterized by cyanosis, hypotension, and death and that results from an inability of the newborn to metabolize the drug. These potentially serious toxicities and the availability of newer drugs have substantially reduced the indications for chloramphenicol use.

TETRACYCLINES Gastrointestinal effects are the most common adverse reactions to the tetracyclines. These problems may be related to a direct irritant effect, since tetracyclines can also cause esophageal ulceration when they dissolve before reaching the stomach. It is important that nighttime doses be taken with sufficient fluid. Concurrent food intake may improve tolerance, but absorption of tetracycline HCl is impaired when the drug is taken with food.

Hepatotoxicity has been reported after administration of >2 g of tetracycline intravenously and at lower doses during pregnancy. There are currently no indications for intravenous tetracycline treatment in pregnancy. All tetracyclines can cause phototoxic skin reactions; these reactions are most common with doxycycline. Other dermatal reactions, including rash, are uncommon. Tetracyclines are contraindicated in children <8 years of age because of mottling of the permanent teeth; doxycycline may be less likely than the other tetracyclines to cause this problem. Worsening of renal function in patients with preexisting renal dysfunction has been reported with use of tetracycline. Doxycycline and perhaps minocycline appear to be free from these renal side effects. Alternative effective agents are nearly always available for use in patients with renal dysfunction. Minocycline can cause vertigo in up to 70% of women receiving therapeutic doses and in a lower percentage of men.

SULFONAMIDES AND TRIMETHOPRIM The sulfonamides are generally safe, but the list of possible adverse reactions is very long. These compounds occasionally cause a number of allergic reactions, from relatively minor skin rashes (including maculopapular rashes and urticarial reactions typically appearing after a week of therapy) to severe or even life-threatening reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. The severe hypersensitivity reactions have occurred most commonly after treatment with the long-acting sulfonamides, such as sulfamethoxypyridazine, which are no longer used. Pyrimethamine plus sulfadoxine (Fansidar), used for malaria prophylaxis, may cause severe allergic reactions, including hepatic and hematologic toxicities, in addition to dermatologic toxicity. Photosensitivity reactions are also relatively common with sulfonamides.

Many patients infected with HIV who receive TMP-SMX have adverse dermatologic reactions. These reactions are usually not life-threatening and appear to regress in many cases despite continuation of therapy. In high doses, trimethoprim interferes with the renal secretion of potassium. Hyperkalemia is relatively common among HIV-positive patients and is most often found after 7 days of TMP-SMX therapy for pneumonia caused by Pneumocystis. Sulfonamides and trimethoprim may also cause severe hematologic complications, including agranulocytosis, hemolytic and megaloblastic anemia, and thrombocytopenia. These dose-related side effects may be more frequent and more severe in patients with renal insufficiency. Hemolytic anemia is most common in patients with glucose-6-phosphate dehydrogenase deficiency who take long-acting compounds; TMP-SMX rarely causes hemolysis in such subjects. Granulocytopenia with TMP-SMX is especially common among HIV-infected patients, occurring in 10 to 50% of this group.

Renal insufficiency, caused by crystals of the relatively insoluble
acetyl metabolite, is observed primarily with the long-acting sulfonamides. Many cases of crystalluria in HIV-infected patients taking sulfadiazine for toxoplasmosis have been reported. A high level of fluid intake may prevent this complication.

It is recommended that sulfonamides not be administered to newborns because of concerns that bilirubin may be displaced from protein-binding sites, with subsequent jaundice and kernicterus.

In addition to the preceding problems, sulfonamides may occasionally cause drug fever with serum sickness, hepatic toxicity (including necrosis), and systemic lupus erythematosus.

**FLUOROQUINOLONES** Fluoroquinolones are relatively safe; adverse reactions rarely require discontinuation of therapy. The most common reactions include gastrointestinal distress, such as nausea or diarrhea (<5%), and central nervous system effects, including insomnia and dizziness (<5%). Phototoxicity is occasionally severe. Rarely, hepatic and renal dysfunction and anaphylactoid and allergic reactions are observed. Quinolones can cause tendon rupture in rare instances. The use of these drugs is currently contraindicated in patients <18 years of age because of evidence in animals of cartilage damage in developing joints. In carefully selected situations in which the perceived benefits outweigh the risks (e.g., in adolescent patients with cystic fibrosis who have pulmonary exacerbations), fluoroquinolones may be useful for short-term therapy. They are contraindicated in pregnancy because of concern for the developing fetus. Quinolones can also increase the QT interval; it is unclear whether the currently available quinolones differ in a clinically important way in this respect. Hypo- and hyperglycemia have been reported and may be more common with gatifloxacin. As of 2003, a number of fluoroquinolones—including tigecloxacin, sparfloxacin, grepafloxacin, and trovafloxacin—have been removed from the U.S. market because of rare but severe adverse effects. It may be prudent to limit the use of the newest drugs in this class until their safety has been fully established.

**RIFAMPIN** Rifampin is generally well tolerated but has several important side effects. Some patients have transient rises in hepatic amino-transferases, but these levels usually return to normal without discontinuation of the drug. Although hepatitis from rifampin itself develops only rarely, the drug is thought by some investigators to potentiate the hepatic toxicity of concurrently administered isoniazid. Intermittent administration of rifampin (usually fewer than three times per week) has been associated with signs and symptoms that seem to have an immunologic basis. These include flulike symptoms and (rarely) hemolysis, thrombocytopenia, shock, and renal failure. Minor gastrointestinal side effects, skin rashes, and interstitial nephritis have also been reported. Patients should be warned that rifampin and its metabolites cause secretions such as urine, tears, sweat, and saliva to turn orange and that contact lenses may be stained.

**METRONIDAZOLE** Serious adverse reactions to metronidazole are uncommon. Gastrointestinal side effects such as nausea are most frequent but rarely necessitate discontinuation of therapy. Pseudomembranous colitis in association with metronidazole has been reported but is very rare. A metallic taste is relatively common, and stomatitis and glossitis are occasionally reported. Peripheral neuropathy develops in some patients, and seizures and encephalopathy have been reported after high doses and in patients with hepatic failure.

Concerns about mutagenicity and carcinogenicity from metronidazole have led to recommendations that it not be used in pregnancy (especially during the first trimester) when alternative agents are available. Although retrospective studies have found no association between metronidazole and carcinogenesis, long-term administration of high doses should be avoided when therapeutic alternatives exist.

**LINEZOLID** The most common adverse events accompanying linezolid therapy include gastrointestinal upset (nausea, vomiting, and diarrhea) and headache. Of most concern is a reversible myelosuppression that is directly related to the duration of therapy. Thrombocytopenia is the most likely hematologic abnormality, although anemia and leukopenia are also observed. If the duration of therapy is expected to exceed 1 week, then weekly complete blood counts are recommended.

**QUINUPRISTIN/DALFOPRISTIN** Quinupristin/dalfopristin is not well tolerated. In particular, venous irritation is a frequent and potentially serious adverse effect when the drug is given by peripheral intravenous infusion. Administration via a central line is often required to complete a course of therapy. In addition, arthralgia and myalgia are substan-

1 = a well-documented interaction with clinically important consequences; 2 = an interaction of uncertain frequency but of potential clinical importance.

a Lovastatin and simvastatin are most affected; pravastatin and atorvastatin are less prone to clinically important effects.

b The macrolide antibiotics and quinupristin/dalfopristin inhibit the same human metabolic enzyme, CYP3A4, and similar interactions are anticipated.

c Gatifloxacin only. Levofloxacin, moxifloxacin, and gatifloxacin do not inhibit theophylline metabolism.

Note: New interactions are commonly reported after marketing. Consult the most recent prescribing information for updates.

Abbreviation: CNS, central nervous system.
sources should be consulted to identify appropriate options.

Table 118-7 is intended only to characterize the clinical relevance of these interactions. Coadministration of drugs paired in the tables does not necessarily result in clinically important adverse interactions. Table 118-7 lists the most common and best-documented interactions of antibacterial agents with other drugs and characterizes the clinical relevance of these interactions. Coadministration of drugs paired in the tables does not necessarily result in clinically important adverse interactions.

* Gentamicin should be added to the amoxicillin regimen for high-risk gastrointestinal and genitourinary procedures; vancomycin should be used in penicillin-allergic patients.
* In these cases, use of antibacterial agents actually constitutes treatment of infection rather than prophylaxis.
* Vancomycin is recommended only in institutions that have a high incidence of infection with methicillin-resistant staphylococci.

There are two clinically important drug interactions involving fluoroquinolones. First, like tetracyclines, all fluoroquinolones are chelated by divalent and trivalent cations, which prevent most of the dose from being absorbed. Second, certain fluoroquinolones, including ciprofloxacin, inhibit hepatic enzymes that metabolize theophylline, with consequent theophylline toxicity. The same mechanism accounts for increases in serum caffeine concentrations, but the clinical significance of this interaction is unknown. Scattered case reports suggest that quinolones can also potentiate the effects of warfarin, but this effect has not been observed in most controlled trials.

**FLUOROQUINOLONES**

**RIFAMPIN** Rifampin is an excellent inducer of many cytochrome P450 enzymes and increases the hepatic clearance of a number of drugs, including the following (with the indicated predictable outcomes): HIV-1 protease inhibitors (loss of viral suppression), oral contraceptives (pregnancy), warfarin (decreased prothrombin times), cyclosporine and prednisone (organ rejection or exacerbations of any underlying inflammatory condition), and verapamil and diltiazem (increased dosage requirements). Before rifampin is prescribed for any patient, a review of concomitant drug therapy is essential.

**METRONIDAZOLE** Metronidazole can cause a disulfiram-like syndrome when alcohol is ingested; thus, patients taking metronidazole should be instructed to avoid alcohol. Inhibition of the metabolism of warfarin by metronidazole leads to significant rises in prothrombin times.
PROPHYLAXIS OF BACTERIAL INFECTIONS

Antibacterial agents are occasionally indicated for use in patients who have no evidence of infection but who have been or are expected to be exposed to bacterial pathogens under circumstances that constitute a major risk of infection. The basic tenets of antimicrobial prophylaxis are as follows: (1) the risk or potential severity of infection should be greater than the risk of side effects from the antibacterial agent, (2) the antibacterial agent should be given for the shortest period necessary to prevent target infections, and (3) the antibacterial agent should be given before the expected period of risk (e.g., surgical prophylaxis) or as soon as possible after contact with an infected individual (e.g., prophylaxis for meningococcal meningitis).

Table 118-8 lists the major indications for antibacterial prophylaxis in adults. (The use of antibacterial agents in children to prevent rheumatic fever and otitis media under certain circumstances is also common practice.) The table includes only those indications that are widely accepted, supported by well-designed studies, or recommended by expert panels. Prophylaxis is also used but is less widely accepted for recurrent cellulitis in conjunction with lymphedema, recurrent pneumococcal meningitis in conjunction with deficiencies in humoral immunity or CSF leaks, traveler’s diarrhea, gram-negative sepsis in conjunction with neutropenia, and spontaneous bacterial peritonitis in conjunction with ascites.

The major use of antibacterial prophylaxis in the United States is for infections following surgical procedures. Antibacterial agents are administered just before the surgical procedure—and, for long operations, during the procedure as well—to ensure high levels in serum and tissues during surgery. The objective is to eradicate bacteria originating from the air of the operating suite, the skin of the surgical team, or the patient’s own flora that may contaminate the wound. In all but colorectal surgical procedures, prophylaxis is predominantly directed against staphylococci. Prophylaxis is intended to prevent wound infection or infection of implanted devices, not all infections that may occur during the postoperative period (e.g., urinary tract infections or pneumonia). Prolonged prophylaxis merely alters the normal flora and favors infections with organisms resistant to the antibacterial agents used.

DURATION OF THERAPY AND TREATMENT FAILURE

It is often difficult to determine the proper duration of therapy for bacterial infections. There are few infections for which trials have established the appropriate treatment duration. Table 118-9 lists those common bacterial infections for which guidelines have been established or for which there is sufficient clinical experience to establish treatment durations. The ultimate test of cure for a bacterial infection is the absence of relapse when therapy is discontinued. Relapse is defined as a recurrence of infection with the identical organism that caused the first infection. In general, therefore, the duration of therapy should be long enough to prevent relapse yet not excessive. Therapy extended beyond the limit of effectiveness will increase side effects of medication and encourage the selection of resistant bacteria. The art of treating bacterial infections lies in the ability to determine the appropriate duration of therapy for infections that are not covered by established guidelines. Re-treatment of infections for which therapy has failed usually requires a prolonged course (>4 weeks) with combinations of antibacterial agents.

ANTIBACTERIAL COSTS AND INAPPROPRIATE USE

Use of antibacterial agents in U.S. hospitals can represent the largest expenditure for any single pharmacologic class. It is not unusual for the purchase cost of a newer parenteral antibiotic (in 2003 dollars) to be $1000 to $2000 for a 10- to 14-day course of treatment. Therapy for 5 to 10 days with a new oral antibiotic can easily cost $60 to $100, compared with a few dollars for older drugs such as doxycycline and amoxicillin. Administration costs, monitoring costs, and pharmacy charges must be added to these figures. While some newer antibacterial agents undeniably represent important advances in therapy, many newer drugs offer no advantage over older, less expensive agents. With rare exceptions, newer drugs are usually found to be no more effective than the comparison antibiotic in controlled trials, despite the “high prevalence of resistance” often touted to market the advantage of the new antibiotic over older therapies.

Clinicians are understandably confused by the bewildering array of available drugs and their competing claims of superiority. Numerous surveys have reported that ~50% of antibiotic use is in some way “inappropriate.” Aside from the monetary cost of unnecessary antibiotics, there are the costs of excess morbidity from adverse effects and drug interactions and the eventual costs of treating more resistant organisms. The following suggestions are intended to provide guidance through the antibiotic maze.

First, objective evidence regarding the merits of newer drugs is available through publications such as The Medical Letter (including periodic updates of the Drugs of Choice) and through online references such as those on the Johns Hopkins website (http://hopkins-abxguide.org), which offers much current information. Second, clinicians should become comfortable using a few drugs recommended by independent experts and professional organizations and should resist the temptation to use a new drug unless the merits are clear. A new antibacterial agent with a “broader spectrum and greater potency,” a “longer half-life and higher tissue levels,” or a “higher serum concentration-to-MIC ratio” does not necessarily translate into greater clinical efficacy. Third, clinicians should become familiar with local bacterial susceptibility profiles. It may not be necessary to use a new drug with “improved activity against P. aeruginosa” if that pathogen is rarely encountered or if it retains full susceptibility to older drugs. Finally, with regard to inpatient use of antibacterial drugs, appropriate empirical treatment with one or more broad-spectrum agents may often be simplified, with use of a narrower-spectrum agent or even an oral drug, once the results of cultures and susceptibility tests become available. While there is an understandable temptation not to alter effective therapy, switching to a more specific agent once the patient has improved clinically does not compromise outcome. A promising and active area of research includes shorter durations of antimicrobial therapy. Many antibiotics that once were given for 7 to 14 days can probably be given for 3 to 7 days. As the clinical trials of shorter duration and equal efficacy are published, prompt adoption of the shorter courses by the clinical community may be an effective counter to the problems of

increasing resistance. Adoption of these guidelines will not undermine the care of patients, many unnecessary complications and expenses will be avoided, and the useful life of valuable drugs will be extended.

**Section 5 Diseases Caused by Gram-Positive Bacteria**

**Pneumococcal Infections**

Daniel M. Musher

*Streptococcus pneumoniae* (the pneumococcus) was recognized as the major cause of pneumonia in the 1880s and has been a central focus of study leading to the modern understanding of humoral immunity. The name *Diplococcus pneumoniae* was assigned to the organism in 1926 because of its appearance in Gram-stained sputum. In 1974, the organism was renamed *Streptococcus pneumoniae* because it grows in chains in liquid medium. Around 1900, pneumococcal serotypes were recognized when the injection of killed organisms into a rabbit stimulated the production of serum antibody that agglutinated the immunizing strain and protected rabbits against challenge with that strain and with some but not all other pneumococcal isolates. Ninety serotyping strain and protected rabbits against challenge with that strain. They produced antibodies that agglutinated the immunizing strain and protected rabbits against challenge with that strain and with some but not all other pneumococcal isolates. Ninety serotypes have now been identified, each possessing a unique polysaccharide capsule.

**Microbiology**

Pneumococci are identified in the clinical laboratory as gram-positive cocci that grow in chains and are catalase-negative. They produce pneumolysin, a toxin that breaks down hemoglobin into a greenish degradation product, thereby causing a-hemolysis on blood agar. More than 98% of pneumococcal isolates are susceptible to ethylhydrocupreine (optochin), and virtually all pneumococcal colonies are dissolved by bile salts; these reactions are the basis for laboratory identification.

Peptidoglycan and teichoic acid are the principal constituents of the pneumococcal cell wall. The cell wall’s integrity depends on the presence of numerous peptide side chains linked by the activity of enzymes such as trans- and carboxypeptidases. β-Lactam antibiotics inactivate these enzymes by covalently binding their active site. Unique to *S. pneumoniae* and present in all strains is C (for “cell-wall”) substance, a polysaccharide consisting of teichoic acid with a phosphorylcholine residue. Surface-exposed choline residues serve as a site of attachment for potential virulence factors, such as pneumococcal surface protein A (PspA), which may prevent phagocytosis. Except for strains that cause conjunctivitis, nearly every clinical isolate of *S. pneumoniae* has a polysaccharide capsule.

There are two systems for numbering the 90 known distinct capsules of *S. pneumoniae*. In the American system, serotypes are numbered in the order in which they were identified. The strains that most frequently cause human disease were generally the earliest to be identified and thus tend to have lower numbers. The more widely accepted Danish system places serotypes into groups based on antigenic similarities; for example, Danish group 19 includes types 19F (“first recognized”), 19A, 19B, and 19C, which in the American system would be types 19, 57, 58, and 59, respectively. Serotyping was clinically relevant in the 1930s, when type-specific antisera were administered as therapy, and again in the 1990s, when it was used to track the spread of antibiotic-resistant isolates (although this method has largely been replaced by molecular biologic techniques such as pulsed-field gel electrophoresis and multilocus sequence typing). Capsule switching has been documented and further limits the epidemiologic reliability of serotyping.

**Epidemiology**

*S. pneumoniae* colonizes the nasopharynx and, on any single occasion, can be isolated from 5 to 10% of healthy adults and from 20 to 40% of healthy children. Once the organisms have colonized an adult, they are likely to persist for 4 to 6 weeks but may persist for as long as 6 months. Pneumococci spread from one individual to another by direct or droplet transmission as a result of close contact; transmission may be enhanced by crowding or poor ventilation. Day-care centers have been a site of spread, especially of penicillin-resistant strains of serotypes 6B, 14, 19F, and 23F. Outbreaks occur among adults in crowded living conditions—e.g., in military barracks, prisons, and shelters for the homeless—as well as among susceptible populations in settings such as nursing homes. The risk of pneumococcal pneumonia is not increased by contact in schools or workplaces (including hospitals).

The incidence of bacteremic pneumococcal infection is relatively high among infants up to 2 years of age and low among teenagers and young adults; rates increase with increasing age beginning at around age 55. A surveillance study in South Carolina showed the incidences of pneumococcal bacteremia among infants, young adults, and persons ≥70 years of age to be 160, 5, and 70 cases per 100,000 population, respectively. (These results antedate implementation of vaccination for infants and young children.) Most cases of pneumococcal bacteremia in adults are due to pneumonia, and there are three to four cases of nonbacteremic pneumonia for every bacteremic case. Thus an estimated 20 cases of pneumococcal pneumonia per 100,000 young adults and 280 cases per 100,000 persons over the age of 70 occur annually. The incidence of pneumococcal bacteremia among adults exhibits a distinct midwinter peak and a striking dip in summer. In children, the incidence of bacteremia is relatively constant throughout the year except for a marked dip in midsummer. For reasons that are unclear but probably are multifactorial, Native Americans, Native Alaskans, and African Americans are unusually susceptible to invasive pneumococcal disease. This enhanced susceptibility is thought to have a genetic basis that thus far remains unelucidated.

**Pathogenic Mechanisms**

*S. pneumoniae* attaches to human nasopharyngeal cells through the specific interaction of bacterial surface adhesins, such as pneumococcal surface antigen A or choline-binding proteins (including PspA), with epithelial cell receptors. Epithelial cell glycoconjugates containing the disaccharide GlcNAcβ1-4Gal or asialo-GM1 glycolipid are possible binding sites. Pneumococcal phase variation, in which organisms may form transparent or opaque colonies, may also play a role in adherence. Organisms from opaque colonies have relatively little peptidoglycan and large capsules; those from transparent colonies have much more phosphorylcholine (which contributes to their capacity to adhere to mammalian cells) and less capsular polysaccharide. When pneumococci are inoculated intranasally into an experimental animal, organisms that form transparent colonies persist; in contrast, after intraperitoneal inoculation, organisms...
that yield transparent colonies are rapidly cleared from the blood, whereas those that make opaque colonies resist clearance.

Once the nasopharynx has been colonized, infection results if the organisms are carried into anatomically contiguous areas such as the eustachian tubes or the nasal sinuses and if their clearance is hindered, for example, by mucosal edema due to allergy or viral infection. Similarly, pneumonia ensues if organisms are inhaled or aspirated into the bronchioles or alveoli and then are not cleared—especially, for example, if viral infection or cigarette smoke or other toxic substances have increased mucus production and/or damaged ciliary action. A mechanism by which pneumococci may bind to pneumocytes after viral infection has been suggested. Pneumocytes activated by cytokines express the receptor for platelet-activating factor, which binds the phospholipid residue of pneumococcal C substance, enhancing the adherence of pneumococci. Pneumococci may invade tissues by penetrating mucosal layers; the clinical significance of this finding remains to be determined.

Once pneumococci reach an area where they do not naturally belong, they activate complement by classic and alternative pathways and stimulate cytokine production, which leads to the attraction of polymorphonuclear leukocytes (PMNs). The polysaccharide capsule, however, renders the organisms resistant to phagocytosis. In the absence of anticapsular antibody, phagocytic cells such as alveolar macrophages have a limited capacity to ingest and kill pneumococci; a large bacterial inoculum and/or a compromise of phagocytic function allows the initiation of lung infection. Infection of the meninges, joints, bones, and peritoneal cavity may result from the spread of pneumococci through the bloodstream, usually but not always from a respiratory tract focus of infection.

The capacity to cause disease reflects the capacities of pneumococci to escape ingestion and killing by host phagocytic cells, on the one hand, and to stimulate an inflammatory response and damage tissues, on the other. Encapsulated pneumococci are poorly ingested and killed in vivo in the immunologically naïve host or in vitro by mammalian phagocytes in the absence of anticapsular antibody and complement. Unencapsulated pneumococci virtually never cause invasive disease (although they can cause conjunctivitis), and mutants lacking a capsule are essentially avirulent in mice. Symptoms of disease are largely attributable to the generation of an inflammatory response that may cause pain by increasing pressure (as in sinusitis or otitis media) or may interfere with vital bodily functions by preventing oxygenation of blood (as in pneumonia) or by inhibiting blood flow (as in vasculitis due to meningitis). Cell-wall constituents of \( S. \ pneumoniae \), including teichoic acid, C substance, and (in particular) peptidoglycan, activate complement by the alternative pathway; the reaction between cell-wall structures and antibody that is present in all humans also activates the classic complement pathway. The result is the release of C5a, a potent attractant for PMNs, into the surrounding medium. Peptidoglycan can also directly stimulate the release of proinflammatory cytokines such as interleukin (IL) 1β, tumor necrosis factor (TNF) \( \alpha \), and IL-6 that activate a cascade of inflammation mediators. These cytokines increase expression of selectins on endothelial cells and integrins on leukocytes, thereby enhancing PMN migration. Pneumolysin, a thiol-activated toxin, exerts a variety of effects on ciliary cells and PMNs and also activates the classic complement pathway by direct binding of C4b. Injection of pneumolysin into the lungs of experimental animals produces the histologic features of pneumonia; in mice, immunization with this substance or challenge with genetically engineered mutants that do not produce it is associated with a significant reduction in virulence. Autolysin may contribute to the pathogenesis of pneumococcal disease by lysing bacteria, thereby releasing their constituents and heightening the reaction with human tissues. Inflammation in the central nervous system (CNS) during meningitis is a major contributor to neuronal cell injury. The release of matrix metalloproteinases, reactive oxygen species, and reactive nitrogen intermediates in neuronal tissue also contributes to damage caused by meningitis.

### HOST DEFENSE MECHANISMS

Mechanisms of host defense may be immunologically nonspecific or specific. Nonspecific mechanisms that protect against pneumonia include laminar airflow across mucous layers that filter inspired air, the glottal reflex, laryngeal closure, the cough reflex, clearance of organisms from the lower airways by ciliated cells, and ingestion by pulmonary macrophages and PMNs of small bacterial inocula that manage to reach alveolar spaces. Respiratory virus infection, chronic pulmonary disease, or heart failure compromises these mechanisms, predisposing to the development of pneumococcal pneumonia.

Anticapsular antibody provides the best specific protection against pneumococcal infection. Most healthy adults lack IgG antibody to the majority of pneumococcal capsular polysaccharides. Antibody appears after colonization, infection, or vaccination. In the first few weeks after colonization, nonspecific mechanisms probably protect the host from infection. Thereafter, newly developed anticapsular antibody provides a high degree of specific protection. Adults who are at risk of aspirating pharyngeal contents and who have diminished mechanisms of lower airway clearance are at risk of developing pneumonia before antibody is produced. Similarly, children whose nasal mucosal membranes become acutely congested around the time of colonization are at risk of developing otitis media. Persons with a diminished capacity to form antibody remain susceptible for as long as they are colonized. Antibody to PspA and other pneumococcal constituents, such as pneumolysin, is prevalent in the population and may contribute to immunity that is immunologically specific but not type specific.

The risk of serious pneumococcal infection is greatly increased in persons with conditions that compromise IgG synthesis and/or the phagocytic function of PMNs and macrophages; this risk is also elevated in the presence of conditions associated with debilitation or malnutrition. Nearly all adults who are hospitalized for pneumococcal pneumonia have at least one predisposing condition and/or fall into a group known to be at high risk epidemiologically (Table 119-1). Prior hospitalization either predisposes to or serves as a strong marker for subsequent pneumococcal infection. The susceptibility of elderly individuals to pneumococcal pneumonia is multifactorial, reflecting diminished clearance mechanisms as well as debilitation, malnutrition, and the presence of comorbid diseases. Although IgG responses to

* The absence of a spleen predisposes to more fulminant infection (see text).
some capsular polysaccharides, as measured by enzyme-linked immunoassay (ELISA), are more or less normal in elderly persons; postvaccination levels of antibody to others are reduced, and the functional capacity of the antibody appears to be decreased. A remarkably high incidence of pneumococcal infection—perhaps 100-fold above baseline—among persons with AIDS is largely related to poor formation of antibody to capsular polysaccharides.

Once a pneumococcal infection has been initiated, the absence of a spleen predisposes to fulminant disease. The liver is able to remove opsonized (antibody-coated) pneumococci from the circulation; in the absence of antibody, however, only the slow passage of blood through the splenic sinuses and prolonged contact with reticuloendothelial cells in the cords of Billroth allow time for bacterial clearance. Patients without spleens may die of pneumococcal pneumonia and sepsis at such an early stage of the illness that pulmonary consolidation is not evident on x-ray but rather is found only at autopsy.

**SPECIFIC INFECTIONS CAUSED BY S. PNEUMONIAE** S. pneumoniae causes infections of the middle ear, sinuses, trachea, bronchi, and lungs (Table 119-2) by direct spread from the nasopharyngeal site of colonization. Infections of the CNS, heart valves, bones, joints, and peritoneal cavity usually arise by hematogenous spread; peritoneal infection also results from ascent via the fallopian tubes. The CNS may also be infected by contiguous spread of organisms, as in patients who have a tear in the dura. Primary pneumococcal bacteremia—i.e., the presence of pneumococci in the blood with no apparent source—occurs commonly in children <2 years of age and as a small percentage of all pneumococcal bacteremias in adults; if no therapy is given, a source and/or a secondary site of infection may become apparent. Pleural infection results either from direct extension of pneumonia to the visceral pleura or from hematogenous spread of bacteria from a pulmonary or extrapulmonary focus to the pleural space; the route cannot be determined in individual cases. Infections listed after meningitis in Table 119-2 are uncommon or rare.

**Otitis Media and Sinusitis** When fluid from the middle ear is cultured during acute otitis media or fluid from a paranasal sinus is cultured during acute sinusitis, S. pneumoniae is the most common isolate or is second only to nontypable Haemophilus influenzae. Whether in adults or in children, pneumococci are identified in ~40 to 50% of cases of otitis in which an etiologic agent is isolated. Prior infection by a respiratory virus or allergy is thought to contribute significantly to these pneumococcal infections by causing congestion of the openings to the eustachian tubes or the paranasal sinuses. Prospective studies of young children have shown that colonization precedes infection in most cases. For reasons that are unclear, serotypes 6B, 14, 19F, and 23F predominate both as colonizing and as infecting organisms of children.

**Pneumonia** The distinctive symptoms and signs of pneumonia, whether due to the pneumococcus or to other bacteria, are (1) cough and sputum production, which reflect the proliferation of bacteria and the resulting inflammatory response in the alveoli; (2) fever; and (3) radiographic detection of an infiltrate.

*Note: The order of the list very roughly approximates the order of frequency among adults, from most to least common.*

**PREDISPOSING CONDITIONS** Pneumococcal pneumonia is most common at the extremes of age. Despite the undisputed role of *S. pneumoniae* as a major pathogenic bacterium for humans, the great majority of adults with pneumococcal pneumonia have underlying diseases that predispose them to infection. Otherwise-healthy military recruits involved in outbreaks of infection may be an exception to this rule; however, many of those affected have an exposure to stress and/or an antecedent viral-type illness that may reduce normal host resistance. In addition to prior viral respiratory illness, the most common predisposing conditions are alcoholism, malnutrition, chronic pulmonary disease of any kind, cigarette smoking, infection with HIV, diabetes mellitus, cirrhosis of the liver, anemia, prior hospitalization for any reason, renal insufficiency, and coronary artery disease (with or without recognized coronary heart disease). HIV infection is a rare but serious complication. Hypoxia or the generalized response to hypoxia may be a major pathogenic factor for humans. The great majority of adults with pneumococcal pneumonia have underlying diseases that predispose them to infection. Otherwise-healthy military recruits involved in outbreaks of infection may be an exception to this rule; however, many of those affected have an exposure to stress and/or an antecedent viral-type illness that may reduce normal host resistance. In addition to prior viral respiratory illness, the most common predisposing conditions are alcoholism, malnutrition, chronic pulmonary disease of any kind, cigarette smoking, infection with HIV, diabetes mellitus, cirrhosis of the liver, anemia, prior hospitalization for any reason, renal insufficiency, and coronary artery disease (with or without recognized coronary heart disease). HIV infection is a rare but serious complication. Hypoxia or the generalized response to
pneumonia may cause the patient to be confused, but the appearance of confusion should also raise concern about meningitis. Obtundation or neck stiffness should lead to an immediate consideration of this complication.

**Radiographic Findings** Pneumococcal pneumonia involves only one lung segment or a portion thereof in one-fourth of cases; it involves more than one segment but only one lobe or a portion thereof in another one-fourth of instances. Thus multilobar disease is seen in half of cases. Air-space consolidation is the predominant finding and is detected in 80% of cases (Fig. 119-1). Air bronchogram (visualization of the air-filled bronchus against a background of consolidation in the alveoli) is evident in fewer than half of cases and is more common in bacteremic than in nonbacteremic disease. In rare instances, pneumococcal pneumonia leads to a lung abscess; an underlying malignancy may be present, and co-infection with a mixture of anaerobic and microaerophilic organisms may be documented as well. Although some pleural fluid may actually be present in half of cases, no more than 20% of patients have a sufficient volume of fluid to allow aspiration, and in only a minority of these patients is empyema documented.

**General Laboratory Findings** Anemia (a hemoglobin level of <10 g/dL) is present in 25% of cases. The peripheral-blood white cell count (WBC) exceeds 12,000/µL in the great majority of patients with pneumococcal pneumonia. However, the count is <6000/µL in 5 to 10% of persons hospitalized for pneumococcal pneumonia. Such a low count is strongly associated with lethal disease and is often but not always associated with bone marrow suppression due to alcohol ingestion. The serum bilirubin level is modestly elevated in one-third of cases; hypoxia, inflammatory changes in the liver, and breakdown of red blood cells in the lung are all thought to contribute to this increase. A serum albumin level of <2.5 g/dL in 30% of cases may indicate malnutrition or may be secondary to sepsis. About 20% of patients have serum sodium concentrations of ≤130 meq/L, and another 20% have serum creatinine concentrations of ≥2 mg/dL. Abnormalities of pleural fluid in empyema are reviewed in Chap. 239.

**Differential Diagnosis** Patients who present with community-acquired pneumonia may actually have infection due to one of many organisms. The extensive list includes the following: *H. influenzae* or *Moraxella catarrhalis* in persons with little to predispose them other than chronic or acute inflammation of the airways; *Staphylococcus aureus* in persons who take glucocorticoids or who have major anatomical disruption of the airways; *Streptococcus pyogenes*; *Neisseria meningitidis*; anaerobic species in persons who have seizures or who may have aspirated oropharyngeal contents for some other reason; *Legionella; Pasteurella multocida* in dog or cat owners; gram-negative bacilli, especially in persons with severely damaged lungs who are taking glucocorticoids; viruses, especially influenza virus (in season), adenovirus, or respiratory syncytial virus; *Mycobacterium tuberculosis*; fungi, including *Pneumocystis* (depending on epidemiologic factors and the possible presence of HIV infection); *Mycoplasma; Chlamydia pneumoniae*, especially in older adults; and *Chlamydia psittaci* in bird owners. Many older men with lung cancer present with pneumonia, as do persons who have acute-onset inflammatory pulmonary conditions of uncertain etiology or those with pulmonary embolus and infarction. The breadth of this list vividly illustrates the deficiency of empirical therapy for community-acquired pneumonia (Table 119-3). Many of these diseases require evaluation, and specific therapy is available for an increasing number. Moreover, pneumococci—perhaps the most common cause of community-acquired pneumonia—are increasingly resistant to available antibiotics. Taken together, these factors favor precise determination of the etiology of a pneumonia syndrome whenever possible.

**Diagnostic Microbiology** An etiologic role for the pneumococcus in pneumonia is strongly suggested by the microscopic demonstration of large numbers of PMNs and slightly elongated gram-positive cocci in pairs and chains in the sputum (Fig. 119-2). Capsules may be seen surrounding the bacterial forms. Examined areas of the slide must be free of buccal epithelial cells, which indicate the admixture of saliva with sputum; saliva may contain viridans streptococci at counts of >10^7/mL. When characteristic microscopic findings are noted, the identification of *S. pneumoniae* in sputum culture strongly indicates pneumococcal infection of the lower respiratory tract. In the absence of such microscopic findings, the identification of pneumococci by culture may be nonspecific, reflecting colonization of the upper airways. Culture is, however, more sensitive than microscopic exami-

![FIGURE 119-1](image)

A retrocardiac infiltrate in a patient with pneumococcal pneumonia. Consolidation is apparent on posterior-anterior view (left) but is better visualized on lateral view of the chest (right).
nation for identifying pneumococci. Since most pneumococci do not produce distinctively mucoid colonies, their identification in the laboratory depends on the ability to select putative pneumococcal colonies for further study from among α-hemolytic streptococci of the mouth. In short, laboratory diagnosis by sputum culture depends on the quality of the specimen provided, the care with which the relevant purulent component is separated for study, and the assiduity with which α-hemolytic colonies are studied. Prior treatment with antibiotics can also rapidly clear pneumococci from sputum. These factors need to be considered when sputum cultures from patients who appear to have pneumococcal pneumonia are said to yield only “normal mouth flora” and when the medical literature describes what appear to be poor results of sputum culture. Because of the central role of microscopic examination in diagnosis, physicians may wish to view the slides with the microbiologist. Blood cultures yield *S. pneumoniae* in ~25% of cases of pneumococcal pneumonia, often within 12 h after the sample is obtained.

**Complications** Empyema is the most common complication of pneumococcal pneumonia, occurring in ~2% of cases. Some fluid appears in the pleural space in a substantial proportion of cases of pneumococcal pneumonia, but this parapneumonic effusion usually reflects an inflammatory response to infection that has been contained within the lung, and its presence is self-limited. When bacteria reach the pleural space—either hematogenously or as a result of contiguous spread, possibly across lymphatics of the visceral pleura—empyema results. The finding of frank pus, a positive result on Gram’s staining, or the presence of fluid with a pH of ≤7.1 indicates the need for aggressive and complete drainage, preferably by prompt insertion of a chest tube, with verification by computed tomography (CT) that fluid has been removed. Failure to drain most or all of the fluid usually indicates the need for thoracotomy. Persistence of fever (even if low-grade) and leukocytosis after 4 or 5 days of appropriate antibiotic treatment for pneumococcal pneumonia suggests empyema. In this setting, the diagnosis is exceedingly likely if the x-ray shows pleural fluid; at this stage, thoracotomy is often needed for cure. Aggressive drainage is likely to reduce morbidity and mortality from empyema (Chap. 245).

**Meningitis** Except during outbreaks of meningococcal infection, *S. pneumoniae* is the most common cause of bacterial meningitis in adults. Because of the remarkable success of *H. influenzae* type b vaccine, *S. pneumoniae* now predominates among cases in infants and toddlers as well (but not among those in newborns). Meningitis develops either by the direct extension of infection from the sinuses or the middle ear or as a result of seeding of meningeal endothelial cells or the choroid plexus during bacteremia. Favoring the former pathogenesis are the association between acute otitis media or sinusitis and meningitis and the role of *S. pneumoniae* as the most common cause of recurrent meningitis associated with head trauma, cerebrospinal fluid (CSF) leak, and/or dural tear. Favoring the latter are the association between pneumococcal bacteremia from any source and meningitis as well as an autopsy study of temporal bone from children who died of bacterial meningitis, which yielded no evidence of extension from the middle ear. In adults, meningitis is usually a complication of bacteremia, which in turn is attributable, in the great majority of cases, to pneumonia.

In the meninges and subarachnoid space, pneumococcal peptidoglycan stimulates an intense inflammatory response mediated by the release of proinflammatory cytokines such as IL-8 and macrophage inflammatory protein (MIP)-1, which are detectable in the CSF of patients with meningitis. The ensuing inflammatory response results in raised intracranial pressure, brain edema, and decreased blood flow leading to meningeal drowsiness, coma. Activated leukocytes migrate across the blood-brain barrier and release matrix metalloproteases and reactive oxygen and nitrogen species that damage neurons. Focal neurologic signs may result from vasculitis with venous or arterial thrombosis, cranial neuropathy due to entrapment or infarction, local cerebritis, subdural effusion, or brain herniation (Chap. 360).

No distinctive clinical or laboratory feature differentiates meningitis due to *S. pneumoniae* from that due to other bacteria. Patients note the sudden onset of fever, headache, and stiffness or pain in the neck. Without treatment, there is a progression over 24 to 48 h to confusion and then obtundation. On physical examination, the patient looks acutely ill and has a rigid neck. In such cases lumbar puncture should not be delayed for CT of the head unless papilledema or focal neurologic signs are evident. Typical CSF findings consist of pleocytosis (500 to 10,000 cells/μL) with ≥85% PMNs, an elevated protein level (100 to 500 mg/dL), and a decrease in glucose content (<30 mg/dL). If antibiotics have not been given, large numbers of pneumococci can be seen in a Gram-stained specimen of CSF in all cases, and specific therapy can be administered, although, because of its similar appearance, *Listeria* may be misidentified as the pneumococcus. If an effective antibiotic has already been given, the number of bacteria may be greatly decreased and microscopic examination of a Gram-stained specimen may yield negative results. In this situation, immunologic methods for the detection of pneumococcal capsule in the CSF may be positive in up to two-thirds of cases, although these methods have fallen out of favor.

**Other Syndromes** The appearance of pneumococcal infection at other, ordinarily sterile body sites indicates hematogenous spread, usually during frank pneumonia or, in a small proportion of cases, from an apparent focus of infection. A case of pneumococcal endocarditis is seen every few years at large tertiary-care hospitals. Purulent periarticular, occurring as a separate entity or together with endocarditis, is even rarer. Septic arthritis can arise spontaneously in a natural or prothetic joint or as a complication of rheumatoid arthritis. Osteomyelitis in adults tends to involve vertebral bones. Pneumococcal peritonitis occurs by one of three pathogenetic pathways: (1) hematogenous spread when ascites or other preexisting peritoneal disease is present; (2) local spread from a perforated viscus (usually appendicitis or perforated ulcer); or (3) transit via the fallopian tubes. Salpingitis may be recognized with or without accompanying peritonitis. Epidural and brain abscesses arise as a complication of sinusitis or mastoiditis. Cel-lulitis develops most often in persons who have connective tissue diseases or HIV infection. The appearance of any of these unusual pneumococcal infections may suggest that tests for HIV infection should be undertaken. Finally, for reasons that are unclear, unencap-
are intermediately susceptible to penicillin [minimal inhibitory concentration (MIC) <0.06 µg/mL]. During the past two decades, an increasing number of isolates have shown some degree of resistance to penicillin. Resistance results when spontaneous mutation or acquisition of new genetic material alters penicillin-binding proteins in a manner that reduces their affinity for penicillin, thereby necessitating a higher concentration of penicillin for their saturation. The genetic information that renders pneumococci resistant to penicillin is generally acquired from oral streptococci and conveys resistance to other antibiotics as well. Selection of antibiotic-resistant strains in the United States—especially in areas of high antibiotic use, such as day-care centers—and importation of strains from other countries where antibiotics are available without prescription have contributed to the prevalence of multidrug resistance.

At present, ~20% of pneumococcal isolates in the United States are intermediately susceptible to penicillin [minimal inhibitory concentration (MIC) 0.1 to 1.0 µg/mL], and 15% are resistant (MIC ≥2.0 µg/mL; Fig. 119-3). These definitions were based on drug levels achievable in CSF during treatment of meningitis, whereas levels reached in the bloodstream, lungs, and sinuses are actually much higher. Thus the MIC needs to be interpreted in light of the infection being treated. Pneumonia caused by a penicillin-resistant strain is likely to respond to 24 million units of penicillin daily, whereas meningitis will not. The recently revised definition of amoxicillin resistance (susceptible, MIC ≤2 µg/mL; intermediately resistant, MIC = 4 µg/mL; resistant, MIC ≥8 µg/mL) is based on serum levels, assuming that no physician would knowingly treat meningitis with this oral medication. Pneumonia due to an intermediately amoxicillin-resistant strain may not respond to treatment with this drug, and that due to a resistant strain is likely not to respond. On the assumption that antibiotic concentrations in middle-ear fluid or sinus cavities approach those in serum, similar inferences can be made about the treatment of otitis or sinusitis.

Penicillin-susceptible pneumococci are susceptible to all commonly used cephalosporins. Penicillin-intermediate strains tend to be resistant to all first- and second-generation cephalosporins (of which cefuroxime retains the best efficacy), but most are susceptible to certain third-generation cephalosporins, including cefotaxime, ceftriaxone, cepafmine, and cefpodoxime. One-half of highly penicillin-resistant pneumococci are also resistant to cefotaxime, ceftriaxone, and cepafmine, and nearly all are resistant to cefpodoxime. Just as in the case of penicillin, susceptibility to cefotaxime and ceftriaxone is defined on the basis of achievable CSF levels. Thus pneumococci caused by intermediately resistant strains (MIC = 2 µg/mL) will respond well to usual doses of these drugs, and pneumococcal meningitis due to a resistant organism (MIC ≥ 4 µg/mL) is likely to respond. Meningitis due to intermediately resistant strains may not respond, and meningitis due to a resistant strain is less likely to respond to treatment with cefotaxime or ceftriaxone.

About one-quarter of all pneumococcal isolates in the United States are resistant to erythromycin and the newer macrolides, including azithromycin and clarithromycin, with much higher rates of resistance in penicillin-resistant strains. This resistance will certainly affect empirical therapy for bronchitis, sinusitis, and pneumonia. In the United States, the majority of macrolide-resistant pneumococci bear the so-called M phenotype (erythromycin MIC = 1 to 8 µg/mL) and are susceptible to clindamycin. In this case, resistance is mediated by an efflux pump mechanism; to some extent, M-type resistance can be overcome by clinically achievable levels of macrolides. In Europe, most macrolide resistance is due to a mutation in ermB, which confers high-level resistance not only to macrolides but also to clindamycin; more than 90% of pneumococcal isolates in the United States are susceptible to clindamycin. Rates of doxycycline resistance among pneumococci of varying susceptibility to penicillin are similar to those observed for macrolides. One-third of pneumococcal isolates exhibit reduced susceptibility to trimethoprim-sulfamethoxazole. The newer fluoroquinolones remain highly effective against pneumococci, with equal efficacy against penicillin-susceptible and -resistant strains; the rate of resistance is generally <1% but approaches 2 to 3% in areas where quinolones are widely used and is increasing. Ketolides appear to be uniformly effective against pneumococci, as does vancomycin, although it is feared that the acquisition of vancomycin resistance by enterococci and other gram-positive bacteria may eventually lead to pneumococcal transformation to resistance. Oxazolidinones and glycopeptides also appear to be effective in vitro, with MICs no higher for drug-resistant S. pneumoniae strains than for penicillin-susceptible strains. Resistance to streptogramins parallels that to macrolides, limiting the usefulness of these drugs for the treatment of pneumonia.

Pneumococcal susceptibility patterns vary greatly between and even within individual communities, and the data are in a state of flux. It does appear, however, that the constant trend is toward more widespread antibiotic resistance.

**Otitis Media and Acute Sinusitis** (Table 119-4) Current treatment recommendations for otitis media and acute sinusitis—conditions whose pathogenesis and microbial etiology are similar—are based on the
There has been increased emphasis on outpatient therapy in patients who are at low risk (as determined by PORT score according to criteria described by the Pneumonia Outcomes Research Team; Chap. 239). This approach appears to be safe. However, if the physician is in doubt about the severity of illness, the social circumstances, or the likelihood of compliance with the prescribed antibiotic regimen, it may be best to hospitalize the patient, at least briefly. Predictions based on PORT score have been validated for pneumococcal pneumonia.

* These regimens are recommended for treatment after a presumptive diagnosis is made on the basis of examination of a Gram-stained sputum sample or as a replacement for more broad-spectrum empirical therapy after a diagnosis of pneumococcal pneumonia is proven by culture. When a valid sputum specimen cannot be obtained, concern for other likely pathogens should prompt the selection of more all-inclusive therapeutic regimens.

† Therapy should continue for 5 days after defervescence, not to exceed 7–10 days total. A switch from parenteral to oral drug administration may be made as soon as the patient can tolerate oral medications.

‡ This regimen is listed more for historic than for practical reasons. The spectrum is overly narrow, although perfectly acceptable if a Gram-stained sputum specimen shows only pneumococci. However, the need for frequent administration, mandated by the short half-life of penicillin, renders this regimen impractical.

§ Usually given in the form of ampicillin/sulbactam.

Not proven to be effective by the extensive clinical experience that applies to the other regimens.

**Pneumonia** (Table 119-5) This section will deal primarily with the treatment of pneumonia that is known to be due to *S. pneumoniae*. The broader issue of empirical therapy for community-acquired pneumonia is covered in detail elsewhere (Chap. 239). However, a few general comments on empirical therapy apply. Without a good sputum sample that can be Gram-stained and examined microscopically, the etiologic agent is not known at the time when treatment needs to be initiated and is not likely to become known later. Empirical therapy in such cases must be effective against *S. pneumoniae*, which remains the most likely causative agent of community-acquired pneumonia, unless epidemiologic, clinical, and radiologic findings strongly favor another etiologic entity. In the past, when pneumococci were uniformly susceptible to nearly all antibiotics, it did not matter which drug was selected. Now that pneumococci are resistant, it clearly makes a difference. If a good sputum sample reveals only organisms consistent with *S. pneumoniae*, therapy can be focused on this organism, although additional treatment may be added for organisms that are not visualized microscopically—e.g., influenza virus in a patient hospitalized during an influenza outbreak. Even if the pneumococcus is suspected, a certain degree of empiricism is required, because the antibiotic susceptibility of the strain involved will not be known for 1 or 2 days.
be treated promptly. Most physicians favor parenteral antibiotics, although oral administration of well-absorbed drugs may be acceptable if the patient is not vomiting or hypotensive. Recommended regimens include ceftriaxone (1 g every 12 to 24 h) or cefotaxime (1 g every 6 to 8 h); the lower doses should suffice except against highly resistant strains. Ampicillin (1 to 2 g every 6 h) is also widely used, usually in the form of ampicillin/sulbactam. Quinolones are effective against all but a small percentage of pneumococcal strains and can be given parenterally or orally. Clindamycin is effective against ~90% of isolates. On the basis of in vitro considerations, vancomycin (500 mg every 6 h) is likely to be uniformly effective against pneumococci, and this drug or a quinolone should be used together with a third-generation cephalosporin for initial therapy in a patient who is likely to be infected with a highly antibiotic-resistant strain or in one who has had a severe allergic reaction to penicillins and cephalosporins. As noted above, there have always been treatment failures unrelated to the antimicrobial susceptibility of the organism; nevertheless, the failure of a patient to respond promptly should raise the question of resistance, and another drug should be given until the susceptibility of the infecting strain has been documented. Of course, evidence for loculated infection for 10 to 14 days. Prolongation of therapy is a two-edged sword, especially in debilitated patients, because the risk of complications increases with each day of antibiotic treatment, particularly in the hospital setting. A few days of close observation and parental therapy followed by an oral antibiotic—with the entire course of treatment continuing for no more than 5 days after the patient becomes afebrile—may be the best approach.

**Meningitis** (Table 119-6) Pneumococcal meningitis should be treated initially with ceftriaxone (1 to 2 g every 12 h) plus vancomycin (500 mg every 6 h or 1 g every 12 h). At this time, studies in experimental animals suggest benefit of the addition of rifampin, but in vitro studies indicate antagonism between this drug and ceftriaxone or vancomycin. This author does not recommend that rifampin be added. Two drugs are given initially because the cephalosporin is likely to be effective against most isolates and readily penetrates the blood-brain barrier, whereas, although all isolates are susceptible to vancomycin, this drug has a somewhat unpredictable capacity to cross the blood-brain barrier. If the isolate is shown to be susceptible or intermediate resistant, treatment can be continued with ceftriaxone, and vancomycin may be discontinued. If the organism is resistant, continued treatment with two drugs is indicated. Cefotaxime (2 g every 6 h) may be used instead of ceftriaxone. Imipenem (500 mg every 6 h) may be used in patients who have had life-threatening reactions to β-lactam antibiotics. As noted above, the author of this chapter does not recommend the addition of rifampin. The total duration of therapy for pneumococcal meningitis is 10 days. Consistent with the central pathogenic role of inflammation in meningitis, a recent study demonstrates clear benefit from the addition of glucocorticoids; heretofore, relevant data were conflicting (Chap. 360). Meningitis should be treated in an intensive care unit and with the participation of appropriate consultants, generally including a neurologist and a specialist in infectious diseases.

**Endocarditis** Pneumococcal endocarditis is associated with rapid destruction of heart valves. Pending results of susceptibility studies, treatment should be initiated with ceftriaxone or cefotaxime; as the prevalence of highly resistant strains increases, it might be prudent to add vancomycin until results of susceptibility studies are available.

* Results of a case-control study involving all cases of invasive pneumococcal disease in Connecticut during 7 years (1984–1990). Vaccinated subjects were matched with controls, and the rate of invasive pneumococcal disease was related to age and time since vaccination. The data, showing protective efficacy, suggest that, within 5 years of vaccination, protection rates decline with age—i.e., from ~90% in persons <65 years of age to ~50% in persons ≥85 years old. Protection also declines with increasing time from vaccination to infection, and this decline is more prominent in older patients.

a serious complication of such an infection. Perhaps most important are those with anatomical or functional asplenia who are at risk for overwhelming, life-threatening infections. Others who might fall within these recommendations are persons (1) over the age of 65; (2) with CSF leak, diabetes mellitus, alcoholism, cirrhosis, chronic renal insufficiency, chronic pulmonary disease, or advanced cardiovascular disease; (3) who have an immunocompromising condition associated with increased risk of pneumococcal disease, such as multiple myeloma, lymphoma, Hodgkin’s disease, HIV infection, organ transplantation, or chronic use of glucocorticoids; (4) who are genetically at increased risk, such as Native Americans and Alaskans; or (5) who live in environments where outbreaks are particularly likely to occur, such as nursing homes.

Recommendations regarding revaccination seem to be somewhat inconsistent. A single revaccination is advocated for persons over the age of 65 if more than 5 years have transpired since the first vaccination. Since antibody levels decline and there is no anamnestic response, it seems more reasonable simply to recommend revaccination at 5-year intervals, especially in persons over the age of 65, who tend to have almost no adverse reaction to vaccination, and in splenectomized patients, who are most in need.

Pneumococcal polysaccharide vaccine is not useful in children <2 years of age, whose immune system does not respond well to polysaccharide antigens. Conjugating the polysaccharide to a protein alters the form in which the antigen is presented to immune-processing cells, yielding an effective immunogen. A heptavalent protein-conjugate pneumococcal polysaccharide vaccine, approved for use in 2000, protects infants and young children against pneumococcal otitis media, pneumonia, bacteremia, and meningitis; efficacy for serotypes contained in the vaccine, which are responsible for about two-thirds of all cases of pneumococcal disease in young children, is 67% for otitis and 97% for bacteremia and meningitis. The rate of nasopharyngeal carriage of vaccine serotypes is also reduced. By its “herd effect” (i.e., the effect on nonvaccinated members of the population), widespread use of this vaccine appears to have decreased the overall incidence of invasive pneumococcal disease in the population. Protein conjugate vaccines that contain antigen from the 11 most common infecting serotypes are being studied. The usefulness of these products may ultimately be limited because they may lead to replacement of serotypes contained in the vaccine with nonvaccine serotypes. Vaccines that contain surface-expressed proteins present in all pneumococci, such as pneumococcal surface protein A (PspA) and surface adhesin A (PsaA), are in the early phases of investigation. Conjugate vaccines do not appear to offer any advantage over polysaccharide vaccine in healthy or diseased adults, although a subpopulation of persons who, on a genetic basis, fail to respond to pneumococcal polysaccharide vaccine may respond to a conjugate vaccine.

**STAPHYLOCOCCAL INFECTIONS**

**Franklin D. Lowy**

*Staphylococcus aureus*, the most virulent of the many staphylococcal species, has demonstrated its versatility by remaining a major cause of morbidity and mortality despite the availability of numerous effective antistaphylococcal antibiotics. *S. aureus* is a pluripotent pathogen, causing disease through both toxin-mediated and non-toxin-mediated mechanisms. This organism is responsible for both nosocomial and community-based infections that range from relatively minor skin and soft tissue infections to life-threatening systemic infections.

The “other” staphylococci, collectively designated *coagulase-negative staphylococci* (CoNS), are considerably less virulent than *S. aureus* but remain important pathogens in selected clinical settings. These include but are not limited to infections associated with prothetic devices.

**MICROBIOLOGY AND TAXONOMY**

The 33 staphylococcal species (with additional staphylococcal species under review) are pathogenic members of the family Micrococaceae. A simple strategy for identification of the more clinically important species is outlined in Fig. 120-1. Automated diagnostic systems as well as kits are available for biochemical characterization of all the staphylococcal species. 16S ribosomal RNA analysis has proved a reliable method for distinguishing among species. With few exceptions, *S. aureus* is distinguished from other staphylococcal species by its production of coagulase, a surface enzyme that converts fibrinogen to fibrin. Most other clinically relevant staphylococci are coagulase-negative. *S. aureus* also ferments mannitol, is positive for protein A, and produces DNase. On blood agar plates, *S. aureus* tends to form golden β-hemolytic colonies; in contrast, CoNS produce white non-hemolytic colonies.

Staphylococci are gram-positive cocci that form grapelike clusters on Gram’s stain (Fig. 120-2). They are catalase-positive (unlike streptococcal species), nonmotile, aerobic, and facultatively anaerobic. These hardy organisms are capable of prolonged survival on environmental surfaces in varying conditions.

Determining whether multiple isolates (especially of CoNS) from a particular patient are the same or different is often an important factor in distinguishing contaminants from genuine pathogens. Determining whether multiple isolates from different patients are the same or different is relevant when there is concern that a nosocomial outbreak may have been due to a common point source (e.g., a contaminated medical instrument). Biochemical tests, often performed in conjunction with antimicrobial susceptibility testing, have been used as a relatively simple means of distinguishing among staphylococcal species or strains. More discriminating molecular typing techniques, such as pulsed-field gel electrophoresis, have also been used for this purpose.

**S. aureus infections**

**EPIDEMIOLOGY** *S. aureus* is a part of the normal human flora. The anterior nares is the most frequent site of human colonization, although the skin (especially when damaged), vagina, axilla, perineum, and oropharynx may also be colonized. Approximately 25 to 50% of healthy persons may be persistently or transiently colonized with *S. aureus*. The rate of colonization is higher among insulin-dependent diabetics, HIV-infected patients, injection drug users, patients under-
going hemodialysis, and individuals with skin damage. Sites of colonization serve as a reservoir of strains for future *S. aureus* infections, and persons colonized with *S. aureus* are at greater risk of subsequent infection (with their colonizing strain) than are uncolonized individuals.

Overall, *S. aureus* is a leading cause of nosocomial infections. It is the most common cause of surgical wound infections and is second only to CoNS as a cause of primary bacteremia. Increasingly, nosocomial isolates are resistant to multiple drugs. In the community, *S. aureus* remains an important cause of skin and soft tissue infections, respiratory infections, and (among injection drug users) infective endocarditis. As the number of patients receiving home infusion therapy increases, so does the number of community-acquired staphylococcal infections.

Several reports have described community-acquired infections (in both rural and urban settings) caused by methicillin-resistant *S. aureus* (MRSA) in individuals with no prior medical exposure. In contrast to hospital-acquired MRSA strains, these community isolates have remained susceptible to many non-β-lactam antibiotics. Of concern has been the apparent capacity of community-acquired MRSA strains to cause serious disease in immunocompetent individuals. This ability may be due to the presence of different toxin-producing genes in these strains as well as the use of β-lactam agents for empirical treatment of patients infected with these strains.

Most individuals who develop *S. aureus* infections do so with their own colonizing strains. However, *S. aureus* may also be acquired from other people or from environmental exposures. Transmission most frequently results from transient colonization of the hands of hospital personnel, who then transfer strains from one patient to another. Spread of staphylococci in aerosols of respiratory or nasal secretions from heavily colonized individuals has also been reported.

**PATHOGENESIS □ General Concepts**  
*S. aureus* is a pyogenic pathogen known for its capacity to induce abscess formation at sites of both local and metastatic infections. This classic pathologic response to *S. aureus* defines the framework within which the infection will progress. The bacteria elicit an inflammatory response characterized by an initial intense polymorphonuclear leukocyte (PMN) response and the subsequent infiltration of macrophages and fibroblasts. Either the host cellular response (including the deposition of fibrin and collagen) contains the infection, or infection spreads to the adjoining tissue or the bloodstream.

In toxin-mediated staphylococcal disease, the clinical infection is not invariably present. For example, once toxin has been elaborated into food, staphylococcal food poisoning can develop in the absence of viable bacteria. In the staphylococcal toxic shock syndrome (TSS), conditions that allow elaboration of toxin at sites of colonization (e.g., the presence of a superabsorbent tampon) are sufficient for initiation of clinical illness.

**The *S. aureus* Genome**  
The entire genome has been sequenced for several strains of *S. aureus*. Among the interesting revelations are the following: (1) There is a high degree of nucleotide sequence similarity among the different strains. (2) A relatively large amount of genetic information is acquired by horizontal transfer from other bacterial species. (3) *S. aureus* contains a number of unique “pathogenicity” or “genomic” islands. These islands are mobile genetic elements that contain clusters of enterotoxin and exotoxin genes or antimicrobial resistance determinants. (4) Among the genes contained in these islands are those carrying mecA, the gene responsible for methicillin resistance. These methicillin resistance–containing islands have been designated *staphylococcal cassette chromosomes* (SCCmec) and range in size from ~20 to 60 kb. To date, four SCCmec types have been identified. The type 4 SCCmec has been associated with the community-acquired MRSA strains that have been responsible for numerous outbreaks.

**Regulation of Virulence Gene Expression**  
In both toxin-mediated and nontoxin-mediated diseases due to *S. aureus*, the expression of virulence determinants associated with infection is dependent on a series of regulatory genes [e.g., accessory gene regulator (agr) and staphylococcal accessory regulator (sar)] that coordinately control the expression of the virulence genes. The regulatory gene agr is part of a quorum-sensing signal transduction pathway that senses and responds to bacterial density. Staphylococcal surface proteins are synthesized during the bacterial exponential growth phase in vitro. In contrast, secreted proteins, such as α toxin, the enterotoxins, and sorted enzymes, are released during the postexponential growth phase.

It has been hypothesized that these regulatory genes serve a similar function in vivo. Successful invasion requires the sequential expression of these different bacterial elements. Bacterial adhesins are needed to initiate colonization of host tissue surfaces. The subsequent release of various enzymes enables the colony to obtain nutritional support and permits bacteria to spread to adjacent tissues. Studies using mutant
strains with these regulatory genes inactivated show reduced virulence in several animal models of *S. aureus* infection.

**Pathogenesis of Invasive *S. aureus* Infection** Staphylococci are opportunists. For these organisms to invade the host and cause infection, some or all of the following steps are necessary: inoculation and local colonization of tissue surfaces, invasion, evasion of the host response, and metastatic spread. The initiation of staphylococcal infection requires a breach in cutaneous or mucosal barriers. Colonizing strains or strains transferred from other individuals are inoculated into damaged skin, a wound, or the bloodstream. Except under these circumstances, staphylococci generally persist as harmless commensals.

In *S. aureus* infections, recurrences develop relatively frequently, apparently because of the capacity of these pathogens to survive, to persist in a quiescent state in various tissues, and then to cause recurrent infections when suitable conditions arise.

**Nasal Colonization** The anterior nares are the principal site of staphylococcal colonization in humans. Surprisingly little is known about the biology of this colonization process. It appears to involve the attachment of *S. aureus* to both nasal mucin and keratinized epithelial cells of the anterior nares. Other factors that may contribute to colonization include the influence of other resident nasal flora and their bacterial density, nasal mucosal damage (e.g., that resulting from inhalational drug use), the antimicrobial properties of nasal secretions, and host genetic factors (e.g., human leukocyte antigen (HLA) type).

**Inoculation and Colonization of Tissue Surfaces** Staphylococci may be introduced into tissue as a result of minor abrasions, administration of medications such as insulin, or establishment of intravenous access with catheters. After their introduction into a tissue site, bacteria replicate and colonize the host tissue surface. A family of structurally related *S. aureus* surface proteins referred to as MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) plays an important role as a mediator of adherence to these sites. MSCRAMMs such as fibronectin-binding protein, clumping factor, and collagen-binding protein enable the bacteria to colonize different tissue surfaces; these proteins contribute to the pathogenesis of invasive infections such as endocarditis and arthritis by facilitating the adherence of *S. aureus* to surfaces with exposed fibronectin, fibrinogen, or collagen.

Although CoNS are classically known for their ability to elaborate a biofilm and colonize prosthetic devices, *S. aureus* also possesses the genes responsible for biofilm formation—the intercellular adhesion (ica) locus. Binding to these devices often involves staphylococcal adherence to serum constituents that have coated the device surface. As a result, *S. aureus* is frequently isolated from biomedical-device infections.

**Invasion** After colonization, staphylococci replicate at the initial site of infection, elaborating enzymes that include serine proteases, hyaluronidases, thermonucleases, and lipases. These enzymes facilitate bacterial survival and local spread across tissue surfaces, although their precise role in infections is still not well defined. The lipases may also facilitate survival in lipid-rich areas such as the hair follicles, where *S. aureus* infections are often initiated. The *S. aureus* toxin Panton-Valentine leukocidin is cytolytic to PMNs, macrophages, and monocytes. Strains elaborating this toxin have been epidemiologically linked with cutaneous infections such as furuncles and carbuncles as well as with serious pulmonary infections in adolescents.

Constitutional findings may result from either localized or systemic infections. The cell wall—consisting of alternating N-acetyl muramic acid and N-acetyl glucosamine units in combination with an additional cell wall component, lipoteichoic acid—can initiate an inflammatory response that includes the sepsis syndrome. Staphylococcal α toxin, which causes pore formation in various eukaryotic cells, can also initiate an inflammatory response with findings suggestive of sepsis.

**Evasion of Host Defense Mechanisms** Evasion of host defense mechanisms is critical to invasion. Staphylococci possess an antiphagocytic polysaccharide microcapsule. Most human *S. aureus* infections are due to capsular types 5 and 8. The *S. aureus* capsule also appears to play an important role in the induction of abscess formation. The capsular polysaccharides are characterized by a zwitterionic charge pattern (the presence of both negatively and positively charged molecules) that is critical to abscess formation. Protein A, an MSCRAMM unique to *S. aureus*, acts as an Fc receptor. This protein can bind the Fc portion of IgG subclasses 1, 2, and 4, preventing opsonophagocytosis by PMNs.

An additional mechanism of *S. aureus* evasion of the host response is its capacity for intracellular survival. Both professional and nonprofessional phagocytes are capable of internalizing staphylococci. Staphylococcal internalization by endothelial cells provides a sanctuary that protects bacteria against the host’s defenses. It also results in cellular changes such as the expression of integrins and Fc receptors that enhance the release of cytokines. These cellular changes may contribute to systemic manifestations of disease, including sepsis and vasculitis.

The intracellular environment favors the phenotypic expression of *S. aureus* small-colony variants. These menadione and hemin auxotrophic mutants are generally deficient in α toxin and are able to persist within endothelial cells. Small-colony variants are often selected after aminoglycoside therapy and are more commonly found in sites of persistent infections (e.g., chronic bone infections) and in respiratory secretions from patients with cystic fibrosis. These variants represent another mechanism for prolonged staphylococcal survival that may enhance the likelihood of recurrences. Finally, *S. aureus* can survive within PMNs and may use these cells to spread and to seed other tissue sites.

**Host Response to *S. aureus* Infection** The primary host response to *S. aureus* infection is the PMN. PMNs are attracted to sites of infection by bacterial components such as formylated peptides or peptidoglycan. These cells are also attracted by the cytokines tumor necrosis factor (TNF) and interleukins (ILs) 1 and 6, which are released by activated macrophages and endothelial cells.

Although most individuals have antistaphylococcal antibodies, it is not clear that the antibody levels are qualitatively or quantitatively sufficient to protect against infection. Anticapsular and anti-MSCRAMM antibodies facilitate opsonization in vitro and have been protective against infection in several animal models.

**Groups at Increased Risk of Infection** Some diseases appear to entail multiple risk factors for *S. aureus* infection; diabetes, for example, entails an increased rate of colonization with *S. aureus*, the use of injectable insulin, and the possibility of impaired leukocyte function. Individuals with congenital or acquired qualitative or quantitative defects in PMNs are at increased risk of *S. aureus* infections; these include neutropenic patients (e.g., those receiving chemotherapeutic agents), individuals with defective intracellular killing of staphylococci (e.g., chronic granulomatous disease), and persons with Job’s syndrome or Chédiak-Higashi syndrome. Other groups at risk include individuals with abnormalities of the skin (e.g., eczema) and those with prosthetic devices.

**Pathogenesis of Toxin-Mediated Disease** *S. aureus* produces three types of toxin: cytotoxins (discussed above), pyrogenic-toxin superantigens, and exfoliative toxins. Both epidemiologic and animal data suggest that the presence of antitoxin antibodies is protective against illness in TSS, staphylococcal food poisoning, and staphylococcal scalded-skin syndrome (SSSS). Illness develops after synthesis and absorption of the toxin followed by the toxin-initiated host response.

**Enterotoxin and Toxic Shock Syndrome Toxin 1 (TSST-1)** The pyrogenic toxin superantigens are a family of small-molecular-size, structurally similar proteins that are responsible for two diseases: TSS and food poisoning. TSS results from the ability of enterotoxins and TSST-1 to function as T cell mitogens. In the normal process of antigen presentation, the antigen is first processed within the cell, and peptides are then presented in the major histocompatibility complex (MHC) class II groove, initiating the measured T cell response. In contrast, enterotoxins bind directly to the invariant region of MHC—outside the MHC class II groove. The enterotoxins can then bind T cell receptors via the vβ motifs and proceed to activate T cells.
chain, resulting in a dramatic overexpansion of T cell clones (up to 20% of the total T cell population).

As a result of this T cell expansion, there is the equivalent of a “cytokine storm,” with the release of inflammatory mediators that include interferon (IFN) γ, IL-1, IL-6, TNF-α, and TNF-β. The result is a multisystem disease that produces a constellation of findings, including myalgias, fever, rash, and hypotension. These findings mimic those found in endotoxin shock; however, the pathogenic mechanisms differ. It has been hypothesized that a contributing factor to TSS is the release of endotoxin from the gastrointestinal tract, which may synergistically enhance the effects of the toxin.

A different region of the enterotoxin molecule is responsible for the symptoms of food poisoning. The enterotoxins are heat stable and can survive conditions that kill the bacteria. Illness results from the ingestion of preformed toxin. As a result, the incubation period is short (1 to 6 h). The toxin stimulates the vagus nerve and the vomiting center of the brain. It also appears to stimulate intestinal peristaltic activity.

Exfoliative Toxins and the Staphylococcal Scalded-Skin Syndrome The exfoliative toxins are responsible for SSSS. The toxins that produce disease in humans have been divided into two serotypes: ETA and ETB. These toxins disrupt the desmosomes that link adjoining cells. Although the mechanism of this disruption remains uncertain, studies suggest that the toxins possess serine protease activity, which—through as-yet-undefined mechanisms—triggers exfoliation. The result is a split in the epidermis at the granular level, and this event is responsible for the superficial desquamation of the skin that typifies this illness.

**DIAGNOSIS** *S. aureus* infections are readily diagnosed by Gram’s stain (Fig. 120-2) and microscopic examination of abscess contents or of infected tissue. Staphylococci appear as large gram-positive cocci that are present singly, in pairs, or in clusters. Routine culture of infected material usually yields positive results, and blood cultures are sometimes positive even when infections are localized to extravascular sites. Polymerase chain reaction (PCR)–based assays have been applied to the rapid diagnosis of *S. aureus* infection and are increasingly being used in clinical microbiology laboratories. To date, serologic assays have not proved useful for the diagnosis of staphylococcal infections. Determining whether patients with documented *S. aureus* bacteremia also have infective endocarditis or a metastatic focus of infection remains a diagnostic challenge (see “Bacteremia, Sepsis, and Infective Endocarditis,” below).

**CLINICAL SYNDROMES** (Table 120-1) ■ Skin and Soft Tissue Infections *S. aureus* causes a variety of cutaneous infections. Common predisposing factors include skin diseases, damage to the skin (e.g., insect bites, minor trauma), injections (e.g., in diabetes, injection drug use), and poor personal hygiene. These infections are characterized by the formation of pus-containing blisters, which often begin in hair follicles and spread to adjoining tissues. *Folliculitis* is a superficial infection that involves the hair follicle, with a central area of purulence (pus) surrounded by induration and erythema. *Furuncles* (boils) are more extensive, painful lesions that tend to occur in hairy, moist regions of the body and extend from the hair follicle to become a true abscess with an area of central purulence. *Carbuncles* are most often located in the lower neck and are even more severe and painful, resulting from the coalescence of other lesions that extend to a deeper layer of the subcutaneous tissue. In general, furuncles and carbuncles are readily apparent, with pus often expressible or discharging from the abscess.

*Mastitis* develops in 1 to 3% of nursing mothers. The infection, which generally presents within 2 to 3 weeks after delivery, is characterized by findings that range from cellulitis to abscess formation. Systemic signs, such as fever and chills, are often present in more severe cases.

Other cutaneous *S. aureus* infections include impetigo, cellulitis, and hidradenitis suppurativa (recurrent follicular infections in regions such as the axilla). *S. aureus* is also one of the most common causes of surgical wound infection.

**Musculoskeletal Infections** *S. aureus* is among the most common causes of bone infections—both those resulting from hematogenous dissemination and those arising from contiguous spread from a soft tissue site. *Hematogenous osteomyelitis* in children most often involves the long bones. Infections present with fever and bone pain or with a child’s reluctance to bear weight. The white blood cell count and erythrocyte sedimentation rate are often elevated. Blood cultures are positive in ~50% of cases. When necessary, bone biopsies for culture and histopathologic examination are usually diagnostic. Routine x-rays may be normal for up to 14 days after the onset of symptoms, *99mTc*-phosphonate scanning often detects early evidence of infection. Magnetic resonance imaging (MRI) is more sensitive than other techniques in establishing a radiologic diagnosis.

In adults, hematogenous osteomyelitis involving the long bones is less common. However, *vertebral osteomyelitis* is among the more common clinical presentations. These infections are most often seen in patients with endocarditis, those undergoing hemodialysis, diabetics, and injection drug users. Vertebral bone infections may present with intense back pain and fever but may also be clinically occult, presenting with chronic back pain and low-grade fever. *S. aureus* is the most common cause of epidural abscess, a complication that can result in neurologic compromise. Patients complain of difficulty voiding or walking and of radicular pain in addition to the symptoms associated with their osteomyelitis. Surgical intervention in this setting often constitutes a medical emergency. MRI most reliably establishes the diagnosis (Fig. 120-3).

Bone infections that result from contiguous spread tend to develop from soft tissue infections, such as those associated with diabetic or vascular ulcers, surgery, or trauma. Exposure of bone, a draining fistulous tract, failure to heal, or continued drainage suggests involvement of underlying bone. Bone involvement is established by bone culture and histopathologic examination. Contamination of culture material from adjacent tissue can make the diagnosis of osteomyelitis difficult in the absence of pathologic confirmation. In addition, it is
Radiologic, and laboratory findings. Ill patients is often difficult and relies on a constellation of clinical, causes of respiratory failure or new pulmonary infiltrates in critically pulmonary infiltrates. Distinguishing bacterial pneumonia from other of purulent sputum and develop respiratory distress, fever, and new infiltrates. Acute right-sided tricuspid valvular S. aureus endocarditis is most often seen in injection drug users. The classic presentation includes a high fever, a toxic clinical appearance, pleuritic chest pain, and the production of purulent (sometimes bloody) sputum. Chest x-rays re-
veal evidence of septic pulmonary emboli (small, peripheral, circular lesions that may cavitate with time). A high percentage of the affected patients have no history of antecedent valvular damage. At the outset of their illness, patients may present with fever alone, without cardiac or other localizing findings. As a result, a high index of clinical suspicion is essential to the diagnosis.

Individuals with antecedent cardiac valvular damage more commonly present with left-sided native-valve endocarditis involving the previously affected valve. These patients tend to be older than those with right-sided endocarditis, their prognosis is worse, and their incidence of complications (including peripheral emboli, cardiac decompensation, and metastatic seeding) is higher.

*S. aureus* is one of the more common causes of prosthetic-valve endocarditis. This infection is especially fulminant in the early post-operative period and is associated with a high mortality rate. In most instances, medical therapy alone is not sufficient and urgent valve replacement is necessary. Patients are prone to develop valvular insufficiency or myocardial abscesses originating from the region of valve implantation.

The increased frequency of nosocomial endocarditis (15 to 30% of cases, depending on the study) reflects in part the increased use of intravascular devices. This form of endocarditis is most commonly caused by *S. aureus*; because patients often are critically ill, are receiving antibiotics for various other indications, and have comorbid conditions, the diagnosis is not easily recognized.

**Urinary Tract Infections** Urinary tract infections are infrequently caused by *S. aureus*. In contrast with that of most other urinary pathogens, the presence of *S. aureus* in the urine is suggestive of hematogenous dissemination. Ascending *S. aureus* infections occasionally result from instrumentation of the genitourinary tract.

**Prosthetic Device–Related Infections** *S. aureus* accounts for a large proportion of prosthetic device–related infections. These infections often involve intravascular catheters, prosthetic valves, orthopedic devices, peritoneal or intraventricular catheters, and vascular grafts. Recently, *S. aureus* isolates have also been responsible for a sizable proportion of infections of left-ventricular-assist devices. In contrast with the more indolent presentation of CoNS infections, *S. aureus* device-related infections often present more acutely, with both localized and systemic manifestations. The latter infections also tend to be more rapidly progressive. It is relatively common for a pyogenic collection to be present at the device site. Aspiration of these collections and performance of blood cultures are important components in establishing a diagnosis. *S. aureus* infections tend to occur more commonly in the early postimplantation period unless the device is used for access (e.g., intravascular or hemodialysis catheters). In the latter instance, infections can occur as long as the device is used. As in most prosthetic-device infections, successful therapy usually involves removal of the device. Left in place, the device is a potential nidus for either persistent or recurrent infections.

**Toxin–Mediated Diseases**

**Toxic Shock Syndrome** TSS was first recognized as a disease in children in 1978. The disease gained national attention in the early 1980s, when a nationwide outbreak occurred among young, otherwise healthy, menstruating women. Epidemiologic investigation demonstrated that these cases were strongly associated with menstruation and the use of a highly absorbent tampon that had recently been introduced to the market. Subsequent studies established the role of TSST-1 in these illnesses. Withdrawal of the tampon from the market resulted in a rapid decline in the incidence of this disease. However, menstrual and nonmenstrual cases continue to be reported.

The clinical presentation is similar in menstrual and nonmenstrual TSS, although the nature of the risk clearly differs. Evidence of a clinical *S. aureus* infection is not a prerequisite for the development of the illness. TSS results from the elaboration of an enterotoxin or the structurally related enterotoxin-like TSST-1. More than 90% of menstrual cases are caused by TSST-1, whereas a high percentage of nonmenstrual cases are caused by enterotoxins.

TSS begins with relatively nonspecific flu-like symptoms. In menstral cases, the onset usually comes 2 or 3 days after the start of menstruation. Patients present with fever, hypotension, and erythroderma of variable intensity. Musculoskeletal involvement is common (e.g., conjunctival hyperemia). The illness can rapidly progress to symptoms that include vomiting, diarrhea, confusion, myalgias, and abdominal pain. These symptoms reflect the multisystemic nature of the disease, with involvement of the liver, kidneys, gastrointestinal tract, and/or central nervous system. Desquamation of the skin occurs during convalescence, usually 1 or 2 weeks after the onset of illness. Laboratory findings may include azotemia, leukocytosis, hyperalimentation, thrombocytopenia, and liver function abnormalities.

Diagnosis of TSS still depends on the presence of a constellation of findings rather than on one specific finding (Table 120-2). Part of the case definition is the absence of laboratory evidence of other illnesses that are often included in the differential (e.g., Rocky Mountain spotted fever, rubeola, leptospirosis). Other diagnoses to be considered are drug toxicities, viral exanthems, sepsis, and Kawasaki disease. Illness occurs only in persons who lack antibody to TSST-1. Recurrences are possible if antibody fails to develop after the illness.

**Food Poisoning** *S. aureus* is among the most common causes of foodborne outbreaks of infection in the United States. *S. aureus* food poisoning results from the inoculation of toxin-producing *S. aureus* into food by colonized food handlers. Toxin is then elaborated in such growth-promoting food as custards, potato salad, or processed meats. Even if the bacteria are killed by warming, the heat-stable toxin is not destroyed. The onset of illness is rapid and explosive, occurring within 1 to 6 h of ingestion. The illness is characterized by nausea and vomiting, although diarrhea, hypotension, and dehydration may also occur.

The differential diagnosis includes diarrhea of other etiologies, especially that caused by similar toxins (e.g., the toxins elaborated by *Bacillus cereus*). The rapidity of onset, the absence of fever, and the epidemic nature of the presentation arouse suspicion regarding this diagnosis. Symptoms generally resolve within 8 to 10 h. The diagnosis can be established by the demonstration of bacteria or the documentation of enterotoxin in the implicated food. Treatment is entirely supportive.

**Staphylococcal Scalded-Skin Syndrome** SSSS most often affects newborns and children. The illness may vary from localized blister formation to exfoliation of much of the skin surface. The skin may be fragile and often tender, with thin-walled, fluid-filled bullae. Gentle pressure results in rupture of the lesions, leaving denuded underlying skin (Ni-

---

**TABLE 120-2 Case Definition of S. aureus Toxic Shock Syndrome**

1. Fever: temperature of ≥38.9°C (≥102°F)
2. Hypotension: systolic blood pressure of ≤90 mmHg, or orthostatic hypotension (orthostatic drop in diastolic blood pressure by ≥15 mmHg, orthostatic syncope, or orthostatic dizziness)
3. Diffuse macular rash with subsequent desquamation in 1 to 2 weeks after onset (including the palms and soles)
4. Multisystem involvement
   a. Hepatic: bilirubin or aminotransferase levels ≥2 times normal
   b. Hematologic: platelet count <100,000/µL
   c. Renal: blood urea nitrogen or serum creatinine level ≥2 times the normal upper limit
   d. Mucous membranes: vaginal, oropharyngeal, or conjunctival hyperemia
   e. Gastrointestinal: vomiting or diarrhea at onset of illness
   f. Muscular: severe myalgias or serum creatine phosphokinase level ≥2 times the upper limit
g. Central nervous system: disorientation or alteration in consciousness without focal neurologic signs and in the absence of fever and hypotension
5. Negative serologic or other tests for measles, leptospirosis, and Rocky Mountain spotted fever as well as negative blood or cerebrospinal fluid cultures for organisms other than *S. aureus*

**Source:** M Wharton et al: Case definitions for public health surveillance. MMWR 39:1, 1990; with permission.
kolsky’s sign; Fig. 120-4). The mucous membranes are usually spared. In more generalized infection, there are often constitutional symptoms, including fever, lethargy, and irritability with poor feeding. Significant amounts of fluid can be lost in more extensive cases. Illness usually follows localized infection at one of a number of possible sites. SSSS is much less common among adults but can follow infections caused by exfoliative toxin—producing strains.

**PREVENTION** Prevention of the spread of *S. aureus* infections in the hospital setting involves hand washing and careful attention to appropriate isolation procedures. Through strict isolation practices, some Scandinavian countries have been remarkably successful at preventing the introduction and dissemination of MRSA in hospitals. Other countries, such as the United States and Great Britain, have been less successful.

The use of topical antimicrobial agents (e.g., mupirocin) to eliminate nasal colonization with *S. aureus* and to prevent subsequent infection has been investigated in a number of clinical settings. Elimination of nasal carriage of *S. aureus* has reduced the incidence of infections among patients undergoing hemodialysis and peritoneal dialysis. A randomized, placebo-controlled study attempted to reduce rates of wound infection among patients undergoing surgery with the prophylactic application of topical mupirocin to the nares. The results failed to demonstrate an overall benefit from the use of mupirocin but did suggest that the incidence of infections might be reduced if the use of mupirocin were limited to patients nasally colonized with *S. aureus*.

The ability of a capsular polysaccharide–protein conjugate vaccine to prevent staphylococcal infections in hemodialysis patients was studied. The results, while inconclusive, did show promise. Other potential vaccine candidates, including those incorporating the ligand-binding domains of several MSCRAMMs, are also under investigation.

**COAGULASE-NEGATIVE STAPHYLOCOCCAL INFECTIONS**

CoNS, although considerably less virulent than *S. aureus*, are among the most common causes of prosthetic-device infections. Approximately half of the 32 identified CoNS species have been associated with human infections. Of these species, *S. epidermidis* is the most common human pathogen overall; this component of the normal human flora is found on the skin (where it is the most abundant bacterial species) as well as in the oropharynx and vagina. *S. saprophyticus*, a novobiocin-resistant species, is a pathogen in urinary tract infections.

**PATHOGENESIS** Among CoNS, *S. epidermidis* is the species most commonly associated with prosthetic-device infections. Infection is a two-step process, with initial adhesion to the device followed by colonization. *S. epidermidis* is uniquely adapted to colonize these devices by its capacity to elaborate the extracellular polysaccharide (slime) that facilitates formation of a protective biofilm on the device surface.

Implanted prosthetic material is often coated with host serum or tissue constituents such as fibrinogen or fibronectin. These molecules serve as potential bridging ligands, facilitating bacterial attachment to the device surface. The surface-associated staphylococcal enzyme autolysin (AtlE) may play a role in attachment to either modified or unmodified prosthetic surfaces. In addition to AtlE, other surface molecules, such as fibrinogen-binding protein and cell wall teichoic acid, appear to mediate adherence to fibrinogen and fibronectin, respectively. The polysaccharide intercellular adhesin facilitates subsequent staphylococcal colonization and accumulation on the device surface. The genes responsible for synthesis of this polysaccharide (the ica genes) are also present in *S. aureus*, although their role in the two species may differ. In *S. epidermidis*, the ica genes are more commonly found in strains associated with device infections than in strains associated with colonization of mucosal surfaces. Biofilm appears to act as a barrier protecting bacteria from host defense mechanisms as well as from antibiotics, while providing a suitable environment for bacterial survival.

Two additional staphylococcal species, *S. lugdunensis* and *S. schleiferi*, produce more serious infections (native-valve endocarditis and osteomyelitis) than do other CoNS. The basis for this enhanced virulence is not known, although both species appear to share more virulence determinants with *S. aureus* (e.g., clumping factor and lipase) than do other CoNS.

The capacity of *S. saprophyticus* to cause urinary tract infections in young women appears to be related to its enhanced capacity to adhere to uroepithelial cells. A 160-kDa hemagglutinin/adhesin may contribute to this affinity.

**DIAGNOSIS** While the detection of CoNS at sites of infection or in the bloodstream is not difficult by standard microbiologic culture methods, interpretation of these results is frequently problematic. Since these organisms are present in large numbers on the skin, they often contaminate cultures. It has been estimated that only 10 to 25% of blood cultures positive for CoNS reflect true bacteremia. Similar problems arise with cultures of other sites. Among the clinical findings suggestive of true bacteremia are fever, evidence of local infection (e.g., erythema or purulent drainage at the intravenous catheter site), leukocytosis, and systemic signs of sepsis. Laboratory findings suggestive of true bacteremia include multiple positive cultures of the same strain (i.e., the same species with the same antibiogram or a closely related DNA fingerprint) from separate cultures, growth of the strain within 48 h, and bacterial growth in both aerobic and anaerobic bottles.

**CLINICAL SYNDROMES** CoNS cause diverse prosthetic device–related infections, including those that involve prosthetic cardiac valves and joints, vascular grafts, intravascular devices, and central nervous system shunts. In all of these settings, the clinical presentation is similar. The signs of localized infection are often subtle, the rate of disease progression is slow, and the systemic findings are often limited. Signs of infection such as purulent drainage, pain at the site, or loosening of prosthetic implants are sometimes evident. Fever is frequently but not always present, and there may be mild leukocytosis.

Infections that are not associated with prosthetic devices are infrequent, although native-valve endocarditis due to CoNS has accounted for ~5% of cases in some reviews. *S. lugdunensis* appears to be a more aggressive pathogen in this setting, causing greater mortality and rapid valvular destruction with abscess formation.

**TREATMENT**

**General Principles of Therapy** In addition to the selection of appropriate antimicrobial therapy for staphylococcal infections, surgical incision and drainage of all supplicative collections are necessary. Prosthetic-device infections are unlikely to be successfully managed unless the device is removed. In the limited number of situations in which re-
organisms in a population) or heterogeneous (i.e., displayed by only a proportion of the total organism population). Detection of methicillin resistance in the clinical microbiology laboratory can be difficult if the strain expresses heterogeneous resistance. Therefore, susceptibility studies are routinely performed at reduced temperatures (30° to 35°C for 24 h), with increased concentrations of salt in the medium to enhance the expression of resistance. In addition to PCR-based techniques, a number of rapid methods for the detection of methicillin resistance have recently been developed.

Vancomycin is the drug of choice for the treatment of methicillin-resistant staphylococcal infections. Because it is less bactericidal than the β-lactams, it should be used only after careful consideration in patients with a history of β-lactam allergies. In 1997, an S. aureus strain with reduced susceptibility to vancomycin (VISA) was reported from Japan. Subsequently, additional clinical isolates of VISA were reported from geographically disparate locations. These strains were all resistant to methicillin and many other antimicrobial agents. The VISA strains appear to evolve (under vancomycin selective pressure) from strains that are susceptible to vancomycin but are heterogeneous, with a small proportion of the bacterial population expressing the resistance phenotype. The mechanism of VISA resistance is uncertain but appears to be an abnormal cell wall, which was first noted by electron microscopy. Vancomycin is trapped by the abnormal peptidoglycan cross-linking and is unable to gain access to its target site.

In 2002, the first clinical isolate of fully vancomycin-resistant S. aureus was reported. Resistance in this and one subsequently reported clinical isolate was due to the presence of \( \text{vanA} \), the gene responsible for expression of vancomycin resistance in enterococci. This observation suggested that resistance was acquired as a result of horizontal conjugal transfer from a vancomycin-resistant strain of \( \text{Enterococcus faecalis} \). The patients had both MRSA and vancomycin-resistant enterococci cultured from sites of infection. The isolates remained susceptible to chloramphenicol, linezolid, minocycline, quinupristin/dalfopristin, and trimethoprim-sulfamethoxazole (TMP-SMX). The \( \text{vanA} \) gene is responsible for the synthesis of the dipeptide D-Ala-D-Lac in place of D-Ala-D-Ala. Vancomycin is not able to bind to the altered peptide.

Alternatives to the β-lactams and vancomycin have less antistaphylococcal activity. Although the quinolones have reasonable in vitro activity against staphylococci, the frequency of fluoroquinolone resistance has increased progressively, especially among methicillin-resistant isolates. Methicillin-susceptible staphylococci have remained more susceptible to the fluoroquinolones than have methicillin-resistant strains. Of particular concern in methicillin-resistant strains is the possible emergence of quinolone resistance during therapy. Resistance to the quinolones is most commonly chromosomal and results from mutations of the topoisomerase IV or DNA gyrase genes, although multidrug efflux pumps may also contribute. While the newer quinolones exhibit increased in vitro activity against staphylococci, it is uncertain whether this increase translates into enhanced in vivo activity. Other antibiotics such as minocycline and TMP-SMX have been successfully used to treat methicillin-resistant staphylococcal infections in the face of vancomycin toxicity or intolerance.

Among the newer antistaphylococcal agents, the parenteral streptogramin quinupristin/dalfopristin displays bactericidal activity against all staphylococci, including VISA strains. This drug has been used successfully to treat serious MRSA infections. In cases of erythromycin or clindamycin resistance, it is bacteriostatic against staphylococci.

Linezolid—one of the first new drug families, the oxazolidinones—is bacteriostatic against staphylococci, has been well tolerated, and offers the advantage of comparable bioavailability after oral or parenteral administration. Cross-resistance with other inhibitors of protein synthesis has not been reported. Resistance to linezolid has been limited, although at least one resistant clinical isolate has been reported. The efficacy of linezolid in the treatment of deep-seated infections such as osteomyelitis has not yet been established. There are currently insufficient data on the efficacy of either quinupristin/dalfopristin or linezolid for the treatment of infective endocarditis. Dap-
tion. Thus blood cultures need to be obtained promptly and followed
ally successful. For other infections, parenteral therapy is indicated.
soft tissue infections, the use of oral antistaphylococcal agents is usu-
using the experimental animal model of endocarditis.
instances, these in vitro observations have been supported by studies
not effective singly because of the frequent emergence of resistance,
(United States). While these agents are
endocarditis), drug combinations are also used to shorten the duration
enhance bactericidal activity in the treatment of serious infections such
new glycopeptide, is undergoing clinical trials.
acrin, a new parenteral bactericidal agent with antistaphylococcal
activity, was recently approved for the treatment of complicated skin
fections. This drug disrupts the cytoplasmic membrane. Oritavancin,
a new glyc peptide, is undergoing clinical trials.
Combinations of antistaphylococcal agents are sometimes used to
hance bactericidal activity in the treatment of serious infections such
endocarditis or osteomyelitis. In selected instances (e.g., right-sided
endocarditis), drug combinations are also used to shorten the duration
of therapy. Among the antimicrobial agents used in combinations are
rifampin, aminoglycosides (e.g., gentamicin), and fusidic acid (which
not readily available in the United States). Quinupristin/dalfopristin is
bactericidal against methicillin-resistant isolates unless the strain is resistant to erythromycin or clindamycin.
The newer quinolones may retain in vitro activity against
prophylaxis-resistant isolates; resistance may develop
during therapy. The efficacy of adj uctive therapy is not well
established in many settings. Both linezolid and quinupristin/dalfopristin have had in vitro activity
against most VISA and VRSA strains. See footnote for
treatment of prosthetic-valve endocarditis.
Resistant to methicillin with intermediate or complete resistance
to vancomycin\(^d\)
Not yet known (i.e.,
empirical therapy)
Vancomycin
(1 g q12h)  
Uncertain  
Same as for methicillin-resistant strains; check antibiotic susceptibilities

by the immediate institution of empirical antimicrobial therapy. For S. aureus
native-valve endocarditis, a combination of antimicrobial
agents is often used. In a large prospective study, an SPRP combined
with an aminoglycoside did not alter the clinical outcome but did re-
duce the duration of S. aureus bacteremia. As a result, many clinicians
begin therapy for life-threatening infections with a 3- to 5-day course
of a \(\beta\)-lactam and an aminoglycoside (gentamicin, 1 mg/kg intra-
venously every 8 h). If a MRSA strain is isolated, vancomycin (30
mg/kg every 24 h, given in two equal doses up to a total of 2 g) is
recommended. Patients are treated for 4 to 6 weeks, depending on the
clinical response.
In prosthetic-valve endocarditis, surgery in addition to antibiotic
therapy is often necessary. The combination of a \(\beta\)-lactam agent—
or, if the isolate is \(\beta\)-lactam resistant, vancomycin (30 mg/kg every 24 h,
given in two equal doses up to a total of 2 g)—with an aminoglycoside
(gentamicin, 1 mg/kg intravenously every 8 h) and rifampin (300 mg
orally every 8 h) is recommended. This combination is used to avoid
the possible emergence of rifampin resistance during therapy if only
two drugs are used.
For hematogenous osteomyelitis or septic arthritis in children, a 4-
week course of therapy is usually adequate: In adults, treatment is often
more prolonged. For chronic forms of osteomyelitis, surgical debride-
ment is necessary in combination with antimicrobial therapy. For joint
fections, a critical component of therapy is the repeated aspiration
or arthroscopy of the affected joint to prevent damage from leukocytes.

Note: TMP-SMX, trimethoprim-sulfamethoxazole; VISA, vancomycin-intermediate S. aureus; VRSA, vancomycin-resistant S. aureus.
The combination of rifampin with ciprofloxacin has been used successfully to treat prosthetic-joint infections, especially when the device cannot be removed. The efficacy of this combination may reflect the enhanced activity against staphylococci in biofilms as well as the attainment of effective intracellular concentrations.

The choice of empirical therapy for staphylococcal infections depends in part on susceptibility data for the local geographic area. Increasingly, vancomycin (in combination with an aminoglycoside or rifampin for serious infections) is the drug of choice for both community- and hospital-acquired infections.

**Therapy for Toxic Shock Syndrome** Supportive therapy with reversal of hypotension is the mainstay of therapy for TSS. Both fluids and pressors may be necessary. Tampons or other packing material should be promptly removed. The role of antibiotics is less clear. Some investigators recommend a combination of clindamycin and a semisynthetic penicillin. Clindamycin is advocated because, as a protein synthesis inhibitor, it reduces toxin synthesis in vitro. A semisynthetic penicillin is suggested to eliminate any potential focus of infection as well as to eradicate persistent carriage that might increase the likelihood of recurrent illness. Anecdotal reports document the successful use of intravenous immunoglobulin to treat TSS. The role of glucocorticoids in the treatment of this disease is uncertain at present.

**Therapy for Other Toxin-Mediated Diseases** Therapy for staphylococcal food poisoning is entirely supportive. For SSSS, antistaphylococcal therapy targets the primary site of infection.
Termed the infections, including necrotizing fasciitis and a systemic syndrome products stimulate specific antibody responses useful in the serodiagnosis of recent streptococcal infection. Tests for these antibodies are used primarily for the detection of preceding streptococcal infection in cases of suspected acute rheumatic fever or poststreptococcal glomerulonephritis.

**Clinical Manifestations**

**Pharyngitis**

Although seen in patients of all ages, group A streptococcal pharyngitis is one of the most common bacterial infections of childhood, accounting for 20 to 40% of all cases of exudative pharyngitis in children; it is rare among those under the age of 3. Younger children may manifest streptococcal infection with a syndrome of fever, malaise, and lymphadenopathy without exudative pharyngitis. Infection is acquired through contact with another individual carrying the organism. Respiratory droplets are the usual mechanism of spread, although other routes, including food-borne outbreaks, have been well described.

The incubation period is 1 to 4 days. Symptoms include sore throat, fever and chills, malaise, and sometimes abdominal complaints and vomiting, particularly in children. Both symptoms and signs are quite variable, ranging from mild throat discomfort with minimal physical findings to high fever and severe sore throat associated with intense erythema and swelling of the pharyngeal mucosa and the presence of purulent exudate over the posterior pharyngeal wall and tonsillar pillars. Enlarged, tender anterior cervical lymph nodes commonly accompany exudative pharyngitis.

The differential diagnosis of streptococcal pharyngitis includes the many other bacterial and viral causes of pharyngitis (Table 121-2). Streptococcal infection is unlikely to be the cause of pharyngitis when symptoms and signs suggestive of viral infection are prominent (conjunctivitis, coryza, cough, hoarseness, or discrete ulcerative lesions of
the buccal or pharyngeal mucosa). Other infections commonly pro-
ducing exudative pharyngitis include infectious mononucleosis and
adenovirus infection. Now rare in the United States, the pseudOMEM-
brane of diphtheria may give a similar appearance. The Coryneform
organism Arcanobacterium haemolyticum may cause pharyngitis, of-
ten in association with a scarlet fever–like rash (Chap. 122). Other
causes of pharyngitis, usually without a purulent exudate, include cow-
sackievirus, influenza virus, mycoplasmas, and Neisseria gonorrhoeae
and acute infection with HIV. Because of the range of clinical pres-
etations of streptococcal pharyngitis and the large number of other
agents that can produce the same clinical picture, diagnosis of strep-
tococcal pharyngitis on clinical grounds alone is not reliable.

The throat culture remains the diagnostic “gold standard.” Culture
of a throat specimen that is properly collected (i.e., by vigorous rub-
ing of a sterile swab over both tonsillar pillars) and properly pro-
cessed is the most sensitive and specific means available to make a
definitive diagnosis. A rapid diagnostic kit for latex agglutination or
enzyme immunoassay of swab specimens can serve as a useful adjunct
to the throat culture. While precise figures on sensitivity and specificity
vary among studies, the rapid diagnostic kits generally are >95% spe-
cific. Thus a positive result can be relied upon for definitive diagnosis
and eliminates the need for a throat culture. However, because the
rapid diagnostic tests are less sensitive than throat culture (with a rela-
tive sensitivity ranging from 55 to 90% in comparative studies), a
negative result should be confirmed with a throat culture.

**TREATMENT**

In the usual course of uncomplicated streptococcal pharyngitis, symp-
toms resolve after 3 to 5 days. The course is shortened little by treat-
ment, which is given primarily to prevent suppurrative complications
and rheumatic fever. Prevention of rheumatic fever depends on eradi-
cation of the organism from the pharynx, not simply on resolution of
symptoms, and requires 10 days of penicillin treatment—either a sin-
gle intramuscular dose of benzathine penicillin G or a 10-day course
of oral penicillin (Table 121-3). Erythromycin may be substituted for
penicillin in the treatment of individuals allergic to penicillin. Once-
daily azithromycin is a more convenient but expensive alternative.

Although azithromycin is approved for a 5-day course of treatment,
only limited data support equivalent efficacy to a standard 10-day treat-
ment course. Resistance to erythromycin and other macrolides is com-
mon in isolates from several countries, including Spain, Italy, Finland,
Japan, and Korea. Macrolide resistance may be becoming more prev-
alent elsewhere with the increasing use of this class of antibiotics. In
areas in which resistance rates exceed 5 to 10%, macrolides should be
avoided unless results of susceptibility testing are known. Follow-up
culture after treatment is no longer routinely recommended but may
be warranted in selected cases, such as those involving patients or
families with frequent streptococcal infections or those occurring in
situations in which the risk of rheumatic fever is thought to be high
(e.g., when cases of rheumatic fever have recently been reported in
the community).

**COMPLICATIONS** Suppurative complications of streptococcal pharyngitis
have become uncommon with the widespread use of antibiotics for
most cases of symptomatic streptococcal infection. The complications
result from the spread of infection from the pharyngeal mucosa to
deeper tissues by direct extension or by the hematogenous or lymph-
atic route and may include cervical lymphadenitis, peritonsillar or
retropharyngeal abscess, sinusitis, otitis media, meningitis, bactere-
emia, endocarditis, and pneumonia. Local complications, such as ab-
scess formation in the peritonsillar or parapharyngeal space, should be
considered in a patient with unusually severe or prolonged symptoms
or localized pain associated with high fever and a toxic appearance.
Nonsuppurative complications include acute rheumatic fever (Chap.
302) and poststreptococcal glomerulonephritis (Chap. 264), both of
which are thought to result from immune responses to streptococcal
infection. Penicillin treatment of streptococcal pharyngitis has been
shown to reduce the likelihood of acute rheumatic fever but not that
of poststreptococcal glomerulonephritis.

**Bacteriologic Treatment Failure and the Asymptomatic Carrier State** Surveillance
culture has shown that up to 20% of individuals in certain
populations may have asymptomatic pharyngeal colonization with
Group A streptococci. There are no definitive guidelines for manage-
ment of these asymptomatic carriers or of asymptomatic individuals
who still have a positive throat culture after a full course of treatment
for symptomatic pharyngitis. A reasonable course of action is to give
a single 10-day course of penicillin for symptomatic pharyngitis and,
if positive cultures persist, not to re-treat unless symptoms recur. Stud-
ies of the natural history of streptococcal carriage and infection have
shown that the risk both of developing rheumatic fever and of trans-
mittting infection to others is substantially lower among asymptomatic
carriers than among individuals with symptomatic pharyngitis. There-
fore, overly aggressive attempts to eradicate carriage are probably not
justified under most circumstances. An exception is the situation in
which an asymptomatic carrier is a potential source of infection to
others. Outbreaks of food-borne infection and nosocomial puerporeal
infection have been traced to asymptomatic carriers who may harbor
the organisms in the throat, on the skin, or in the vagina or anus.

* Penicillin allergy: Erythromycin (10 mg/kg PO qid up to a maximum of 250 mg per dose) may be substituted for oral penicillin. Alternative agents for parenteral therapy include first-generation cephalosporins—if the nature of the allergy is not an immediate hypersensitivity reaction (anaphylaxis or urticaria) or another potentially life-threatening manifestation (e.g., severe rash and fever)—or vancomycin.

* Efficacy unproven, but recommended by several experts. See text for discussion.
action in those with specific immunity. Subsequent studies have suggested that development of the scarlet fever rash may reflect a hypersensitivity reaction requiring prior exposure to the toxin. For reasons that are not clear, scarlet fever has become less common in recent years, although strains of group A streptococci that produce pyrogenic exotoxins continue to be prevalent in the population.

The symptoms of scarlet fever are the same as those of pharyngitis alone. The rash typically begins on the first or second day of illness over the upper trunk, spreading to involve the extremities but sparing the palms and soles. The rash is made up of minute papules, giving a characteristic “sandpaper” feel to the skin. Associated findings include circumoral pallor, “strawberry tongue” (enlarged papillae on a coated tongue, which later may become denuded), and accentuation of the rash in the skin folds (Pastia’s lines). Subsidence of the rash in 6 to 9 days is followed after several days by desquamation of the palms and soles. The differential diagnosis of scarlet fever includes other causes of fever and generalized rash, such as measles and other viral exanthems, Kawasaki disease, toxic shock syndrome, and systemic allergic reactions (e.g., drug eruptions).

Skin and Soft Tissue Infections

Group A streptococci— and occasionally other streptococcal species—cause a variety of infections involving the skin, subcutaneous tissues, muscles, and fascia. While several clinical syndromes, recognized according to the tissues involved, offer a useful means for classification of skin and soft tissue infections, not all cases fit exactly into a single category. The classic syndromes should be considered as general guides to predicting the level of tissue involvement in a particular patient, the probable clinical course, and the likelihood that surgical intervention or aggressive life-support will be required.

IMPEITGO (PYODERMA) Impetigo is a superficial infection of the skin caused primarily by group A streptococci and occasionally by other streptococci or by Staphylococcus aureus. Impetigo is seen most often in young children, tends to occur during the warmer months, and is more common in semitropical or tropical climates than in cooler regions. Infection is more common among children living under conditions of poor hygiene. Prospective studies have shown that colonization of unbroken skin with group A streptococci precedes the development of clinical infection. Minor trauma, such as a scratch or an insect bite, may then serve to inoculate organisms into the skin. Impetigo is best prevented, therefore, by attention to adequate hygiene. The usual sites of involvement are the face (particularly around the nose and mouth) and the legs, although lesions may occur at other locations. Individual lesions begin as red papules, which evolve quickly into vesicular and then pustular lesions that break down and coalesce to form characteristic honeycomb-like crusts (Fig. 121-2). Lesions are generally not painful, and patients do not appear ill. Fever is not a feature of impetigo and, if present, suggests either infection extending to deeper tissues or another diagnosis.

The classic presentation of impetigo usually poses little diagnostic difficulty. Cultures of impetiginous lesions often yield S. aureus as well as group A streptococci. In a prospective study, 86% of patients with group A streptococcal infection had positive throat cultures. Longitudinal studies have shown that, in almost all cases, streptococci can be isolated initially, with staphylococci appearing later, presumably as secondary colonizing flora. In the past, penicillin was nearly always effective against these infections; in recent years, however, penicillin treatment failures have become more common, an observation suggesting that S. aureus infection may have become more prominent as a cause of impetigo. Bullous impetigo due to S. aureus is distinguished from typical streptococcal infection by the presence of more extensive, bullous lesions that break down and leave thin paper-like crusts instead of the thick amber crusts of streptococcal impetigo. Other skin lesions that may be confused with impetigo include herpetic lesions— either those of orolabial herpes simplex or those of chickenpox or zoster. Herpetic lesions can generally be distinguished by their appearance as more discrete, grouped vesicles and by a positive Tzanck test. In difficult cases, cultures of vesicular fluid should yield group A streptococci in impetigo and the responsible virus in Herpesvirus infections.

**TREATMENT**

Treatment of streptococcal impetigo is the same as that for streptococcal pharyngitis. In view of evidence that S. aureus has become a relatively frequent cause of impetigo, empirical regimens should cover both streptococci and S. aureus. For example, either dicloxacillin or cephalaxin can be given at a dose of 250 mg four times daily for 10 days. Topical mupirocin ointment is also effective. Rheumatic fever is not a sequela to streptococcal skin infections, although poststreptococcal glomerulonephritis may follow either skin or throat infection. The reason for this difference is not known. One hypothesis is that the immune response necessary for development of rheumatic fever occurs only after infection of the pharyngeal mucosa. In addition, the strains of group A streptococci that cause pharyngitis are generally of different M protein types than those associated with skin infections; thus the strains that cause pharyngitis may have rheumatogenic potential, while the skin-infecting strains may not.

**FIGURE 121-1** Scarlet fever exanthem. Finely punctated erythema has become confluent (scarlatiform); petechiae can occur and have a linear configuration within the exanthem in body folds (Pastia’s lines). (From Fitzpatrick, Johnson, Wolff: Color Atlas and Synopsis of Clinical Dermatology, 4th ed., New York, McGraw-Hill, 2001, with permission.)

**FIGURE 121-2** Impetigo contagiosa is a superficial streptococcal or Staphylococcus aureus infection consisting of honey-colored crusts and erythematous weeping erosions. Occasionally, bullous lesions may be seen. (Courtesy of Mary Spraker, MD.)
Inoculation of organisms into the skin may lead to infection involving the skin and subcutaneous tissues, or cellulitis. The portal of entry may be a traumatic or surgical wound, an insect bite, or any other break in skin integrity. Often, no entry site is apparent.

One form of streptococcal cellulitis, *erysipelas*, is characterized by a bright red appearance of the involved skin, which forms a plateau sharply demarcated from surrounding normal skin (Fig. 121-3). The lesion is warm to the touch, may be tender, and appears shiny and swollen. The skin often has a *peau d’orange* texture, which is thought to reflect involvement of superficial lymphatics; superficial blebs or bullae may form, usually 2 or 3 days after onset. The lesion typically develops over a few hours and is associated with fever and chills. *Erysipelas* tends to occur in certain characteristic locations: the malar area of the face (often with extension over the bridge of the nose to the contralateral malar region) and the lower extremities. After one episode, recurrence at the same site—sometimes years later—is not uncommon.

Classic cases of *erysipelas*, with the typical features described above, are almost always due to β-hemolytic streptococci, usually those of group A and occasionally those of group C or G. Often, however, the appearance of streptococcal cellulitis is not sufficiently distinctive to permit a specific diagnosis on clinical grounds. The area of involvement may not be one of the typical sites for *erysipelas*, the lesion may be less intensely red than usual and may fade into surrounding skin, and/or the patient may appear only mildly ill. In such cases, it is prudent to broaden the spectrum of empiric antimicrobial therapy to include other pathogens, particularly *S. aureus*, that can produce cellulitis with the same appearance. Staphylococcal infection should be suspected if cellulitis develops around a wound or an ulcer.

Streptococcal cellulitis tends to develop at anatomic sites in which normal lymphatic drainage has been disrupted, such as sites of prior episodes of cellulitis, the arm ipsilateral to a mastectomy and axillary lymph node dissection, a lower extremity previously involved in deep venous thrombosis or chronic lymphedema, or the leg from which a saphenous vein has been harvested for coronary artery bypass grafting. The organism may enter via a breach in the dermal barrier at a location some distance from the eventual site of clinical cellulitis. For example, some patients with recurrent episodes of leg cellulitis following saphenous vein removal stop having recurrent episodes only after treatment of tinea pedis on the affected extremity. Fissures in the skin presumably serve as a portal of entry for streptococci, which then produce infection more proximally in the leg at the site of previous injury. Streptococcal cellulitis may also involve recent surgical wounds. Group A streptococci are among the few bacterial pathogens that typically produce signs of wound infection and surrounding cellulitis within the first 24 h after surgery. These wound infections are usually associated with a thin exudate and may spread rapidly, either as cellulitis in the skin and subcutaneous tissue or as a deeper tissue infection (see below). Streptococcal wound infection or localized cellulitis may also be associated with *lymphangiitis*, manifested by red streaks extending proximally along superficial lymphatics from the site of infection.

**FIGURE 121-3** *Erysipelas* is a streptococcal infection of the superficial dermis and consists of well-demarcated, erythematous, edematous, warm plaques.

**TREATMENT**

See Table 121-3 and Chap. 110.

**Deep Soft-Tissue Infections** Necrotizing fasciitis, also referred to as *hemolytic streptococcal gangrene*, is an infection involving the superficial and/or deep fascia investing the muscles of an extremity or the trunk. The source of the infection is either the skin, with organisms introduced into the tissue as a result of trauma (sometimes trivial), or the bowel flora, with organisms released during abdominal surgery or from an occult enteric source, such as a diverticular or appendiceal abscess. The site of inoculation in both forms of necrotizing fasciitis may be inapparent and is often some distance from the site of clinical involvement; e.g., the introduction of organisms via minor trauma to the hand may be associated with clinical infection of the tissues overlying the shoulder or chest. In cases associated with the bowel flora, the infection is usually polymicrobial, involving a mixture of anaerobic bacteria (such as *Bacteroides fragilis* or anaerobic streptococci) and facultative organisms (usually gram-negative bacilli). Cases unrelated to contamination from bowel organisms are most commonly caused by group A streptococci, either alone or in combination with other organisms (most often *S. aureus*). Overall, group A streptococci are implicated in about 60% of cases of necrotizing fasciitis. The onset of symptoms is usually quite acute and is marked by severe pain at the site of involvement, malaise, fever, chills, and a toxic appearance. The physical findings, particularly early in the illness, may not be striking, with only minimal erythema of the overlying skin. Pain and tenderness are usually severe; in contrast, in more superficial cellulitis, the skin appearance is more abnormal, but pain and tenderness are only mild or moderate. As the infection progresses (often in a matter of several hours), the severity and extent of symptoms worsen, and skin changes become more evident, with the appearance of dusky or mottled erythema and edema. The marked tenderness of the involved area may evolve into anesthesia as the spreading inflammatory process produces infarction of cutaneous nerves.

Although myositis is more commonly due to *S. aureus* infection, group A streptococci occasionally produce abscesses in skeletal muscles (*streptococcal myositis*), with little or no involvement of the surrounding fascia or overlying skin. The presentation is usually subacute, but a fulminant form has been described in association with severe systemic toxicity, bacteremia, and a high mortality rate. The fulminant form may reflect the same basic disease process as that seen in necrotizing fasciitis, but with the necrotizing inflammatory process extending into the muscles themselves rather than remaining limited to the fascial layers.

Once necrotizing fasciitis is suspected, early surgical exploration is both diagnostically and therapeutically indicated. Surgery reveals necrosis and inflammatory fluid tracking along the fascial planes above and between muscle groups, without involvement of the muscles themselves. The process usually extends beyond the area of clinical involvement, and extensive debridement is required. Drainage and debridement are central to the management of necrotizing fasciitis; antibiotic treatment is a useful adjunct (Table 121-3), but surgery is life-saving.

Treatment for streptococcal myositis consists of surgical drainage—usually by an open procedure that permits evaluation of the extent of the infection and ensures adequate debridement of involved tissues—and high-dose penicillin (Table 121-3).

**Pneumonia and Empyema** Group A streptococci are an occasional cause of pneumonia, generally in previously healthy individuals. The onset of symptoms may be abrupt or gradual. Pleuritic chest pain, fever, chills, and dyspnea are the characteristic symptoms. Cough is usually present but may not be prominent. Approximately one-half of patients...
with group A streptococcal pneumonia have an accompanying pleural effusion. In contrast to the sterile parapneumonic effusions typical of pneumococcal pneumonia, those complicating streptococcal pneumonia are almost always infected. The empyema fluid is usually visible by chest radiography on initial presentation and may enlarge rapidly. These pleural collections should be drained early, as they tend to become loculated rapidly, resulting in a chronic fibrotic reaction that may require thoracotomy for removal.

**Bacteremia, Puerperal Sepsis, and Streptococcal Toxic Shock Syndrome**

Group A streptococcal bacteremia is usually associated with an identifiable local infection. Bacteremia occurs rarely with otherwise uncomplicated pharyngitis, occasionally with cellulitis or pneumonia, and relatively frequently with necrotizing fasciitis. Bacteremia without an identified source raises the possibility of endocarditis, an occult abscess, or osteomyelitis. A variety of focal infections may arise secondarily from streptococcal bacteremia, including endocarditis, meningitis, septic arthritis, osteomyelitis, peritonitis, and visceral abscesses.

Group A streptococci are occasionally implicated in infectious complications of childbirth, usually endometritis and associated bacteremia. In the preantibiotic era, puerperal sepsis was commonly caused by group A streptococci, but currently it is more often caused by group B streptococci. Several nosocomial outbreaks of puerperal infection due to group A streptococci have been traced to an asymptomatic carrier, usually an individual present at the delivery of the infant. The site of carriage may be the skin, throat, anus, or vagina.

Beginning in the late 1980s, several reports described patients who had group A streptococcal infections associated with shock and multisystem organ failure. This syndrome has been called the streptococcal toxic shock syndrome (TSS) because it shares certain features with staphylococcal TSS. In 1993, a case definition for group A streptococcal TSS was formulated by a group of clinicians, microbiologists, and epidemiologists in conjunction with the CDC (Table 121-4). The general features of the illness include fever, hypotension, renal impairment, and respiratory distress syndrome. Various types of rash have been described, but rash usually does not develop. Laboratory abnormalities include a marked shift to the left in the white blood cell differential, with many immature granulocytes; hypocalcemia; hypoalbuminemia; and thrombocytopenia, which usually becomes more pronounced on the second or third day of illness. In contrast to those with staphylococcal TSS, the majority of patients with streptococcal TSS are bacteremic. The most common associated infection is a soft tissue infection—necrotizing fasciitis, myositis, or cellulitis—although a variety of other associated local infections have been described, including pneumonia, peritonitis, osteomyelitis, and myonecrosis. Streptococcal TSS is associated with a mortality rate of 30%, with most deaths secondary to shock and respiratory failure. Because of its rapidly progressive and lethal course, early recognition of the syndrome is essential. Patients should be given aggressive supportive care in the form of fluid resuscitation, pressors, and mechanical ventilation in addition to antimicrobial therapy and, in cases associated with necrotizing fasciitis, surgical debridement. Exactly why certain patients develop this fulminant syndrome is not known. Early studies of the streptococcal strains isolated from these patients demonstrated a strong association with the production of pyrogenic exotoxin A. This association has been inconsistent in subsequent cases series. Pyrogenic exotoxin A and several other streptococcal exotoxins act as superantigens to trigger release of inflammatory cytokines from T lymphocytes. Fever, shock, and organ dysfunction in streptococcal TSS may reflect, in part, the systemic effects of superantigen-mediated cytokine release.

### Treatment

In light of the possible role of pyrogenic exotoxins or other streptococcal toxins in streptococcal TSS, treatment of the affected patients with clindamycin has been advocated by some authorities, who argue that, through its direct action on protein synthesis, clindamycin is more effective in rapidly terminating toxin production than penicillin—a cell-wall agent (Table 121-3). Support for this view comes from studies of an experimental model of streptococcal myositis, in which mice treated with clindamycin had a higher rate of survival than those given penicillin. Comparable data on the treatment of human infections are not available. Although clindamycin resistance in group A streptococci is uncommon (<2% among U.S. isolates), it has been documented. Thus, if clindamycin is used for initial treatment of a critically ill patient, penicillin should be given as well until the antibiotic susceptibility of the streptococcal isolate is known.

Intravenous immunoglobulin has been used as adjunctive therapy for streptococcal TSS; pooled immunoglobulin preparations contain antibodies capable of neutralizing the effects of streptococcal toxins (Table 121-3). Anecdotal reports and case series have suggested favorable clinical responses to intravenous immunoglobulin, but no prospective controlled trials of this modality of therapy have yet been reported.

### Streptococci of Groups C and G

Group C and group G streptococci are β-hemolytic bacteria that occasionally cause human infections similar to those caused by group A streptococci, including pharyngitis, cellulitis and soft-tissue infections, pneumonia, bacteremia, endocarditis, and septic arthritis. Puerperal sepsis, meningitis, epidural abscess, intraabdominal abscess, urinary tract infection, and neonatal sepsis have also been reported. Group C streptococci are a common cause of infection in domesticated animals, especially horses and cattle, and some human infections have been acquired through contact with animals or through consumption of unpasteurized milk. Bacteremia and septic arthritis more frequently involve group G than group C streptococci. Group C or G streptococcal bacteremia occurs most often in patients who are elderly or chronically ill and, in the absence of an obvious local infection, is likely to reflect endocarditis. Septic arthritis, sometimes involving multiple joints, may complicate endocarditis or develop in its absence.

### TABLE 121-4 Proposed Case Definition for the Streptococcal Toxic Shock Syndrome

| I. Isolation of group A streptococci (Streptococcus pyogenes) |
|---|---|
| A. From a normally sterile site (e.g., blood, cerebrospinal fluid, pleural or peritoneal fluid, tissue biopsy, surgical wound) |
| B. From a nonsterile site (e.g., throat, sputum, vagina, superficial skin lesion) |
| II. Clinical signs of severity |
| A. Hypotension: Systolic blood pressure of ≤90 mmHg in adults or in the 5th percentile for age in children and |
| B. Two or more of the following signs: |
| 1. Renal impairment: Serum creatinine level of ≥177 μmol/L (≥2 mg/dL) for adults or at least twice the upper limit of normal for age; in patients with preexisting renal disease, elevation over baseline by a factor of at least 2 |
| 2. Coagulopathy: Platelet count of ≤100 × 10^9/L (100,000/μL) or disseminated intravascular coagulation, defined by prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products |
| 3. Liver involvement: Alanine aminotransferase (SGOT), aspartate aminotransferase (SGPT), or total bilirubin level at least twice the upper limit of normal for age; in patients with preexisting liver disease, elevation over baseline by a factor of at least 2 |
| 4. Adult respiratory distress syndrome, defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure; or evidence of diffuse capillary leak manifested by acute onset of generalized edema; or pleural or peritoneal effusions with hypoalbuminemia |
| 5. Generalized erythematous macular rash that may desquamate |
| 6. Soft tissue necrosis, including necrotizing fasciitis or myositis; or gangrene |

* An illness fulfilling criteria IA, IIA, and IIB is defined as a definite case. An illness fulfilling criteria IB, IIA, and IIB is defined as a probable case if no other etiology for the illness is identified.

Penicillin is the drug of choice for treatment of infections due to group C or G streptococci. Antibiotic treatment is the same as for patients with similar syndromes due to group A Streptococcus (Table 121-3). Patients with bacteremia or septic arthritis should receive intravenous penicillin (2 to 4 μg/kg every 4 h). All group C and G streptococci are sensitive to penicillin; nearly all are inhibited in vitro by concentrations of ≤0.03 μg/mL. Occasional isolates exhibit tolerance: although inhibited by low concentrations of penicillin, they are killed only by significantly higher concentrations. The clinical significance of tolerance is unknown. Because of the poor clinical response of some patients to penicillin alone, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) is recommended by some authorities for treatment of endocarditis or septic arthritis due to group C or G streptococci; however, combination therapy has not been shown to be superior to treatment with penicillin alone. Patients with joint infections often require repeated aspiration or open drainage and debridement for cure; the response to treatment may be slow, particularly in debilitated patients and those with involvement of more than one joint. Infection of prosthetic joints almost always requires removal of the prosthesis in addition to antibiotic therapy.

GROUP B STREPTOCOCCI
Identified first as a cause of mastitis in cows, streptococci belonging to Lancefield’s group B have since been recognized as a major cause of sepsis and meningitis in human neonates. Group B streptococci are also a frequent cause of peripartum fever in women and an occasional cause of serious infection in nonpregnant adults. Lancefield group B consists of a single species, *S. agalactiae*, which is definitely identified with specific antiserum to the group B cell wall–associated carbohydrate antigen. A streptococcal isolate can be classified presumptively as belonging to group B on the basis of biochemical tests, including hydrolysis of sodium hippurate (in which 99% of isolates are positive), hydrolysis of bile esculin agar (in which 99 to 100% are negative), bacitracin susceptibility (in which 92% are resistant), and production of CAMP factor (in which 98 to 100% are positive). CAMP factor is a phospholipase produced by group B streptococci that results in synergistic hemolysis with β-lysin produced by certain strains of *S. aureus*. Its presence can be demonstrated by cross-streaking of the test isolate and an appropriate staphylococcal strain on a blood agar plate. Group B streptococci causing human infections are encapsulated by one of nine antigenically distinct polysaccharides. The capsular polysaccharide has been shown experimentally to be important in the virulence of the organism. Antibodies to the capsular polysaccharide afford protection against group B streptococci of the same (but not of a different) capsular type.

INFECTION IN NEONATES
Two general types of group B streptococcal infection in infants are defined by the age of the patient at presentation. Early-onset infections occur within the first week of life, with a median age of 20 h at the onset of illness. Approximately half of these infants have signs of group B streptococcal disease at birth. The infection is acquired during or shortly before birth from organisms colonizing the maternal genital tract. Surveillance studies have shown that 5 to 40% of women are vaginal or rectal carriers of group B streptococci. Approximately 50% of infants delivered vaginally by carrier mothers become colonized, although only 1 to 2% of those colonized develop clinically evident infection. Prematurity and maternal risk factors (prolonged labor, obstetric complications, and maternal fever) are often involved. The presentation of early-onset infection is the same as that of other forms of neonatal sepsis. Typical findings include respiratory distress, lethargy, and hypotension. Essentially all infants with early-onset disease are bacteremic, one-third to one-half have pneumonia and/or respiratory distress syndrome, and one-third have meningitis.

Late-onset infections occur in infants between 1 week and 3 months of age, with a mean age at onset of 3 to 4 weeks. The infecting organism may be acquired during delivery (as in early-onset cases) or during later contact with a colonized mother, nursery personnel, or another source. Meningitis is the most common manifestation of late-onset infection and in most cases is associated with a strain of capsular type III of the organism. Infants present with fever, lethargy or irritability, poor feeding, and seizures. The various other types of late-onset infection include bacteremia without an identified source, osteomyelitis, septic arthritis, and facial cellulitis associated with submandibular or preauricular adenitis.

**Prevention**
The incidence of group B streptococcal infection is usually high among infants of women with risk factors: preterm delivery, early rupture of membranes (>24 h before delivery), prolonged labor, fever, or chorioamnionitis. Because the usual source of the organisms infecting a neonate is the mother’s birth canal, efforts have been made to prevent group B streptococcal infections by the identification of high-risk carrier mothers and their treatment with various forms of antibiotic or immunophrophylaxis. Prophylactic administration of ampicillin or penicillin to such patients during delivery has been shown to reduce the risk of infection in the newborn. This approach has been hampered by the logistical difficulties of identifying colonized women before delivery, since the results of vaginal cultures early in pregnancy are poor predictors of carrier status at delivery. The CDC has recommended that women be screened for anogenital colonization at 35 to 37 weeks of pregnancy by means of a swab culture of the lower vagina and anorectum; intrapartum chemoprophylaxis is recommended for women who are culture-positive and to all women, regardless of culture status, who have previously given birth to an infant with group B streptococcal infection or who have a history of group B streptococcal bacteruria during pregnancy. Women whose culture status is unknown and who develop premature labor (<37 weeks), prolonged rupture of membranes (>18 h), or intrapartum fever should also receive intrapartum chemoprophylaxis. The recommended regimen for chemoprophylaxis is 5 million units of penicillin G followed by 2.5 million units every 4 h until delivery. Cefazolin is an alternative for women with a history of penicillin allergy who are thought not to be at high risk for anaphylaxis. For women with a history of an immediate hypersensitivity reaction, clindamycin or erythromycin may be substituted, but only if the colonizing isolate has been demonstrated to be susceptible. If susceptibility testing results are not available or indicate resistance, vancomycin should be used in this situation.

Treatment of all pregnant women who are colonized or who have risk factors for neonatal infection will result in exposure of 15 to 25% of pregnant women and newborns to antibiotics, with the attendant risks of allergic reactions and selection for resistant organisms. Although still in the developmental stages, a group B streptococcal vaccine may ultimately offer a better solution to prevention. Because transplacental passage of maternal antibodies produces protective antibody levels in the newborn, efforts are under way to develop a vaccine against group B streptococci that can be given to childbearing women before or during pregnancy. Results of phase 1 clinical trials of group B streptococcal capsular polysaccharide–protein conjugate vaccines suggest that a multivalent conjugate vaccine would be safe and highly immunogenic.
INFECTION IN ADULTS The majority of group B streptococcal infections in adults are related to pregnancy and parturition. Peripartum fever, the most common manifestation, is sometimes accompanied by symptoms and signs of endometritis or chorioamnionitis (abdominal distention and uterine or adnexal tenderness). Blood cultures are often positive, as are cultures of vaginal swabs. Bacteremia is usually transitory but occasionally results in meningitis or endocarditis. Infections in adults that are not associated with the peripartum period generally involve individuals who are elderly or have some underlying chronic illness, such as diabetes mellitus or a malignancy. Among the infections that develop with some frequency in adults are cellulitis and soft tissue infection (including infected diabetic skin ulcers), urinary tract infection, pneumonia, endocarditis, and septic arthritis. Other reported infections include meningitis, osteomyelitis, and intraabdominal or pelvic abscesses.

TREATMENT

Group B streptococci are less sensitive to penicillin than group A organisms, requiring somewhat higher doses. Adults with serious localized infections (pneumonia, pyelonephritis, abscess) should receive doses in the range of 12 million units of penicillin G daily, while patients with endocarditis or meningitis should receive 18 to 24 million units per day in divided doses. Vancomycin is an acceptable alternative for patients allergic to penicillin.

ENTEROCOCCI AND NONENTEROCOCCAL GROUP D STREPTOCOCCI

ENTEROCOCCI Lancefield group D includes the enterococci, organisms now classified in a separate genus from other streptococci, and nonenterococcal group D streptococci. Enterococci are distinguished from nonenterococcal group D streptococci by their ability to grow in the presence of 6.5% sodium chloride and by the results of other biochemical tests. The enterococcal species that are significant pathogens for humans are _E. faecalis_ and _E. faecium_. These organisms tend to produce infection in patients who are elderly or debilitated or in whom mucosal or epithelial barriers have been disrupted or the balance of the normal flora altered by antibiotic treatment. Urinary tract infections due to enterococci are quite common, particularly among patients who have received antibiotic treatment or undergone instrumentation of the urinary tract. Enterococci are a frequent cause of nosocomial bacteraemia in patients with intravascular catheters. These organisms account for 10 to 20% of cases of bacterial endocarditis on both native and prosthetic valves. The presentation of enterococcal endocarditis is usually subacute but may be acute, with rapidly progressive valve destruction. Enterococci are frequently cultured from bile and are involved in infectious complications of biliary surgery and in liver abscesses. Moreover, enterococci are often isolated from polymicrobial infections arising from the bowel flora (e.g., intraabdominal abscesses), from abdominal surgical wounds, and from diabetic foot ulcers. While such infections are arising from the bowel flora (e.g., intraabdominal abscesses), from abdominalsurgicalwounds, and from diabeticfootulcers. Whilesuch infections are due to enterococci are quite common, particularly among patients who are elderly or debilitated or in whom mucosal or epithelial barriers have been disrupted or the balance of the normal flora altered by antibiotic treatment. Urinary tract infections due to enterococci are quite common, particularly among patients who have received antibiotic treatment or undergone instrumentation of the urinary tract. Enterococci are a frequent cause of nosocomial bacteraemia in patients with intravascular catheters. These organisms account for 10 to 20% of cases of bacterial endocarditis on both native and prosthetic valves. The presentation of enterococcal endocarditis is usually subacute but may be acute, with rapidly progressive valve destruction. Enterococci are frequently cultured from bile and are involved in infectious complications of biliary surgery and in liver abscesses.

Unlike streptococci, enterococci are not reliably killed by penicillin or ampicillin alone at concentrations achieved clinically in the blood or tissues. Ampicillin reaches sufficiently high urinary concentrations to constitute adequate monotherapy for uncomplicated urinary tract infections. Because in vitro testing has shown evidence of synergistic killing of most enterococcal strains by the combination of penicillin or ampicillin with an aminoglycoside, combined therapy is recommended for enterococcal endocarditis and meningitis; the regimen is penicillin (3 to 4 million units every 4 h) or ampicillin (2 g every 4 h) plus moderate-dose gentamicin (1 mg/kg every 8 h for patients with normal renal function). Enterococcal endocarditis should be treated for a minimum of 4 weeks and for 6 weeks if symptoms have been present for $\geq 3$ months or if the infection involves a prosthetic heart valve. For nonendocarditis bacteremia and other serious enterococcal infections, it is not known whether the efficacy of single-agent $\beta$-lactam therapy is improved by the addition of gentamicin, but many infectious disease specialists use combination therapy for such infections, especially in critically ill patients. Vancomycin, in combination with gentamicin, may be substituted for penicillin in allergic patients. Enterococci are resistant to all cephalosporins; therefore, this class of antibiotics should not be used for treatment of enterococcal infections.

Antimicrobial susceptibility testing should be performed routinely on enterococcal isolates from patients with serious infections, and therapy should be adjusted according to the results (Table 121-5). Most enterococci are resistant to streptomycin, and this drug should not be used for treatment of enterococcal infection unless in vitro testing of the strain indicates susceptibility. Though less widespread than streptomycin resistance, high-level resistance to gentamicin—with a minimum inhibitory concentration (MIC) of $>2000 \mu g/mL$—has become common. Gentamicin-resistant enterococci should be tested for susceptibility to streptomycin; occasional gentamicin-resistant enterococci are sensitive to streptomycin. If the isolate is resistant to all aminoglycosides, treatment with penicillin or ampicillin alone may be successful. The prolonged administration (i.e., for at least 6 weeks) of high-dose ampicillin (e.g., 12 g/d) is recommended for endocarditis due to these highly resistant enterococci.

Enterococci may be resistant to penicillins via two distinct mechanisms. The first is the production of $\beta$-lactamase (mediating resistance to penicillin and ampicillin), which has been reported for _E. faecalis_ isolates from several locations in the United States and other countries. Because the amount of $\beta$-lactamase produced by enterococci may be insufficient for detection by routine antibiotic susceptibility testing, isolates from serious infections should be screened specifically for $\beta$-lactamase production with use of a chromogenic cephalosporin or by another method. For the treatment of $\beta$-lactamase-producing strains, vancomycin, ampicillin/sulbactam, amoxicillin/clavulanate, or imipenem may be used in combination with gentamicin.

The second mechanism of penicillin resistance is not mediated by $\beta$-lactamase and may be due to altered penicillin-binding proteins. This intrinsic penicillin resistance is common among _E. faecium_ isolates, which routinely are more resistant to $\beta$-lactam antibiotics than are isolates of _E. faecalis_. Moderately resistant enterococci (MICs of penicillin and ampicillin, 16 to 64 $\mu g/mL$) may be susceptible to high-dose penicillin or ampicillin plus gentamicin, but strains with MICs of $\geq 200 \mu g/mL$ must be considered resistant to clinically achievable levels of $\beta$-lactam antibiotics, including imipenem. Vancomycin plus gentamicin is the recommended regimen for infections due to enterococci with high-level intrinsic resistance to $\beta$-lactams.

Vancomycin-resistant enterococci, first reported from clinical sources in the late 1980s, have become common in many hospitals.

</table>
Three major vancomycin resistance phenotypes have been described: VanA, VanB, and VanC. The VanA phenotype is associated with high-level resistance to vancomycin and to teicoplanin, a related glycopeptide antibiotic not currently available in the United States. VanB and VanC strains are resistant to vancomycin but susceptible to teicoplanin, although teicoplanin resistance may develop during treatment in VanB strains. For enterococci resistant to both vancomycin and β-lactams, there are no established therapies that provide uniformly bactericidal activity. Regimens that have been tried with some success in individual cases or experimentally include ciprofloxacin plus rifampin plus gentamicin; ampicillin plus vancomycin (particularly if in vitro testing shows synergistic bacteriostatic activity); and chloramphenicol or tetracycline (if the strain is susceptible in vitro). Two newer agents with activity against vancomycin-resistant enterococci are quinupristin/dalfopristin and linezolid, which were approved for use in the United States in 1999 and 2000, respectively. Quinupristin/dalfopristin is a streptogramin combination with in vitro bacteriostatic activity against *E. faecium*, including vancomycin-resistant isolates, but not against *E. faecalis* or other enterococcal species.

**TREATMENT**

Isolates from neutropenic patients with bacteremia are often resistant to penicillin; thus these patients should be treated presumptively with vancomycin until the results of susceptibility testing become available. Viridans streptococci isolated in other clinical settings usually are sensitive to penicillin.

**ABIOTROPHIA SPECIES (NUTRITIONALLY VARIANT STREPTOCOCCI)**

Occasional isolates cultured from the blood of patients with endocarditis fail to grow when subcultured on solid media. These *nutritionally variant streptococci* require supplemental thiol compounds or active forms of vitamin B₆ (pyridoxal or pyridoxamine) for growth in the laboratory. The nutritionally variant streptococci are generally grouped with the viridans streptococci because they cause similar types of infections. However, they have been reclassified on the basis of 16S ribosomal RNA sequence comparisons into a separate genus, *Abiotrophia*, with two species: *A. defectivus* and *A. adjacens*.

**TREATMENT**

Treatment failure and relapse appear to be more common in cases of endocarditis due to nutritionally variant streptococci than in those due to the usual viridans streptococci. Thus the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) to the penicillin regimen is recommended in therapy for endocarditis due to the nutritionally variant organisms.

**OTHER STREPTOCOCCI**

*S. suis* is an important pathogen in swine and has been reported to cause meningitis in humans, usually in individuals with occupational exposure to pigs. Strains of *S. suis* associated with human infections have generally reacted with Lancefield group R typing serum and sometimes with group D typing serum as well. Isolates may be α- or β-hemolytic and are sensitive to penicillin. *S. iniae*, a pathogen of fish, has been associated with infections in humans who have handled live or freshly killed fish. Cellulitis of the hand is the most common form of human infection, although bacteremia and endocarditis have been reported. *Anaerobic streptococci*, or *peptostreptococci*, are part of the normal flora of the oral cavity, bowel, and vagina. Infections caused by the anaerobic streptococci are discussed in Chap. 148.

**FURTHER READING**

DEFINITION  
Diphtheria is a localized infection of mucous membranes or skin that is caused by Corynebacterium diphtheriae and may be associated with a characteristic pseudomembrane at the site of infection (Fig. 122-1). Some strains of C. diphtheriae produce diphtheria toxin, a protein that can cause myocarditis, polyneuropathy, and other systemic toxic effects. Respiratory diphtheria is usually caused by toxigenic (tox+) C. diphtheriae, but infections of the skin (cutaneous diphtheria) and other anatomical sites are often caused by nontoxigenic (tox-) C. diphtheriae. Respiratory diphtheria caused by either tox+ or tox- isolates of C. diphtheriae—but not cutaneous diphtheria—is a nationally notifiable infectious disease in the United States.

ETIOLOGY  
C. diphtheriae is an aerobic, nonmotile, nonsporulating, irregularly staining, gram-positive rod. The bacteria are club-shaped and are often arranged in clusters (Chinese letters) or parallel arrays (palisades). Selective media containing either tellurite or colistin plus nalidixic acid are recommended for cultivation of C. diphtheriae. The gravis, mitis, and intermedius biotypes are distinguished by colonial morphology and laboratory tests. Both tox+ and tox- strains are infectious, but tox- strains can produce toxemic diphtheria and are more likely to cause pseudomembranes. Diphtheria toxin is encoded by specific corynephages, and tox- C. diphtheriae (or other Corynebacterium species, such as C. ulcerans and C. pseudodurinosis) can acquire the ability to produce diphtheria toxin by infection with tox+ phages (phage conversion). Growth of C. diphtheriae under low-iron conditions that mimic the environment of host tissues induces production of diphtheria toxin and expression of systems for siderophore-dependent iron uptake, utilization of iron from heme, and several other iron-regulated functions.

IMMUNOLOGY  
Treatment of diphtheria toxin with formaldehyde converts it to a nontoxic but immunogenic product (diphtheria toxoid). Immunization with toxoid elicits antibody (antitoxin) that neutralizes the toxin and prevents diphtheria. The attack rate and mortality rate for diphtheria are low in immune individuals with antitoxin titers of >0.01 unit per milliliter. Antitoxin neither prevents colonization by C. diphtheriae nor eradicates the carrier state. When most individuals in a population have protective levels of antitoxin (herd immunity), the carrier rate for tox+ strains of C. diphtheriae falls to a low level, and the risk that susceptible individuals will be exposed to tox+ C. diphtheriae decreases dramatically. Susceptible individuals may contract diphtheria if they travel to regions where the disease is present or if tox- strains of C. diphtheriae are introduced into their community.

EPIDEMIOLOGY AND IMMUNITY  
Humans are the principal reservoir for C. diphtheriae. Transmission occurs primarily by close personal contact. The risk that C. diphtheriae will be transmitted to susceptible individuals from patients with diphtheria is greater than the risk that it will be transmitted to them from carriers. The incubation period for respiratory diphtheria is typically 2 to 5 days (range, 1 to 10 days). Cutaneous diphtheria is usually a secondary infection whose signs develop an average of 7 days (range, 1 to >21 days) after the appearance of other primary dermatologic lesions.

In temperate climates, diphtheria primarily involves the respiratory tract. It occurs throughout the year, with a peak incidence in colder months, and it is usually caused by tox+ C. diphtheriae. Before immunization was introduced, diphtheria was primarily a disease of children; it affected up to 10% of individuals in this group and sometimes caused devastating epidemics. Most young infants were immune because of transplacental transfer of maternal IgG antitoxin, but children became susceptible by 6 to 12 months of age. Approximately 75% of individuals became immune by 10 years of age as a result of contact with C. diphtheriae. Mortality rates of 30 to 40% were common in untreated disease and were sometimes >50% in epidemics. Treatment with antitoxin reduced the case-fatality rate to 5 to 10%.

Routine immunization of children in the United States resulted in a progressive decrease of diphtheria from the peak of 206,939 cases (incidence rate, 191 cases per 100,000 population) in 1921 to ≤5 cases per year since 1980. Circulation of tox- strains of C. diphtheriae among the population decreased dramatically throughout this period, but endemic foci of clonally related tox+ and tox- strains, belonging predominantly to the ET215 complex, have persisted for the past 25 years in South Dakota and Ontario. As the incidence of diphtheria decreased, a higher proportion of cases occurred in older persons (who were never immunized or whose immunity waned because they did not receive booster doses of vaccine or did not have contact with C. diphtheriae), but the case-fatality ratio remained unchanged at 5 to 10%. High rates of immunization are achieved by school entry (>96%), but immunization rates for younger children are substantially lower. Immunity to diphtheria among adults declines gradually with increasing age, and only 30% of men in the 60- to 69-year-old age group have protective levels of diphtheria antitoxin. Among adults immunity to diphtheria is typically lower among women than among men; likewise, it is lower among Mexican-Americans than among other racial or ethnic groups. The most recent large diphtheria outbreak in the United States (about 1100 cases) occurred in Seattle, Washington, between 1972 and 1982. Alcoholism, low socioeconomic status, crowded living conditions, and Native-American ethnic background were significant risk factors in this outbreak.

A massive diphtheria epidemic (>157,000 cases and >5000 deaths) occurred during the 1990s in Russia and the newly independent states of the former Soviet Union and accounted for >80% of diphtheria cases reported worldwide during that decade. The epidemic began in 1990 with 1436 cases (0.49 per 100,000 population) and peaked in 1995 with 50,425 cases (17.29 per 100,000 population). Clonally related tox- C. diphtheriae strains of the ET8 complex, which constituted only a small percentage of archival C. diphtheriae isolates from Russia before that epidemic, increased dramatically in prevalence, ac-
counting for >80% of isolates by 1994. Molecular analysis of tox gene alleles from isolates of the ET8 complex demonstrated that the existing diphtheria toxoid vaccine remained appropriate for ongoing use as a protective immunogen, and a mass vaccination program succeeded in reducing the number of cases to 2720 in 1998 (0.93 per 100,000 population). A majority of cases throughout this epidemic occurred in persons ≥15 years old, and adults from 40 to 49 years old had very high incidence and death rates. In 1994, case-fatality rates varied from 2.8% in the Russian Federation to 23% in Lithuania and Turkmenistan. Factors that facilitated the spread of this epidemic included large-scale population movements, socioeconomic instability, deteriorating health infrastructure, delayed implementation of aggressive control measures in response to the epidemic, inadequate information for physicians and the public, and frequent shortages of supplies for prevention and treatment of the disease. The most important risk factor for diphtheria in the Republic of Georgia was lack of vaccination (matched odds ratio, 19.2), but household diphtheria exposure, exposure to skin lesions, the presence of tonsils, a history of eczema, preceding fever with myalgia, sharing a bed, sharing glasses and cups, and taking a bath less often than weekly were also significant risk factors. Although small numbers of imported cases from this epidemic occurred in western European countries, none resulted in secondary transmission of diphtheria, notwithstanding a high proportion of susceptible adults in countries with imported cases. Inadequate primary immunization of children in the states of the former Soviet Union in the years preceding the epidemic, along with failure to maintain adequate immunity in adults by booster immunization, appear to have been primary factors in the development of the massive diphtheria epidemic in this region.

In the tropics, cutaneous diphtheria is more common than respiratory diphtheria, occurs throughout the year, and often develops as a complication of the massive diphtheria epidemic in this region. Isolates of C. diphtheriae from skin lesions are more often tox- than tox+. Cutaneous diphtheria is increasingly recognized in temperate climates and accounted for 86% of the 1100 cases in the Seattle epidemic of 1972 to 1982. Since 1980, cutaneous diphtheria has not been a reportable disease in the United States, and recent health statistics include only respiratory diphtheria.

During the 1990s, tox- strains of C. diphtheriae were associated with new types of infections. In the United Kingdom, these strains caused asymptomatic pharyngitis, predominantly among homosexual men, that was sometimes accompanied by tonsillar exudate. In Switzerland, strains with a high potential for invasiveness were isolated from 38 intravenous drug users and shown by ribotyping to be clonally related. The latter strains caused infections of the skin (15 cases), respiratory tract (10 cases), and blood (13 cases). Among the patients with bloodstream infections, 9 had endocarditis, and 4 of these 9 patients died.

**PATHOLOGY AND PATHOGENESIS** C. diphtheriae infects mucous membranes, most commonly in the respiratory tract, and also invades open skin lesions resulting from insect bites or trauma. In infections caused by tox+ C. diphtheriae, initial edema and hyperemia are often followed by epithelial necrosis and acute inflammation. Coagulation of the dense fibrinous exudate produces a pseudomembrane (Fig. 122-1), and the inflammatory reaction accompanied by vascular congestion extends into the underlying tissues. The pseudomembrane contains large numbers of C. diphtheriae organisms, but the bacteria are rarely isolated from the blood or internal organs.

Diphtheria toxin acts both locally and systemically, and the lethal dose for humans is ~0.1 μg/kg. Toxin contributes locally to pseudomembrane formation; systemically, it can cause myocarditis, polymyoneuropathy, and focal necrosis in various organs, including the kidneys, liver, and adrenal glands. Changes in the myocardium include cloudy swelling of muscle fibers and interstitial edema. These changes are followed within weeks by hyaline and granular degeneration (sometimes with fatty degeneration), progressing to myolysis and finally to the replacement of lost muscle by fibrosis. Thus, diphtheria can cause permanent cardiac damage. In diphtheritic polymyoneuropathy, pathologic changes include patchy breakdown of myelin sheaths in peripheral and autonomic nerves, but recovery of nerve damage is the rule if the patient survives.

Diphtheria toxin is produced by C. diphtheriae as an extracellular polypeptide. Proteolytic cleavage of the intact toxin forms nicked toxin consisting of fragments A and B. Fragment B binds to a plasma-membrane receptor (a precursor of a heparin-binding growth factor resembling epidermal growth factor), and the bound toxin is internalized by receptor-mediated endocytosis. Fragment A is translocated across the membrane of acidified endosomes and released into the cytoplasm, where it catalyzes the transfer of the adenosine diphosphate ribose moiety from nicotinamide adenine dinucleotide (NAD) to a modified histidine residue (diphthamide) on elongation factor 2 (EF-2), thereby inactivating EF-2 and inhibiting protein synthesis. One molecule of fragment A in the cytoplasm can kill a cell. Other metabolic alterations are secondary to inhibition of protein synthesis.

**CLINICAL MANIFESTATIONS**

### Respiratory Diphtheria

The current epidemiologic case definition of diphtheria used by the Centers for Disease Control and Prevention (CDC) is based on both a clinical syndrome (upper respiratory tract illness with sore throat, low-grade fever, and an adherent membrane of the tonsil(s), pharynx, and/or nose) and laboratory criteria (isolation of C. diphtheriae from a clinical specimen or a histopathologic diagnosis of diphtheria). Clinically compatible cases are classified as confirmed if they are either confirmed by the laboratory or epidemiologically linked to a laboratory-confirmed case and as probable if they are neither confirmed by the laboratory nor linked to a laboratory-confirmed case. By these criteria, both asymptomatic individuals and patients with respiratory findings but no pseudomembrane are classified as carriers if C. diphtheriae is isolated from the respiratory tract. On clinical grounds, diphtheria is graded as tonsillar if pseudomembranes are localized to the tonsils, as combined types or delayed diagnosis if more extensive pseudomembranes are present, and as severe if cervical adenopathy or cervical edema is also present. Onset is often gradual, but most patients seek medical care within a few days of becoming ill. Fever [a temperature of 37.8°C to 38.9°C (100° to 102°F)], sore throat, and weakness are the most common symptoms, while dysphagia, headache, and change of voice occur in fewer than half of patients. Neck edema and difficulty breathing are noted in ≥10% of patients and are associated with an increased risk of death. Systemic manifestations are due primarily to toxic effects of diphtheria toxin. Patients without toxicity exhibit discomfort and malaise associated with local infection, whereas severely toxic patients may develop listlessness, pallor, and tachycardia that can progress rapidly to vascular collapse.

Primary infection in the respiratory tract is most often tonsillopharyngeal but may also be (in decreasing order of frequency) laryngeal, nasal, and tracheobronchial. Multiple sites are frequently involved, and secondary spread of pharyngeal infection upward to the nasal mucosa or downward to the larynx and tracheobronchial tree is much more common than primary infection at those sites. Systemic toxicity is usually most severe when extensive pseudomembrane extends from the tonsils and pharynx into contiguous regions. A small percentage of patients present with malignant or “bull-neck” diphtheria, with extensive pseudomembrane formation, foul breath, massive swelling of the tonsils and uvula, thick speech, cervical lymphadenopathy, striking edematous swelling of the submandibular region and anterior neck, and severe toxicity.

In tonsillopharyngeal diphtheria, isolated spots of gray or white exudate may appear first. These spots often extend and coalesce within a day to form a confluent, sharply demarcated pseudomembrane (Fig. 122-1) that becomes progressively thicker, more tightly adherent to the underlying tissue, and darker gray in color. Unlike the exudate in streptococcal pharyngitis, the diphtheritic pseudomembrane often extends beyond the margin of the tonsils onto the tonsillar pillars, palate, or uvula. Dislodging the membrane is likely to cause bleeding. Laryn-
geal diphtheria often presents as hoarseness and cough. Demonstration of laryngeal pseudomembrane by laryngoscopy helps distinguish diphtheria from other infectious forms of laryngitis. Patients with nasal diphtheria may present with unilateral or bilateral serosanguineous nasal discharge associated with irritation of the nares or lip. Primary or secondary diphtheritic infection occasionally involves other mucous membranes, including the conjunctiva and the membranes of the genitourinary and gastrointestinal tracts.

**Cutaneous Diphtheria** Cutaneous diphtheria usually presents as an infection by *C. diphtheriae* of preexisting dermatoses involving the lower extremities, upper extremities, head, or trunk. The clinical features are similar to those of other secondary cutaneous bacterial infections. In the tropics, cutaneous diphtheria may present as a primary cutaneous lesion, typically with morphologically distinct “punched-out” ulcers that are covered by necrotic slough or membrane and have well-demarcated edges.

**Other Clinical Presentations** *C. diphtheriae* is an occasional cause of invasive infections, including endocarditis and septic arthritis. Risk factors for such infections include preexisting cardiac abnormalities, abuse of intravenous drugs, and alcoholic cirrhosis.

**Complications** Obstruction of the respiratory tract can be caused by extensive pseudomembrane formation and swelling early in the disease or by sloughed pseudomembrane that becomes lodged in the airways later in the disease. The risk is greater when infection involves the larynx or the tracheobronchial tree and in children because of the small size of the airways.

Myocarditis and polyneuropathy are the prominent toxic manifestations of diphtheria. The risk of each is proportional to the severity of local disease. Myocarditis occurred in 22% and neuropathy in 5% of 656 hospitalized patients (54% female, 70% ≥15 years old) with diphtheria in the Kyrgyz Republic in 1995; 7% of patients with myocarditis and 2% of patients without myocarditis died. The median interval from hospitalization to death was 4.5 days (range, 0 to 13 days). Manifestations of diphtheritic myocarditis include various dysrhythmias, conduction disturbances, and dilated cardiomyopathy. Although complete heart block from diphtheritic myocarditis is almost always fatal before temporary cardiac pacemakers were developed, approximately one-fourth of patients with this complication have recently been treated successfully.

Polyneuropathy typically begins 3 to 5 weeks after onset of diphtheria and has a slow course. It appears earliest in patients who experience the most severe and prolonged neurologic abnormalities. The initial presentation commonly involves gingival, lingual, or facial numbness as well as dysphonia, dysphagia, and paresthesias of the extremities. These findings may be followed by cranial motor nerve pareses, respiratory and abdominal muscle weakness that may require artificial ventilation, quadriparesis or quadriplegia, peripheral sensory disturbances, sensory ataxia, pain in the extremities, and a variety of autonomic disturbances. Cranial nerve dysfunction typically appears earlier than motor disturbances of the trunk and extremities. In severely affected patients, paresis or paralysis of the trunk and extremities may become worse during the second month, as cranial nerve dysfunction is improving, and peak at 7 to 9 weeks after the onset of polyneuropathy. Severe arterial hypotension attributable to autonomic dysfunction may occur from 4 to 7 weeks after the onset of polyneuropathy and last from 3 to 10 days. Polyneuropathy usually resolves completely in patients who survive.

Pneumonia occurs in more than one-half of fatal cases of diphtheria. Less common complications include renal failure, encephalitis, cerebral infarction, pulmonary embolism, and bacteraemia or endocarditis due to invasive infection by *C. diphtheriae*. Serum sickness may result from antitoxin therapy.

**Course and Prognosis** Most cases of diphtheria develop in non-immunized patients. The attack rate, severity of disease, and risk of complications are much lower in immunized patients. The pseudomembrane may continue to increase in size during the first day after administration of antitoxin. During the next several days to a week, it becomes softer, less adherent, and nonconfluent and eventually disappears. In the preantibiotic era, *C. diphtheriae* persisted in the throat for ~2 weeks in one-half of patients and for ≥1 month in about one-fifth. Mortality increases with the severity of local disease, the extent of pseudomembrone formation, and the delay between onset of local disease and administration of antitoxin. The death rate is highest during the first week of illness; among patients with bull-neck diphtheria; among patients with myocarditis who develop ventricular tachycardia, atrial fibrillation, or complete heart block; among patients with laryngeal or tracheobronchial involvement; among infants and patients >60 years of age; and among alcoholics. Both the mortality rate and the risk of myocarditis or peripheral neuropathy are significantly lower in cutaneous diphtheria than in respiratory diphtheria.

**Diagnosis** A characteristic pseudomembrane (Fig. 122-1) on the mucosa of the tonsils, palate, oropharynx, nasopharynx, nose, or larynx suggests diphtheria but is not uniformly present. Diphtheritic pseudomembrane must be distinguished from other pharyngeal exudates, including those of group A β-hemolytic streptococcal infections, infectious mononucleosis, viral pharyngitis, fusospirochetal infection, and candidiasis. Diphtheria should be considered in patients with sore throat, cervical adenopathy or swelling, and low-grade fever, especially when these manifestations are accompanied by systemic toxicity, hoarseness, stridor, palatal paralysis, or serosanguineous nasal discharge with or without demonstrable pseudomembrane. Treatment with diphtheria antitoxin should begin as soon as the clinical diagnosis of diphtheria is made.

Definitive diagnosis of respiratory diphtheria is based on compatible clinical findings supported by the isolation of *C. diphtheriae* from local lesions or by histopathology. Rarely, respiratory diphtheria may be caused by infection with tox* C. ulcerans*, and such cases should be managed like cases caused by *C. diphtheriae*. *C. pseudodiphtheriticum*, a tox* organism that is often part of the normal throat flora, can be associated with pseudomembranous pharyngitis or lower respiratory tract infection; however, unlike, *C. diphtheriae*, it does not pose a significant risk to contacts of infected patients. Specimens from the nose, throat, and membrane (and, when possible, from beneath the membrane) should be submitted for culture. The laboratory should be notified that diphtheria is suspected to ensure that one appropriate selective medium, such as cysteine-tellurite blood agar or Tinsdale medium, is used in addition to a nonselective medium (e.g., sheep blood agar) for primary plating of the specimens. Biochemical tests needed to differentiate *C. diphtheriae* from corynebacteria of the normal flora (diphtheroids) require several days. Group A β-hemolytic streptococci and *Staphylococcus aureus* are also isolated frequently from patients with diphtheria. All laboratory isolates of *C. diphtheriae*, whether or not they are associated with disease, should be submitted to the Diphtheria Laboratory, National Center for Infectious Diseases, CDC, for confirmation of biotype and toxigenicity and for other specialized tests.

Cutaneous diphtheria may present as a characteristic “punched-out” ulcer with a membrane, but it is more often indistinguishable from other inflammatory dermatoses. Diagnosis depends on a high degree of suspicion and on culture of cutaneous lesions on laboratory media appropriate for isolation of *C. diphtheriae*. Throat samples from all patients with cutaneous diphtheria should be cultured for *C. diphtheriae*.

**Treatment** Administration of diphtheria antitoxin is the most important element in the treatment of respiratory diphtheria. The decision to administer diphtheria antitoxin must be based on the clinical diagnosis of respiratory diphtheria, without waiting for definitive laboratory confirmation. Since antitoxin cannot neutralize toxin that is already bound to tissues, each day of delay in initiating treatment with antitoxin is associated with a significant increase in mortality risk. Because diphthe-
Antitoxin is produced in horses, it is necessary to question patients about possible allergy to horse serum and to perform a conjunctival or intracutaneous test with diluted antitoxin for immediate hypersensitivity. Epinephrine must be available for immediate administration to patients with severe allergic reactions. Patients with immediate hypersensitivity should be desensitized before a full therapeutic dose of antitoxin is given. The risk of serum sickness associated with administration of equine antitoxin is acceptable because of the established therapeutic value of antitoxin in decreasing mortality from respiratory diphtheria. Since 1997, diphtheria antitoxin has been available in the United States only from the CDC and is distributed under an Investigational New Drug (IND) protocol. Physicians should promptly notify their state health departments of suspected diphtheria cases. To obtain diphtheria antitoxin and consultation on its use, physicians should promptly contact staff at the National Immunization Program at (404) 639-8255 during office hours from 8:00 A.M. to 4:30 P.M. eastern standard time or through the CDC operator at (404) 639-2889 or (404) 639-2888 at any time.

Antibiotics have little demonstrated effect on the healing of local infection in diphtheria patients treated with antitoxin. The primary goal of antibiotic therapy for patients or carriers is therefore to eradicate C. diphtheriae and prevent its transmission from the patient to susceptible contacts. Regimens currently recommended by the CDC for the treatment of patients with respiratory diphtheria are erythromycin given orally or by injection for 14 days (40 mg/kg per day; maximum, 2 g/d) or procaine penicillin G given intramuscularly for 14 days (300,000 U/d for patients weighing ≤10 kg and 600,000 U/d for those weighing >10 kg). Rifampin or clindamycin has also been used successfully and is an acceptable alternative for treating patients who cannot take penicillin G or erythromycin. Eradication of C. diphtheriae should be documented by negative cultures of samples taken on two or three successive days at least 24 h after the completion of antibiotic therapy. Some authorities also recommend a repeat throat culture 2 weeks later. The small percentage of patients who continue to be infected with C. diphtheriae after treatment with penicillin or erythromycin should receive an additional 10-day course of oral erythromycin following by a repeat culture for C. diphtheriae. Plasmid-mediated resistance to erythromycin emerged transiently in C. diphtheriae during the Seattle epidemic, but its frequency declined dramatically after the routine use of erythromycin was discontinued.

Patients with respiratory or cutaneous diphtheria caused by tox+ C. diphtheriae or by C. diphtheriae strains of unknown toxinogenicity should be hospitalized, kept in bed initially, handled with isolation procedures appropriate for the site of infection, and given supportive care as needed. Respiratory and cardiac function must be monitored closely. Early intubation or tracheostomy is recommended when the larynx is involved or signs of impending airway obstruction are detected. Tracheobronchial membrane can sometimes be removed mechanically via the endotracheal tube or tracheostomy. Primary or secondary pneumonia should be diagnosed and treated promptly. Sedative or hypnotic drugs that may mask respiratory symptoms are contraindicated. Close electrocardiographic monitoring, treatment of arrhythmias, and electrical pacing for heart block are essential. Congestive heart failure should be treated as described in Chapter 16. Steroids do not reduce the risk of diphtheritic myocarditis or polyneuropathy. Ulcerative or erythematous cutaneous lesions should be treated with Burrow’s solution applied on wet compresses after debridement of necrotic areas, and treatment for associated conditions such as pediculosis, scabies, or underlying dermatoses should be instituted. Recovery from diphtheria does not always confer active immunity, and initiation of an immunization regimen for diphtheria that is appropriate for the patient’s age should be an integral part of the treatment plan.

**PREVENTION**

DTaP (diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed) is currently recommended for all doses in the primary childhood schedule for patients without past history of diphtheria who do not have contraindications. Td (tetanus and diphtheria toxoids adsorbed; for adult use) is currently recommended for routine booster immunizations at 10-year intervals in adults who do not have contraindications. Td is also recommended for adults who require prophylactic booster immunizations for tetanus-prone wounds. Currently recommended schedules for primary immunization of children and adults against diphtheria and for maintenance of immunity by periodic booster doses of appropriate vaccines throughout life are summarized in Chap. 107.

Close contacts of patients with respiratory diphtheria, especially household contacts, should have throat and nasal specimens collected and cultured for C. diphtheriae, should receive a 7- to 10-day course of either benzathine penicillin G (600,000 U for persons ≤6 years old or 1,200,000 U for persons ≥6 years old) or oral erythromycin (40 mg/kg per day for children and 1 g/d for adults), and should promptly receive diphtheria antitoxin if they become ill. Contacts whose immunization status is inadequate should receive a booster dose of diphtheria toxoid appropriate for their age. In situations where surveillance of contacts cannot be maintained, the benzathine penicillin G regimen should be used for treatment to ensure compliance. Contacts of patients with cutaneous diphtheria should be treated similarly, except that ongoing investigation of contacts can be discontinued if the strain of C. diphtheriae from the patient is found to be nontoxigenic. Identified carriers of C. diphtheriae in the community should also be treated with the recommended regimen for contacts.

**OTHER CORYNEBACTERIAL INFECTIONS**

**DEFINITION**

Medically important coryneform bacteria include 36 of 59 currently recognized species in the genus *Corynebacterium* plus numerous other taxonomically related organisms that share specific 16S rDNA signature nucleotides and belong to the high-guanosine-plus-cytosine lineage of gram-positive bacteria. They include environmental organisms and members of the normal flora that cause opportunistic infections, human pathogens of relatively low virulence, and animal pathogens that cause zoonotic infections. Reported infections caused by coryneform bacteria have increased substantially in number over the past several decades. Isolates of *C. jeikeium* and *C. urealyticum* are often resistant to multiple antibiotics.

**ETIOLOGY AND LABORATORY DIAGNOSIS**

Because coryneform bacteria are potential pathogens, it is important not to dismiss them arbitrarily as components of the normal flora or as contaminants when they are found in clinical specimens. Coryneform bacteria should be identified to the species level when they are isolated from normally sterile body sites (unless only one of several specimens is positive for growth), when they represent the predominant organisms in appropriately collected clinical specimens, and when they are present as the only organism in urine at a count of >10^9/mL or as the predominant organisms in urine with a total bacterial count of >10^9/mL.

The coryneform bacteria are a large, heterogeneous group of gram-positive, pleomorphic, irregularly staining bacilli or coccobacilli that superficially resemble *C. diphtheriae*, have widely varying guanosine-plus-cytosine contents (from 46 to 74% guanosine plus cytosine) for members of the genus *Corynebacterium*, and are often difficult to identify and classify. Club-shaped rod forms are observed only for true *C. diphtheriae*. Classification of *Corynebacterium* species. The genus *Corynebacterium* is currently divided into three groups: the nonlipoiphilic, fermentative corynebacteria (including *C. diphtheriae*, *C. ulcerans*, *C. pseudotuberculosis*, *C. xerosis*, *C. striatum*, *C. minutissimum*, and others); the nonlipophilic, nonfermentative corynebacteria (including *C. pseudodiptheriticum* and others); and the lipophilic corynebacteria (including *C. jeikeium*, *C. urealyticum*, and others). The coryneform group includes additional genera, such as *Arcanobacterium* and *Rhodococcus*. Classification of coryneform bacteria is based on routine and molecular genetics—based diagnostic methods; these methods are often supplemented by chemotaxonomic methods that include identification of the short-chain mycolic acids present in most *Corynebacterium* species but absent in other coryneform bacteria, determination of the specific diamino acid present in peptidoglycan, and characterization of the major cellular
fatty acids. The classification system for coryneform bacteria is evolving rapidly, with 14 new species defined in the past 5 years. All coryneform bacteria that are clinically significant but cannot be readily identified in routine diagnostic laboratories should be submitted to an appropriate reference laboratory experienced in this area.

ECOLOGY AND EPIDEMIOLOGY Humans are the probable natural reservoir for C. xerosis, C. pseudodiphtheriticum, C. striatum, C. minutissimum, C. jeikeium, C. urealyticum, and Arcanobacterium haemolyticum. Animals are the probable natural reservoir for Arcanobacterium pyogenes (cows, sheep, pigs), C. ulcerans (cows, horses), and C. pseudotuberculosis (sheep, horses, goats, cattle). The natural reservoir for Rhodococcus equi is soil. The ecologic niches for many other coryneform bacteria of medical importance are not well defined.

Corynebacterial species that are found frequently as components of the normal human flora include C. pseudodiphtheriticum (pharynx, skin), C. xerosis (conjunctival sac, nasopharynx, skin), C. auris (external auditory canal), and C. striatum (anterior nares, skin). Corynebacterial species that commonly colonize the skin of hospitalized patients include C. jeikeium (axilla, groin, perineum) and C. urealyticum. C. jeikeium most often colonizes patients with malignancies or severe immunodeficiency; it is also isolated from environmental sources (surfaces, air) in hospitals and from the hands of ward staff. C. ulcerans infections are acquired by consumption of raw milk. C. pseudotuberculosis infections are acquired by contact with animals or animal products or by consumption of raw milk.

PATHOGENESIS AND CLINICAL MANIFESTATIONS C. ulcerans infections of humans usually present as pharyngitis and can mimic respiratory diphtheria, whereas infections caused by C. pseudotuberculosis typically present as suppurative granulomatous lymphadenitis. Some strains of C. ulcerans and C. pseudotuberculosis can produce diphtheria toxin, but infections of humans with tox+ strains have been reported only for C. ulcerans. C. ulcerans infections that are presumed on clinical grounds to be caused by tox+ strains should be managed like diphtheria, and diphtheria antitoxin should be administered. C. pseudodiphtheriticum, a tox+ commensal of low virulence, is an uncommon cause of pneumonia in men with AIDS and of pharyngitis. It has also been associated with necrotizing tracheitis, tracheobronchitis, endocarditis, and urinary tract infection in patients without known immune deficiencies. Pharyngeal infections associated with C. pseudodiphtheriticum can be confused with diphtheria until the bacteriologic diagnosis is established; however, unlike diphtheria, these infections do not pose a danger to contacts. C. xerosis and C. striatum are constituents of the normal human flora that are of low virulence and rarely cause human infections.

C. jeikeium causes severe infections primarily in patients with hematologic malignancies and neutropenia. Skin colonization precedes clinical infection. Risk factors for nosocomial C. jeikeium sepsis include prolonged hospitalization, breaks in the integument, chronic intravascular catheterization, and prior treatment with broad-spectrum antibiotics. Other presentations of C. jeikeium infection include endocarditis, device-related infections, pulmonary infiltrates, cutaneous septic emboli, soft tissue infections, and rashes. Endocarditis due to C. jeikeium occurs primarily in patients with prosthetic heart valves. C. jeikeium is a rare cause of central nervous system infections in patients with ventricular shunts.

C. urealyticum is a significant cause of nosocomial urinary tract infections, including acute and chronic cystitis and pyelonephritis. The organism closely resembles C. jeikeium but differs from the latter by producing urease and failing to convert glucose to acidic metabolites. Hydrolysis of urea by urease causes alkalinization of the urine and formation of ammonium magnesium phosphate (struvite) stones. C. urealyticum is a cause of alkaline-encrusted cystitis in patients with previous bladder lesions that serve as foci for precipitation of struvite crystals. Risk factors associated with symptomatic urinary tract infections include preexisting immunosuppression, recent urologic procedures (including renal transplantation), underlying disorders of the genitourinary tract, and a history of urinary tract infections.

C. minutissimum is frequently isolated from the lesions of erythrasma, a common superficial skin infection characterized by the presence in intertriginous areas of reddish-brown, scaly, pruritic, macular patches that exhibit coral-red fluorescence under a Wood’s light. The etiology of erythrasma appears to be polymicrobial; infection of the skin by C. minutissimum follows the onset of maceration and scaling. Deep infections caused by C. minutissimum, which are rare, include abscesses, bacteremia, endocarditis, peritonitis, pyelonephritis, and infection of central venous catheters.

A. haemolyticum causes pharyngitis and chronic skin ulcers. Less frequently, it causes a variety of deep tissue infections, septicemia, and endocarditis. Some 90% of A. haemolyticum infections occur in patients between 10 and 30 years old. A. haemolyticum pharyngitis in this age group is 5 to 13% as frequent as Streplococcus pyogenes pharyngitis. An erythematous rash is present in 30 to 67% of cases. The rash is usually scarlatiniform and most pronounced on the trunk and proximal extremities, but it sometimes resembles urticaria or erythema multiforme. Because rash is more frequent in A. haemolyticum infections than in S. pyogenes infections, A. haemolyticum should be considered as a possible etiology in older children and adults who present with the scarlet fever syndrome. Infection due to A. haemolyticum can also present as extensive pharyngeal exudate and can mimic diphtheria. A. haemolyticum occasionally causes peritonsillar abscess, sepsis, endocarditis, or meningitis.

A. pyogenes causes bovine mastitis, a disease transmitted by flies. Yearly epidemics of leg ulcers infected with A. pyogenes among schoolchildren in Thailand occurred between 1979 and 1984 and were postulated to have resulted from introduction of the organism into traumatic skin lesions by flies. Reported A. pyogenes infections in adults in Denmark have included abscesses, cystitis, intraabdominal infections, and mastoiditis with bacteremia. A. haemolyticum, which causes broncho-pneumonia in horses and occasional infections in other animals, has emerged as an important intracellular opportunistic pathogen in immunocompromised patients. Most reported cases are necrotizing pulmonary infections that resemble tuberculosis or nocardiosis in patients with severely defective cell-mediated immunity, including those with AIDS.

DIAGNOSIS Pharyngitis caused by tox+ strains of C. ulcerans may be clinically indistinguishable from diphtheria. The presentations of infections caused by other coryneform bacteria are not pathognomonic, and diagnosis of these infections is based on a high index of suspicion, identification of the organism by culture in appropriate clinical specimens, and exclusion of other likely causes of infection. Sheep blood agar containing fosfomycin (100 µg/mL) or colistin—nalidixic acid blood agar is useful as a selective medium for most coryneform bacteria, and medium containing 0.1 to 1% Tween 80 is useful for isolation of lipophilic coryneform bacteria.

Since C. urealyticum is often undetected by routine urine cultures; it is necessary to incubate cultures for 24 to 48 h on blood agar or on special media for selected patients (especially elderly men with pre-existing genitourinary abnormalities) with alkaline urine, ammonium magnesium phosphate stones, gram-positive bacilli in the urine, or negative standard urine cultures despite clinical evidence of bacteruria. Other microbes that can cause urinary tract infections with alkaline urine include Proteus, Ureaplasma, and some staphylococci and streptococci. Alkaline-encrusted cystitis is an anatomic diagnosis made by cystoscopy.

The differential diagnosis of A. haemolyticum pharyngitis with rash includes scarlet fever; rubella; staphylococcal and streptococcal toxic shock syndromes; infections caused by Epstein-Barr virus, cytomegalo-virus, and enteroviruses (especially coxsackieviruses); disseminated gonococcal infection; secondary syphilis; and drug allergy. Routine diagnostic methods for throat cultures are not ideal for the detection of A. haemolyticum, nor is this organism detected by the rapid tests for S. pyogenes that are sometimes substituted for throat cultures. Pharyngitis caused by A. haemolyticum in adolescents and
adults is likely to remain underdiagnosed until improved tests for the organism are developed and used by diagnostic laboratories.

Erythrasma is diagnosed clinically. Because of uncertainty about the etiologic role of *C. minutissimum*, culture of erythrasma lesions is not currently recommended.

### Treatment

Since prediction of susceptibility patterns on the basis of isolate identification to the species level is not necessarily reliable, antimicrobial susceptibility testing should be performed on all isolates of clinically significant coryneform bacteria. In light of the emergence and spread of vancomycin resistance in several gram-positive bacterial species as well as the observation of intrinsic vancomycin resistance in some species of coryneform bacteria (e.g., *Microbacterium resistens*), some authorities have recently recommended that glycopeptide antibiotics not be used as first-line agents to treat infections caused by coryneform bacteria. Physicians treating infections caused by coryneform bacteria that are likely to exhibit resistance to multiple antibiotics should obtain expert consultation concerning current treatment recommendations.

Strains of *C. jejue* are typically resistant to most antibiotics. Vancomycin has been recommended most often as the drug of choice for empirical treatment of infections caused by this organism, although antimicrobial susceptibility testing may reveal other antibiotic options for some isolates. For device-related *C. jejue* infections, removal of the infected device is usually required in addition to appropriate antibiotic therapy.

*C. urealyticum* is often resistant to the antibiotics used commonly for the treatment of urinary tract infections. Empirical treatment with vancomycin has often been recommended pending the results of antimicrobial susceptibility testing. Several courses of antibiotic therapy may be necessary for bacteriologic cure. Patients with alkaline-encrusted cystitis require resection of the encrusted lesions in addition to antibiotic therapy.

No controlled trials of treatment for *A. haemolyticum* infections have been performed. In vitro tests usually demonstrate susceptibility to penicillins, erythromycin, azithromycin, clindamycin, doxycycline, ciprofloxacin, and vancomycin, but treatment failures have been reported with appropriate doses of penicillins. Limited data suggest that the clinical course of *A. haemolyticum* pharyngitis may be shortened by treatment with erythromycin.

Infections with *C. ulcerans* that present like diphtheria or are known to be caused by tox- strains should be treated like diphtheria. Oral erythromycin is usually effective for treatment of erythrasma. For infections caused by *R. equi*, vancomycin has often been recommended as the drug of choice. Possible alternatives include erythromycin, rifampin, amnoglycosides, and chloramphenicol; the combination of erythromycin and rifampin is attractive because of possible synergy. Penicillins should not be used, because *R. equi* rapidly develops resistance. Many weeks of antibiotic treatment, sometimes supplemented by surgical intervention, are often needed for infections caused by *R. equi*. Suppressive therapy with antibiotics should be continued indefinitely in patients with AIDS after initial treatment of infections caused by *R. equi*. Initial treatment of infections caused by other coryneform bacteria should be based on the identity of the organism and published data regarding antibiotic susceptibility. Therapy should be modified, when necessary, in light of the results of antibiotic susceptibility tests.

### Further Reading

### Infections Caused by *Listeria Monocytogenes*

Anne Schuchat, Claire V. Broome

*Listeria monocytogenes* is a gram-positive rod that can be isolated from soil, vegetation, and many animal reservoirs. Human disease due to *L. monocytogenes* generally occurs in the setting of pregnancy or of immunosuppression caused by illness or medication. Increasing evidence suggests that a substantial portion of cases of human listeriosis are attributable to the food-borne transmission of *L. monocytogenes*. Unlike most food-borne pathogens, which cause primarily gastrointestinal illness, *L. monocytogenes* causes invasive syndromes, such as meningitis, sepsis, chorioamnionitis, and stillbirth.

### Pathogenesis

*L. monocytogenes* is an intracellular pathogen characteristic consistent with its predilection for causing illness in persons with deficient cell-mediated immunity. The organism can be found as part of the gastrointestinal flora in healthy individuals. Lack of gastric acidity and abnormal gastrointestinal functioning may increase the risk of invasive disease following exposure to the organism in the gastrointestinal tract. The increased risk of *L. monocytogenes* infection in pregnant women may be due to both systemic and local immunologic changes associated with pregnancy. For example, local immunosuppression at the maternal-fetal interface of the placenta may facilitate intrauterine infection following transient maternal bacteremia.

The molecular pathogenesis of *L. monocytogenes* has been elucidated. The cell-surface protein internalin interacts with specific receptors to induce phagocytosis. Both listeriolysin O and phospholipases permit the organism to escape from the phagosome into the cytosol while avoiding intracellular killing. Through the surface protein Act A, *L. monocytogenes* uses actin-based motility to move to the cell membrane. Efficient cell-to-cell spread is accomplished by both actin filament formation and phospholipase production. Genetic determinants of these proteins have been characterized. Because the organism is adapted for both intracellular survival and direct cell-to-cell spread, it is not eliminated by antibodies.
Early-onset disease may include sepsis, respiratory distress, skin lesions, and the syndrome called granulomatosis infantisepticum, which is characterized by disseminated abscesses involving the liver, spleen, adrenal glands, lungs, and other sites. Infants with late-onset neonatal disease are more likely than those with early-onset disease to develop meningitis. While early-onset disease is often associated with obstetric complications such as premature delivery and chorioamnionitis, late-onset disease typically affects infants born at term by uncomplicated deliveries. Infants may acquire L. monocytogenes during passage through the birth canal; except in several clusters of late-onset neonatal infections linked to nosocomial transmission, the pathogenesis of late-onset disease is not well understood.

Listeriosis not associated with pregnancy usually affects persons with immunosuppressive conditions, although invasive disease can also affect immunocompetent adults, particularly elderly persons. The most common underlying conditions in nonpregnant adults with listeriosis are chronic glucocorticoid therapy, solid or hematologic malignancies (particularly in fludarabine-treated patients), diabetes mellitus, renal disease, liver disease, and AIDS. Although the prevalence of listeriosis among persons infected with HIV is much higher than that in the general population, listeriosis is a relatively uncommon opportunistic infection in AIDS.

Sepsis Clinical studies have shown that bacteremic infection without an evident focus is the most common clinical manifestation of listeriosis among immunocompromised hosts, while infection of the central nervous system (CNS) ranks second in frequency. Listerial sepsis cannot be distinguished clinically from bacteremia involving other organisms. Patients are usually febrile, often appear extremely ill, and may have prodromal symptoms including myalgia, nausea, vomiting, and diarrhea. Immunocompromised patients with listeriosis are less likely than other Listeria-infected adults to present with CNS infection, possibly because they are more likely to have blood cultured during febrile episodes and thus to have transient bacteremia recognized.

CNS Infection The most common presentation of CNS infection due to L. monocytogenes is meningitis, which can present as either an acute or (less often) a subacute illness. Presenting symptoms include fever, headache, and an altered level of consciousness. Examination of CSF usually reveals pleocytosis, increased protein concentrations, and normal glucose levels, although other patterns are sometimes found. Gram’s stain is positive in only 25% of cases. The diagnosis is made when L. monocytogenes is identified on culture. Despite its name, L. monocytogenes is rarely associated with mononucleosis of either CSF or blood. Other syndromes seen in CNS infection include meningoencephalitis, cerebritis, and brain stem, spinal cord, or intracranial abscesses. The unusual syndrome of rhombencephalitis includes asymmetric cranial-nerve palsies, altered consciousness, cerebellar signs, and motor or sensory loss. Symptoms of other nonnongtitic CNS infections include fever, ataxia, seizures, personality changes, and coma. Nuchal rigidity is rare in nongtitic infections. CSF cultures may be sterile; blood cultures are usually diagnostic.

Endocarditis Like most forms of bacterial endocarditis, listerial endocarditis typically occurs in patients with prosthetic or previously damaged valves. The organism has a predilection for the left side of the heart. Endocarditis due to L. monocytogenes is often associated with systemic embolization.

Focal Infections Other focal infections that can follow unrecognized bacteremia include endophthalmitis, peritonitis, osteomyelitis, visceral abscess, pleuropulmonary infection, and cholecystitis. Cutaneous lesions may develop without systemic involvement and have been reported in veterinarians and poultry workers.

Gastrointestinal Illness Several common-source outbreaks of acute febrile gastroenteritis suggest that L. monocytogenes can cause an acute diarrhea syndrome in persons without immunocompromising conditions. The importance of L. monocytogenes in sporadic diarrheal illness is unclear. Although the organism is not identified by the culture methods routinely used for stool specimens, studies using selective enrichment media for evaluation of consecutive specimens from patients hospitalized with acute diarrhea have suggested that L. monocytogenes is not a major cause of sporadic diarrhea.

EPIDEMIOLOGY Long recognized as a veterinary pathogen, L. monocytogenes causes basilar meningitis (“circling disease”) and stillbirth in sheep and cattle. The occurrence of listeriosis among humans has received increasing attention as the role of contaminated foods in the pathogenesis of epidemic listeriosis has been recognized and reports of disease associated with the expanding immunosuppressed population have accumulated.

Invasive listeriosis—confirmed by culture of blood or cerebrospinal fluid (CSF)—occurs in approximately 3 to 5 individuals per million population annually in the United States. Perinatal listeriosis complicates 9 births per 100,000. A 40% decline in incidence since the period from 1986 through 1990 may be attributable to aggressive food regulation and industrial clean-up efforts. Incidence further declined by 35% from 1996 through 2001. Multistate surveillance for sporadic listeriosis suggests that 20% of infections are fatal or result in stillbirth, although higher case-fatality rates have been reported during listeriosis epidemics and were described in early series. Most cases of disease due to L. monocytogenes are sporadic; however, investigation of several outbreaks of listeriosis since 1980 has demonstrated common-source food-borne transmission as a cause of human illness and has shown that the incubation period for disease following consumption of contaminated food can be 2 to 6 weeks. The largest North American outbreak, which took place in Los Angeles in 1985, involved more than 100 cases and 48 deaths or stillbirths. A nationwide outbreak in France in 1992 involved 279 cases and 63 deaths. Foods implicated in outbreaks of listeriosis include contaminated coleslaw, pasteurized milk, soft cheeses, pâté, ready-to-eat turkey and pork products, hot dogs, butter, and prepared salads; epidemiologic studies have implicated undercooked chicken, uncooked hot dogs, soft cheeses, and food from store delicatessen counters in sporadic disease. Listerial contamination of foods is relatively common. Among foods contaminated with the organism, those that are purchased ready to eat, are contaminated with serotype 4b, and are contaminated at a relatively high level may be the most likely to cause illness. The long incubation period associated with listeriosis contributes to the difficulty of implicating specific foods as the cause of either common-source outbreaks or sporadic cases.

Although food-borne transmission appears to be the foremost cause of epidemic and sporadic disease, several clusters of late-onset neonatal infection suggest nosocomial transmission of L. monocytogenes. Contaminated multistate materials and equipment have been suggested as causes of some nosocomial clusters. Listeriosis has been reported in veterinarians and other persons in close contact with infected animals.

CLINICAL PRESENTATION Pregnancy-associated listeriosis may occur during any stage of pregnancy, although most infections are detected during the third trimester, possibly because of failure to obtain specimens for bacterial culture earlier during gestation in instances of abortion and stillbirth. One-half to two-thirds of pregnant women with perinatal listeriosis experience a mild illness characterized by fever, myalgias, malaise, and backache, which sometimes are accompanied by diarrhea, abdominal pain, nausea, and/or vomiting during the bacteremic phase. Blood cultures should be used for diagnosis. Transplacental spread of the organism results in intrauterine infection, which can lead to chorioamnionitis, premature labor, intrauterine fetal demise, or early-onset disease of the newborn. Women with listeriosis diagnosed during pregnancy have a favorable clinical outcome after antibiotic therapy or delivery. Although often included in the differential diagnosis of recurrent spontaneous abortion, infection with L. monocytogenes appears to cause fewer than 2% of stillbirths.

Neonatal listeriosis can be classified under the same categories used for group B streptococcal infection (Chap. 121), with early-onset disease evident during the first week of life and late-onset disease developing thereafter. Infants may be symptomatic at birth; most infants with late-onset disease are symptomatic by the second day of life. Aspiration of infected amniotic fluid contributes to pathogenesis. Early-onset disease may include sepsis, respiratory distress, skin lesions, and the syndrome called granulomatosis infantisepticum, which is characterized by disseminated abscesses involving the liver, spleen, adrenal glands, lungs, and other sites. Infants with late-onset neonatal disease are more likely than those with early-onset disease to develop meningitis. While early-onset disease is often associated with obstetric complications such as premature delivery and chorioamnionitis, late-onset disease typically affects infants born at term by uncomplicated deliveries. Infants may acquire L. monocytogenes during passage through the birth canal; except in several clusters of late-onset neonatal infections linked to nosocomial transmission, the pathogenesis of late-onset disease is not well understood.

Listeriosis not associated with pregnancy usually affects persons with immunosuppressive conditions, although invasive disease can also affect immunocompetent adults, particularly elderly persons. The most common underlying conditions in nonpregnant adults with listeriosis are chronic glucocorticoid therapy, solid or hematologic malignancies (particularly in fludarabine-treated patients), diabetes mellitus, renal disease, liver disease, and AIDS. Although the prevalence of listeriosis among persons infected with HIV is much higher than that in the general population, listeriosis is a relatively uncommon opportunistic infection in AIDS.

Sepsis Clinical studies have shown that bacteremic infection without an evident focus is the most common clinical manifestation of listeriosis among immunocompromised hosts, while infection of the central nervous system (CNS) ranks second in frequency. Listerial sepsis cannot be distinguished clinically from bacteremia involving other organisms. Patients are usually febrile, often appear extremely ill, and may have prodromal symptoms including myalgia, nausea, vomiting, and diarrhea. Immunocompromised patients with listeriosis are less likely than other Listeria-infected adults to present with CNS infection, possibly because they are more likely to have blood cultured during febrile episodes and thus to have transient bacteremia recognized.

CNS Infection The most common presentation of CNS infection due to L. monocytogenes is meningitis, which can present as either an acute or (less often) a subacute illness. Presenting symptoms include fever, headache, and an altered level of consciousness. Examination of CSF usually reveals pleocytosis, increased protein concentrations, and normal glucose levels, although other patterns are sometimes found. Gram’s stain is positive in only 25% of cases. The diagnosis is made when L. monocytogenes is identified on culture. Despite its name, L. monocytogenes is rarely associated with mononucleosis of either CSF or blood. Other syndromes seen in CNS infection include meningoencephalitis, cerebritis, and brain stem, spinal cord, or intracranial abscesses. The unusual syndrome of rhombencephalitis includes asymmetric cranial-nerve palsies, altered consciousness, cerebellar signs, and motor or sensory loss. Symptoms of other nonnongtitic CNS infections include fever, ataxia, seizures, personality changes, and coma. Nuchal rigidity is rare in nongtitic infections. CSF cultures may be sterile; blood cultures are usually diagnostic.

Endocarditis Like most forms of bacterial endocarditis, listerial endocarditis typically occurs in patients with prosthetic or previously damaged valves. The organism has a predilection for the left side of the heart. Endocarditis due to L. monocytogenes is often associated with systemic embolization.

Focal Infections Other focal infections that can follow unrecognized bacteremia include endophthalmitis, peritonitis, osteomyelitis, visceral abscess, pleuropulmonary infection, and cholecystitis. Cutaneous lesions may develop without systemic involvement and have been reported in veterinarians and poultry workers.

Gastrointestinal Illness Several common-source outbreaks of acute febrile gastroenteritis suggest that L. monocytogenes can cause an acute diarrhea syndrome in persons without immunocompromising conditions. The importance of L. monocytogenes in sporadic diarrheal illness is unclear. Although the organism is not identified by the culture methods routinely used for stool specimens, studies using selective enrichment media for evaluation of consecutive specimens from patients hospitalized with acute diarrhea have suggested that L. monocytogenes is not a major cause of sporadic diarrhea.
Recurrents Recurrent infection with *L. monocytogenes* has been reported but is rare. Many recurrences are due to the subtype responsible for the initial infection. The implication is that such recurrences result either from insufficient treatment of a focus of primary infection or from repeated exposure to a persistently contaminated source.

**DIAGNOSIS** Invasive listeriosis is diagnosed when the organism is cultured from a site that is usually sterile, such as blood, CSF, or amniotic fluid. The organism grows readily within 36 h on routine culture media, but morphologic similarities between *Listeria* and diphtheroids make it necessary to use biochemical tests to identify the species. Serologic assays with whole-cell antigens have not been useful for the diagnosis of listeriosis, both because exposure to the organism (and thus the presence of antibody) may be common and because infected individuals may not produce antibody. Assays for antibody to listeriolysin O have been applied in epidemiologic investigations and, retrospectively, in the diagnosis of culture-negative CNS infection. Culture of the organism from nonsterile sites such as the vagina and rectum is not useful for clinical diagnosis, as the organism may be carried at these sites by ~5% of healthy individuals.

**Differential diagnosis** of prematurity, spontaneous abortion, or stillbirth includes infectious diseases such as group B streptococcal infection, congenital syphilis, and toxoplasmosis; pathogens such as group B streptococci and *Escherichia coli* are more common than *L. monocytogenes* as causes of meningitis and sepsis in the newborn period. Listerial infection should always be considered in the differential diagnosis of meningitis in immunosuppressed persons, particularly transplant recipients and others undergoing glucocorticoid treatment, patients with hematologic malignancy, and HIV-infected patients. Among healthy adults, meningitis is much more likely to be caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*, or viral pathogens than by *L. monocytogenes*.

**TREATMENT**

The treatment of choice for listeriosis is intravenous administration of either ampicillin or penicillin, often in combination with an aminoglycoside for synergy. Trimethoprim-sulfamethoxazole is bactericidal against *L. monocytogenes* and has been used successfully in the treatment of patients with penicillin allergy. *L. monocytogenes* is susceptible in vitro to penicillin G, ampicillin, erythromycin, trimethoprim-sulfamethoxazole, chloramphenicol, rifampin, tetracyclines, aminoglycosides, and imipenem. However, chloramphenicol and rifampin may antagonize the bactericidal effect of penicillins.

Because *L. monocytogenes* is not sensitive to cephalosporins, these agents should not be used for single-agent empirical treatment of neonatal sepsis or of meningitis in newborns or immunocompromised hosts.

Dosages and durations of therapy have not been subjected to controlled trials. For nonpregnant adults with listeriosis, the regimen of choice is either ampicillin (12 g intravenously per day in six divided doses) or penicillin G (15 to 20 million units intravenously per day in six divided doses); for immunosuppressed patients with meningitis, some experts add gentamicin (1.3 mg/kg intravenously every 8 h) for synergy. Penicillin-allergic patients may be treated with trimethoprim-sulfamethoxazole (15/75 mg/kg intravenously per day in three equal portions every 8 h). Meningitis in an immunocompetent patient may require 2 to 3 weeks of antibiotic therapy after defervescence. Meningitis, bacteremia, endocarditis, and nonmeningitic listeriosis in immunosuppressed patients should be treated longer, probably for 4 to 6 weeks. Neonatal listeriosis can be treated with a 2-week course of ampicillin. Infants weighing <2000 g should receive 100 mg/kg per day in two equal doses during the first week of life and 150 mg/kg per day during the second week. Infants weighing ≥2000 g should receive 150 mg/kg per day in three equal doses during the first week of life and 200 mg/kg per day during the second week. The addition of an aminoglycoside should be considered for neonatal infection (gentamicin, 5 mg/kg per day in two divided doses during the first week of life; 7.5 mg/kg per day in three equal doses during the second week).

For listeriosis in pregnant women, a 2-week course of ampicillin (4 to 6 g per day in four equal doses) is recommended. During the last month of pregnancy, infected women with serious penicillin allergies may be treated with erythromycin.

**PROGNOSIS** Treatment of maternal bacteremia during pregnancy can prevent neonatal infection. Antibiotic therapy for the newborn can limit sequelae, although the widely disseminated disease characteristic of granulomatosis infantisepticum is frequently fatal regardless of treatment. Early-onset disease carries a higher mortality risk than late-onset infection, and immunocompromised hosts have a worse prognosis than do otherwise-healthy adults with listeriosis.

**PREVENTION** *L. monocytogenes* is frequently isolated from food; the Food and Drug Administration, the U.S. Department of Agriculture, and manufacturers are pursuing further measures to reduce *L. monocytogenes* contamination of foods that have been subjected to listerial processing. Prevention of listeriosis requires dietary counseling of persons at increased risk of disease (Table 123-1). There is no role for the administration of prophylaxis to contacts of patients with listeriosis. Clinicians are encouraged to report cases of listeriosis to local or state health departments. Case reporting and subtyping of clinical isolates can facilitate early recognition of outbreaks and prevention of subsequent cases.

TETANUS

DEFINITION Tetanus is a neurologic disorder, characterized by increased muscle tone and spasms, that is caused by tetanospasmin, a powerful protein toxin elaborated by Clostridium tetani. Tetanus occurs in several clinical forms, including generalized, neonatal, and localized disease.

ETIOLOGIC AGENT C. tetani is an anaerobic, motile gram-positive rod that forms an oval, colorless, terminal spore and thus assumes a shape resembling a tennis racket or drumstick. The organism is found worldwide in soil, in the inanimate environment, in animal feces, and occasionally in human feces. Spores may survive for years in some environments and are resistant to various disinfectants and to boiling for 20 min. Vegetative cells, however, are easily inactivated and are susceptible to several antibiotics (metronidazole, penicillin, and others).

Tetanospasmin is formed in vegetative cells under plasmid control. It is a single polypeptide chain. With autolysis, the single-chain toxin is released and cleaved to form a heterodimer consisting of a heavy chain (100 kDa), which mediates binding to nerve-cell receptors and entry into these cells, and a light chain (50 kDa), which acts to block neurotransmitter release. The genome sequence of C. tetani has been reported. The amino acid structures of the two most powerful toxins known, botulinum toxin and tetanospasmin, are partially homologous.

EPIDEMIOLOGY Tetanus occurs sporadically and almost always affects nonimmunized persons, partially immunized persons, or fully immunized individuals who fail to maintain adequate immunity with booster doses of vaccine. Although tetanus is entirely preventable by immunization, the burden of disease is large worldwide. The disease is common in areas where soil is cultivated, in rural areas, in warm climates, during summer months, and among males. In countries without a comprehensive immunization program, tetanus occurs predominantly in neonates and other young children. It is noteworthy that international programs to eliminate neonatal tetanus have been in place for some time. In the United States and other nations with successful immunization programs, neonatal tetanus is rare (only one case was reported in the United States during the period 1998–2000), and the disease affects other age groups and groups inadequately covered by immunization (such as nonwhites). The success of immunization in the United States is depicted in Fig. 124-1. Since 1976, fewer than 100 cases have been reported yearly; this figure contrasts remarkably with that of 500 to 600 cases reported annually in the late 1940s, when vaccine administration became routine and tetanus became notifiable. In 1947, the incidence of tetanus was 3.9 cases per 1 million population. In contrast, the average annual incidence rate for 1998–2000 was 0.16 per 1 million population. The risk for the development of tetanus is highest among the elderly. A large-scale national serologic survey for tetanus and diphtheria antibody performed in 1988–1994 showed that, overall, 72% of Americans over the age of 6 years were protected against tetanus. Whereas 91% of children 6 to 11 years old were protected, the percentage protected fell with age: only 30% of persons >70 years old (men, 45%; women, 21%) had adequate antibody levels. Notably, individuals 20 to 49 years old now account for a large proportion of cases, because fewer cases occurred in the elderly without a similar reduction among young and middle-aged adults.

In the United States, most cases of tetanus follow an acute injury, such as a puncture wound, laceration, or abrasion. Tetanus is acquired indoors or during farming, gardening, and other outdoor activities. The injury may be major but often is trivial, so that medical attention is not sought; in some instances no injury can be identified. The disease may complicate chronic conditions such as skin ulcers, abscesses, and gangrene. Tetanus is also associated with burns, frostbite, middle-ear infection, surgery, abortion, childbirth, body piercing, and drug abuse, notably “skin popping.” In some patients no portal of entry for the organism can be identified.

PATHOGENESIS Contamination of wounds with spores of C. tetani is probably a frequent occurrence. Germinaton and toxin production, however, take place only in wounds with low oxidation-reduction potential, such as those with devitalized tissue, foreign bodies, or active infection. C. tetani does not itself evoke inflammation, and the portal of entry retains a benign appearance unless infection with other organisms is present.

Toxin released in the wound binds to peripheral motor neuron terminals, enters the axon, and is transported to the nerve-cell body in the brainstem and spinal cord by retrograde intraneuronal transport. The toxin then migrates across the synapse to presynaptic terminals, where it blocks release of the inhibitory neurotransmitters glycine and γ-aminobutyric acid (GABA). The blocking of neurotransmitter release by tetanospasmin, a zinc metalloprotease, involves the cleavage of protein(s) critical to proper function of the synaptic vesicle release apparatus. With diminished inhibition, the resting firing rate of the α motor neuron increases, producing rigidity. With lessened activity of reflexes that limit polysynaptic spread of impulses (a glycnergic activity), agonists and antagonists may be recruited rather than inhibited, with the consequent production of spasms. Loss of inhibition may also affect preganglionic sympathetic neurons in the lateral gray matter of the spinal cord and produce sympathetic hyperactivity and high circulating catecholamine levels. Tetanospasmin, like botulinum toxin, may block neurotransmitter release at the neuromuscular junction and produce weakness or paralysis; recovery requires sprouting of new nerve terminals.

In local tetanus, only the nerves supplying the affected muscles are involved. Generalized tetanus occurs when toxin released in the wound enters the lymphatics and bloodstream and is spread widely to distant nerve terminals; the blood-brain barrier blocks direct entry into the central nervous system. If it is assumed that intraneuronal transport times are equal for all nerves, short nerves are affected before long nerves: this fact explains the sequential involvement of nerves of the head, trunk, and extremities in generalized tetanus.

CLINICAL MANIFESTATIONS Generalized tetanus, the most common form of the disease, is characterized by increased muscle tone and generalized spasms. The median time of onset after injury is 7 days; 15% of cases occur within 3 days and 10% after 14 days.

Typically, the patient first notices increased tone in the masseter muscles (trismus, or lockjaw). Dysphagia or stiffness or pain in the neck, shoulder, and back muscles appears concurrently or soon thereafter. The subsequent involvement of other muscles produces a rigid abdomen and stiff proximal limb muscles; the hands and feet are relatively spared. Sustained contraction of the facial muscles results in a grimace or sneer (risus sardonicus), and contraction of the back mus-
General Measures The goals of therapy are to eliminate the source of toxin, neutralize unbound toxin, and prevent muscle spasms, monitoring the patient’s condition and providing support—especially respiratory support—until recovery. Patients should be admitted to a quiet room in an intensive care unit, where observation and cardiopulmonary monitoring can be maintained continuously but stimulation can be minimized. Protection of the airway is vital. Wounds should be explored, carefully cleansed, and thoroughly debrided.

Antibiotic Therapy Although of unproven value, antibiotic therapy is administered to eradicate vegetative cells—the source of toxin. The use of penicillin (10 to 12 million units intravenously, given daily for 10 days) has been recommended, but metronidazole (500 mg every 6 h or 1 g every 12 h) is preferred by some experts on the basis of this drug’s excellent antimicrobial activity, a survival rate higher than that obtained with penicillin in one nonrandomized trial, and the absence of activity antagonistic to GABA, as seen with penicillin. Clindamycin and erythromycin are also alternatives for the treatment of penicillin–allergic patients. Additional specific antimicrobial therapy should be given for active infection with other organisms.

Antitoxin Given to neutralize circulating toxin and unbound toxin in the wound, antitoxin effectively lowers mortality; toxin already bound to neural tissue is unaffected. Human tetanus immune globulin (TIG) is the preparation of choice and should be given promptly. The dose is 3000 to 6000 units intramuscularly, usually in divided doses because the volume is large. The optimal dose is not known, however, and results from one study indicated that a 500-unit dose was as effective as higher doses. Pooled intravenous immunoglobulin may be an alternative to TIG, but the specific antitoxin concentration in this formulation is not standardized. It may be best to administer antitoxin before manipulating the wound; the value of injecting a dose proximal to the wound or infiltrating the wound is unclear. Additional doses are unnecessary because the half-life of antitoxin is long. Antibody does not penetrate the blood-brain barrier. Intrathecal administration should be considered experimental. Equine tetanus antitoxin (TAT) is not available in the United States but is used elsewhere. It is cheaper than human antitoxin, but its half-life is shorter and its administration commonly elicits hypersensitivity and serum sickness.

Control of Muscle Spasms Many agents, alone and in combination, have been used to treat the muscle spasms of tetanus, which are painful and can threaten ventilation by causing laryngospasm or sustained contraction of ventilatory muscles. The ideal therapeutic regimen would abolish spasmodic activity without causing oversedation and hypventilation. Diazepam, a benzodiazepine and GABA agonist, is in wide use. The dose is titrated, and large doses (≥250 mg/d) may be required. Lorazepam, with a longer duration of action, and midazolam, with a short half-life, are other options. Barbiturates and chlorpromazine are considered second-line agents. Therapeutic paralysis with a nondepolarizing neuromuscular blocking agent and mechanical ventilation may be required for the treatment of spasms unresponsive to medication or spasms that threaten ventilation. However, prolonged paralysis after the discontinuation of therapy with such agents has been described, and both the need for continued paralysis and the occurrence of complications should be assessed daily. Alternative agents include propofol, which is expensive; dantrolene and intrathecal baclofen, which are being investigated in the hope of shortening the period of therapeutic paralysis; succinylcholine, which has been associated with hyperkalemia; and magnesium sulfate, which requires monitoring of neurologic (patellar reflex) and respiratory function as well as daily measurement of serum magnesium levels.

Respiratory Care Intubation or tracheostomy, with or without mechanical ventilation, may be required for hypoventilation due to overextension or laryngospasm or for the avoidance of aspiration by patients with trismus, disordered swallowing, or dysphagia. The need for these procedures should be anticipated, and they should be undertaken effectively and early.

Autonomic Dysfunction The optimal therapy for sympathetic overactivity has not been defined. Agents that have been considered include betalol (an α- and β-adrenergic blocking agent that is recommended by some experts but that reportedly has caused sudden death), esmolol administered by continuous infusion (a beta blocker whose short half-life may be advantageous in the event of severe hypertension from unopposed α-adrenergic activity), clonidine (a central-acting antidiurenergic drug), and morphine sulfate. Parenteral magnesium sulfate
and continuous spinal or epidural anesthesia have been used but may be more difficult to administer and monitor. The relative efficacy of these modalities has yet to be determined. Hypotension or bradycardia may require volume expansion, use of vasopressors or chronotropic agents, or pacemaker insertion.

**Vaccine**  Patients recovering from tetanus should be actively immunized (see below) because immunity is not induced by the small amount of toxin that produces disease.

**Additional Measures**  Additional therapeutic measures include hydration to control insensible and other fluid losses, which may be significant; the meeting of the patient’s increased nutritional requirements by enteral or parenteral means; physiotherapy to prevent contractures; and administration of heparin or another anticoagulant to prevent pulmonary emboli. Bowel, bladder, and renal function must be monitored. Gastrointestinal bleeding and decubitus ulcers must be prevented, and intercurrent infection should be treated.

**PREVENTION**  

**Active Immunization**  All partially immunized and unimmunized adults should receive vaccine, as should those recovering from tetanus. The primary series for adults consists of three doses: the first and second doses are given 4 to 8 weeks apart, and the third dose is given 6 to 12 months after the second. A booster dose is required every 10 years and may be given at mid-decade ages—35, 45, and so on. Combined tetanus and diphtheria toxoid, adsorbed (Td, for adult use)—rather than single-antigen tetanus toxoid—is preferred for persons >7 years of age. Adsorbed vaccine is preferred because it produces more persistent antibody titers than fluid vaccine. In response to a vaccine shortage in 2001, the Centers for Disease Control and Prevention recommended that routine booster doses of Td for adolescents and adults be deferred until 2002, pending a better supply, but that all other existing recommendations for vaccine use be followed.

**Wound Management**  Proper wound management requires consideration of the need for (1) passive immunization with TIG and (2) active immunization with vaccine, preferably Td in persons over age 7 (Table 124-1). The dose of TIG for passive immunization of persons with wounds of average severity is 250 units intramuscularly, which produces a protective antibody level in the serum for at least 4 to 6 weeks; the appropriate dose of TAT, an equine-derived product, is 3000 to 6000 units. Vaccine and TAT should be administered at separate sites with separate syringes.

**Neonatal Tetanus**  Measures aimed at preventing neonatal tetanus include maternal vaccination, even during pregnancy; efforts to increase the proportion of births that take place in the hospital; and the provision of training for nonmedical birth attendants.

**PROGNOSIS**  The application of methods to monitor and support oxygenation has markedly improved the prognosis in tetanus; mortality rates as low as 10% have been reported from units accustomed to handling such cases. In the United States during the periods 1995–

**Botulism**

**Elias Abrutyn**

---

**DEFINITION**  Botulism is a paralytic disease caused by potent protein neurotoxins elaborated by Clostridium butylicum. Illness begins with cranial nerve involvement, and progression proceeds caudally to involve the extremities. Cases may be classified as (1) food-borne botulism, from ingestion of preformed toxin in food contaminated with C. butylicum; (2) wound botulism, from toxin produced in wounds contaminated with the organism; and (3) intestinal botulism, from ingestion of spores and production of toxin in the intestine of infants (infant botulism) or adults. Botulinum toxin, because of its extraordinary potency, has long been considered a threat as an agent of bioterrorism or biological warfare (see Chap. 205).

**ETIOLOGIC AGENT**  C. botulinum, a species encompassing a heterogeneous group of anaerobic gram-positive organisms that form subterminal spores, is found in soil and marine environments throughout the world and elaborates the most potent bacterial toxin known. Organisms of types A through G have been distinguished by the antigenic specificities of their toxins; a classification system based on physiologic characteristics has also been described. Rare strains of other clostridial...
species—*C. butyricum* and *C. baratti*—have also been found to produce toxin. *C. botulinum* strains with proteolytic activity can digest food and produce a spoiled appearance; nonproteolytic types leave the appearance of food unchanged.

Of the eight distinct toxin types described (A, B, C1, C2, D, E, F, and G), all except C2 are neurotoxins; C2 is a cytotoxin of unknown clinical significance. Botulism neurotoxin, whether ingested, inhaled, or produced in the intestine or a wound, enters the vascular system and is transported to peripheral cholinergic nerve terminals, including neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. The central nervous system is not involved. Active neurotoxin (150 kDa) is composed of a heavy chain (a 100-kDa fragment responsible for neurospecific binding and translocation in the nerve cell) and a light chain (a 50-kDa fragment responsible for intracellular catalytic activity). The steps involved in neurotoxin activity include (1) specific binding to presynaptic nerve cells at the myoneural junction, (2) internalization of the toxin inside the nerve cell in endocytic vesicles, (3) translocation of the toxin into the cytosol, and (4) proteolysis by toxin (a zinc endopeptidase) of components of the neuroexocytosis apparatus curtailing release of the neurotransmitter acetylcholine. Cure follows sprouting of new nerve terminals.

Toxin is heat-labile, but spores are highly heat-resistant; both can be inactivated under appropriate conditions (see “Prevention,” below). In the gastrointestinal tract, toxin is complexed with nontoxic proteins and resists degradation. Toxin types A, B, E, and (rarely) F cause human disease; type G (from *C. argentinense*) has been associated with sudden death, but not with neuroparalytic illness, in a few patients in Switzerland; and types C and D cause animal disease.

**Epidemiology** Human botulism occurs worldwide. In the United States, the geographic distribution of cases by toxin type parallels the distribution of organism types found in the environment. Type A predominates west of the Rocky Mountains; type B is generally distributed but is more common in the East; and type E is found in the Pacific Northwest, Alaska, and the Great Lakes area. In the United States, food-borne botulism has been associated primarily with home-canned food, particularly vegetables, fruit, and condiments, and less commonly with meat and fish. Type E outbreaks are frequently associated with fish products. Commercial products occasionally cause outbreaks, but some of these outbreaks have resulted from improper handling after purchase. Outbreaks in restaurants, schools, and private homes have been traced to uncommon sources (commercial potpies, beef stew, turkey loaf, sautéed onions, baked potatoes, and chopped garlic in oil). Food-borne botulism can occur when (1) a food to be preserved is contaminated with spores, (2) preservation does not inactivate the spores but kills other putrefactive bacteria that might inhibit growth of *C. botulinum* and provides anaerobic conditions at a pH and temperature that allow germination and toxin production, and (3) food is not heated to a temperature that destroys toxin before being eaten.

**Clinical Manifestations**

**Food-Borne Botulism** After ingestion of food containing toxin, illness varies from a mild condition for which no medical advice is sought to very severe disease that can result in death within 24 h. The incubation period is usually 18 to 36 h but, depending on toxin dose, can extend from a few hours to several days. Symmetric descending paralysis is characteristic and can lead to respiratory failure and death. Cranial nerve involvement, which almost always marks the onset of symptoms, usually produces diplopia, dysarthria, dysphonia, and/or dysphagia. Weakness progresses, often rapidly, from the head to involve the neck, arms, thorax, and legs; occasionally, weakness is asymmetric. Nausea, vomiting, and abdominal pain may precede or follow the onset of paralysis. Dizziness, blurred vision, dry mouth, and very dry, occasionally sore throat are common. Patients are generally alert and oriented, but they may be drowsy, agitated, and anxious. Typically, they have no fever. Piosis is frequent; the pupillary reflexes may be depressed, and fixed or dilated pupils are noted in half of patients. The gag reflex may be suppressed, and deep tendon reflexes may be normal or decreased. Sensory findings are usually absent. Paralytic ileus, severe constipation, and urinary retention are common.

**Wound Botulism** Wound botulism occurs when the spores contaminating a wound germinate and form vegetative organisms that produce toxin. This rare condition resembles food-borne illness except that the incubation period is longer, averaging about 10 days, and gastrointestinal symptoms are lacking. Wound botulism has been documented after traumatic injury involving contamination with soil; in injection drug users, for whom black-tar heroin use has been identified as a risk factor; and after cesarean delivery. The illness has occurred even after antibiotics have been given to prevent wound infection. When present, fever is probably attributable to concurrent infection with other bacteria. The wound may appear benign.

**Intestinal Botulism** In intestinal botulism, toxin is produced in and absorbed from the intestine after the germination of ingested spores. Infant botulism is the most common form of botulism. The severity ranges from mild illness with failure to thrive to fulminant severe paralysis with respiratory failure. Infant botulism may be one cause of sudden infant death. The identification of contaminated honey as one source of spores has led to the recommendation that honey not be fed to children <12 months of age. Most cases cannot be attributed to a particular food source. The factors permitting intestinal colonization with *C. botulinum* are not fully defined, but cases usually involve infants <6 months of age; susceptibility may decrease as the normal intestinal flora develops. Intestinal botulism involving adults is uncommon. The patient may have a history of gastrointestinal disease, gastrointestinal surgery, or recent antibiotic therapy. Toxin and organisms may be identified in the stool.

**Bioterrorism and Biological Warfare** (See also Chap. 205) Botulinum toxin could be dispersed as an aerosol (producing inhalational botulism) or as a contaminant in material to be ingested (producing food-borne botulism). Inhalational botulism resembles food-borne illness, but gastrointestinal symptoms are absent. Botulism follows adsorption of toxin from mucosal surfaces (gut, lung) and wounds, but the toxin does not penetrate intact skin. As a toxin-mediated illness, botulism is noncommunicable, and standard isolation precautions are sufficient unless bacterial meningitis is being considered. Features suggestive of an outbreak due to deliberate release of botulinum toxin are shown in Table 125-1.

**Diagnosis** A diagnosis of botulism must be considered in patients with symmetric descending paralysis who are afibrile and mentally intact. The bulbar musculature is involved initially, but sensory findings are absent and, early on, deep tendon reflexes remain intact. The differential diagnosis of botulism and differentiating features are listed in Table 125-2. The demonstration of toxin in serum by bioassay in mice is definitive, but this test may be negative, particularly in wound and infant botulism. It is performed only by specific laboratories, which can be identified through regional public health authorities. Other assays are

---

**Table 125-1 Features of Outbreaks Suggesting Deliberate Release of Botulinum Toxin**

- Outbreak of large number of cases of acute flaccid paralysis with prominent bulbar palsies
- Outbreak with an unusual botulinum toxin type (i.e., type C, D, F, or G or type E toxin not associated with food of aquatic origin)
- Outbreak with a common geographic factor among cases (e.g., airport, work location) but without a common dietary exposure (i.e., features suggesting an aerosol attack)
- Multiple simultaneous outbreaks with no common source

* A careful travel and activity history, as well as a dietary history, should be taken in any suspected botulism outbreak. Patients should also be asked whether they know of other persons with similar symptoms.

**Source:** Reproduced with permission of the publisher from Arnon et al, 2002
Patients should be hospitalized and monitored closely, both clinically and by spirometry, pulse oximetry, and measurement of arterial blood gases for incipient respiratory failure. Intubation and mechanical ventilation should be strongly considered when the vital capacity is <30% of predicted, especially when paralysis is progressing rapidly and hypoxemia with absolute or relative hypercarbia is documented (Chap. 252). Serial measurements of the maximal static inspiratory pressure may be useful in predicting respiratory failure.

In food-borne illness, equine antitoxin should be administered as soon as possible after specimens are obtained for laboratory analysis. Treatment should not await laboratory analyses, which may take days. The previous trivalent antitoxin (types A, B, and E) preparation is no longer available. Instead, a bivalent preparation containing toxin types A and B and an investigational monovalent type E preparation can be obtained. The bivalent preparation is given routinely; monovalent type E antitoxin is given in addition when exposure to type E toxin is suspected (after seafood ingestion, for example). In the United States, antitoxin as well as help in clinical management and laboratory confirmation are available at any time from state health departments or from the Centers for Disease Control and Prevention (CDC: 404-639-2206; emergency number, 404-639-2888). A limited supply of an investigational heptavalent antitoxin (types A through G) is maintained by the U.S. military for emergency use.

After testing for hypersensitivity to horse serum, antitoxin is given as recommended by the CDC; repeated doses are not considered necessary. Anaphylaxis and serum sickness are risks inherent in use of the equine product, and desensitization of allergic patients may be required. If there is no ileus, cathartics and enemas may be given to purge the gut of toxin; emetics or gastric lavage can also be used if the time since ingestion is brief (only a few hours). Neither the use of antibiotics to eliminate an intestinal source for possible continued toxin production nor the administration of guanidine hydrochloride and other drugs to reverse paralysis is of proven value.

Treatment of infant botulism requires supportive care and administration of human botulism immune globulin (obtainable at all times from the California Department of Health Services at 510-540-2646). Neither equine antitoxin nor antibiotics have been shown to be beneficial. In wound botulism, equine antitoxin is administered. The wound should be thoroughly explored and debrided, and an antibiotic such as penicillin should be given to eradicate C. botulinum from the site, even though the benefit of this therapy is unproven. Results of wound cultures should guide the use of other antibiotics.

Botulinum toxins have been approved for therapeutic use. Botulinum toxin type A has been approved for the treatment of strabismus, blepharospasm, cervical dystonia, and glabellar lines; therapy appears safe and effective. Botulinum toxin type B has been approved for the treatment of cervical dystonia. The value of these preparations in many other conditions is being evaluated. Generalized botulism-like weakness complicating therapy has been reported but is rare.

**PROGNOSIS** Type A disease is generally more severe than type B, and mortality from botulism is higher among patients above age 60 than among younger patients. With improved respiratory and intensive care, the case-fatality rate in food-borne illness has been reduced to ~7.5% and is low in infant botulism as well. Artificial respiratory support may be required for months in severe cases. Some patients experience residual weakness and autonomic dysfunction for as long as a year after disease onset.

**PREVENTION** A pentavalent vaccine (A–E) is available for use in highly exposed individuals. Spores can be inactivated by exposure to high temperature (116°C to 121°C) and pressure, as in steam sterilizers or pressure cookers used in accordance with the manufacturer’s instructions. Toxin can be inactivated by exposure to a temperature of 100°C for 10 min. Newly identified cases should be reported immediately to public health authorities.

* Pharyngeal erythema can occur in botulism. **Note:** CNS, central nervous system; CSF, cerebrospinal fluid; EEG, electroencephalogram; EMG, electromyogram.

*Source:* Reproduced with the permission of the publisher from Armon et al., 2002.

being developed and remain experimental. The demonstration of the organism or its toxin in vomitus, gastric fluid, or stool is strongly suggestive of the diagnosis, because intestinal carriage is rare. Isolation of the organism from food without toxin is insufficient grounds for the diagnosis. Wound cultures yielding the organism are suggestive of botulism. The edrophonium chloride (Tensilon) test for myasthenia gravis may be falsely positive in botulism but is usually less dramatically positive than in the former condition. Nerve conduction velocity is normal, but compound muscle action potentials on routine nerve stimulation studies are decreased with a supramaximal stimulus, and facilitation is evident after repetitive stimulation at high frequency. Single-fiber electromyography may be helpful. The white blood cell count and erythrocyte sedimentation rate are normal.
DEFINITION  Bacteria of the genus Clostridium are gram-positive, spore-forming, obligate anaerobes that are ubiquitous in nature. There are >60 recognized species of clostridia, many of which are generally considered saprophytic. Some of these species are pathogenic for humans and animals, particularly under conditions of lowered oxidation-reduction potential. Infections associated with these organisms range from localized wound contamination to overwhelming systemic disease. The four major disease categories for which clostridia are responsible are intestinal disorders, suppurative deep-tissue infections, skin and soft tissue infections, and bacteremia. Toxins play a major role in some of these syndromes.

ETIOLOGY  In humans, clostridia normally reside in the gastrointestinal tract and in the female genital tract, although they occasionally are isolated from the skin or the mouth. Of the known species of the genus Clostridium, at least 30 have been isolated from human infections. Like several other pathogenic anaerobic bacterial species, clostridia are quite aerotolerant, but they do not grow on artificial media in the presence of oxygen. Clostridia characteristically produce abundant gas from localized wound contamination to overwhelming systemic disease. The four major disease categories for which clostridia are responsible are intestinal disorders, suppurative deep-tissue infections, skin and soft tissue infections, and bacteremia. Toxins play a major role in some of these syndromes.

PATHOGENESIS  Despite the isolation of clostridial species from many serious traumatic wounds, the prevalence of severe infections due to these organisms is low. Two factors that appear to be essential to the development of severe disease are tissue necrosis and a low oxidation-reduction potential. Clostridium perfringens requires at least 14 amino acids and at least 6 additional growth factors for optimal growth. These nutrients are not found in appreciable concentrations in normal body fluids but are present in necrotic tissue. When C. perfringens grows in necrotic tissue, a zone of tissue damage due to the toxins elaborated by the organism allows progressive growth. In contrast, when only a few bacteria leak into the bloodstream from a small defect in the intestinal wall, the organisms do not have the opportunity to multiply rapidly because blood as a medium for growth is relatively deficient in certain amino acids and growth factors. Therefore, in a patient without tissue necrosis, bacteremia is usually benign.

C. perfringens possesses at least 17 possible virulence factors, including 12 active tissue toxins and enterotoxins. The enterotoxins include four major lethal toxins: α, β, ε, and ι. The α toxin is a phospholipase (lecithinase) that splits lecithin into phosphorylcholine and diglyceride. It has been associated with gas gangrene and is known to be hemolytic, to destroy platelets and polymorphonuclear leukocytes (PMNs), and to cause widespread capillary damage. When injected intravenously, it causes massive intravascular hemolysis and damages liver mitochondria. The α toxin may be important in the initiation of muscle infections that may progress to gas gangrene. Experimentally, the higher the concentration of α toxin in the culture fluid, the smaller the dose of C. perfringens required to produce infection. The protective effect of antiserum is directly proportional to its content of α antitoxin. Studies suggest that θ toxin, a thiol-activated cytolsin that is also called perfringolysin O, may also play an important role in pathogenesis by promoting vascular leukostasis, endothelial cell injury, and regional tissue hypoxia. The resulting perfusion defects extend the anaerobic environment and contribute to rapidly advancing tissue destruction. A characteristic pathologic finding in gas gangrene is the near absence of PMNs despite extensive tissue destruction. Experimental data indicate that both α and θ toxins are essential in the leukocyte aggregation that occurs at the margins of tissue injury instead of the expected infiltration of these cells into the area of damage. Genetically altered strains induce less leukocyte aggregation when α toxin is absent and none when θ toxin is missing. The other major toxins, β, ε, and ι, are known to increase capillary permeability.

CLINICAL MANIFESTATIONS  

FOOD POISONING  

C. perfringens, primarily type A, is the second or third most common cause of food poisoning in the United States (Chap. 113). The responsible toxin is thought to be a cytotxin produced by >75% of strains isolated from cases of foodborne disease. The cytotxin binds to a receptor on the small-bowel brush border and induces a calcium ion–dependent alteration in permeability. The associated loss of ions alters intracellular metabolism, resulting in cell death. Outbreaks generally have resulted from problems in the cooling and storage of food cooked in bulk. The food sources primarily involved are meat, meat products, and poultry. Generally, the implicated meats have been cooked, allowed to cool, and then recooked the following day, often in a stew or hash. Strains of C. perfringens that contaminate meat manage to survive initial cooking. During reheating, the organisms sporulate and germinate. The disease is associated with an attack rate that is often high as 70%. Symptoms of food poisoning from type A strains develop 8 to 24 h after ingestion of foods heavily contaminated with the organism. The primary symptoms include epigastric pain, nausea, and watery diarrhea usually lasting 12 to 24 h. Fever and vomiting are
uncommon. Molecular methods including ribotyping and pulsed-field gel electrophoresis have been used to detect fecal cytotoxin in outbreaks of food poisoning caused by C. perfringens.

C. perfringens has also been implicated in a more severe form of diarrhea than that of classic food poisoning. This more severe disease tends to occur in the elderly and has been associated with antibiotic use in hospitalized populations. In this form of disease, diarrhea is generally more profuse, of longer duration, and accompanied by abdominal pain. Blood and mucus have been detected in the feces of the affected patients. In one hospital-based study of a cluster of cases, widespread environmental contamination with C. perfringens spores was documented.

**ENTERITIS NECROTICANS** Necrotizing enteritis (enteritis necroticans, or pig-bel) is caused by β toxin produced by type C strains of C. perfringens following ingestion of a high-protein meal in conjunction with trypsin inhibitors (e.g., in sweet potatoes) by a susceptible host who has limited intestinal proteolytic activity. This disease has been reported among children and adults in New Guinea. A similar disease, darmbrand, was epidemic in Germany after World War II. Clinical features of pig-bel include acute abdominal pain, bloody diarrhea, vomiting, shock, and peritonitis; 40% of patients die. Pathologic studies reveal an acute ulcerative process of the bowel restricted to the small intestine. The mucosa is lifted off the submucosa, with the formation of large denuded areas. Pseudomembranes composed of sloughed epithelium are common, and gas may dissect into the submucosa. The source of the organisms may be the patient’s own intestinal flora; cultures of ingested pork have failed to yield the organism. Antibodies to the β toxin of C. perfringens have been of considerable benefit in changing the course of established disease. In a large-scale trial, children immunized with C. perfringens β toxoid were protected.

**NEUTROPENIC ENTEROCOLITIS (TYPHILITIS)** See Chaps. 72 and 148.

**Suppurative Deep Tissue Infections** Clostridia are frequently recovered from various suppurrative conditions in conjunction with other anaerobic and aerobic bacteria but can also be the only organisms isolated. These suppurative conditions, which exist with severe local inflammation but usually without the characteristic systemic signs induced by clostridial toxins, include intraabdominal sepsis, empyema, pelvic abscess, subcutaneous abscess, frostbite with gas gangrene, infection of a stump in an amputee, brain abscess, prostatic abscess, perianal wounds. A major site for such a malignancy is the gastrointestinal tract, particularly the colon. An association with leukemia or with other solid tumors has also been noted, and one case of fatal myonecrosis has been reported in a patient with ovarian cancer. Some of these patients present with C. septicum bacteremia; these cases have a fulminant clinical course (discussed below). Others develop localized suppurative infection in the abdomen or the abdominal wall without bacteremia. Presumably, this infection arises from a silent perforation that leads to intraabdominal abscess formation.

Clostridia have been isolated from suppurrative infections of the female genital tract, particularly tuboovarian and pelvic abscesses. The major species involved has been C. perfringens. Most of these are mild suppurative infections without evidence of uterine gangrene. C. perfringens has been isolated from as many as 20% of diseased gallbladders at surgery. One clinical syndrome, emphysematous cholecystitis, is caused by clostridial species at least 50% of the time. In this syndrome, gas forms in the biliary radicles and the wall of the gallbladder.

Emphysematous cholecystitis is seen most often in diabetic patients. Although the mortality rate in this entity is higher than in more common forms of cholecystitis, there is no evidence of myonecrosis.

Clostridia are among the many organisms found in empyema fluid or isolated by transtracheal aspiration from patients with lung abscesses. There is no unique clinical clue to the presence of clostridia (as opposed to other organisms) in these infections. C. perfringens has been reported as a cause of empyema arising from aspiration pneumonitis, pulmonary emboli, and infarction. However, the majority of cases of clostridial empyema are secondary to trauma.

**Skin and Soft Tissue Infections** Various categories of traumatic wound infections due to clostridia have been described: simple contamination, anaerobic cellulitis, fasciitis with or without systemic manifestations, and anaerobic myonecrosis.

**SIMPLE CONTAMINATION** Clostridia are cultured most often from wounds in the absence of clinical signs of sepsis. As many as 30% of battle wounds are contaminated by clostridia without signs of suppuration, and 16% of penetrating abdominal wounds yield clostridia on culture despite treatment with cephalothin and kanamycin. In cases of trauma, clostridia are isolated with equal frequency from suppurrative and well-healing wounds. Thus the diagnosis of clostridial infection should be based on clinical rather than bacteriologic criteria.

**LOCALIZED INFECTION OF THE SKIN AND SOFT TISSUE WITHOUT SYSTEMIC SIGNS** This condition, originally referred to as anaerobic cellulitis, is a localized infection involving the skin and soft tissue and is due to clostridia alone or with other bacteria. There are no systemic signs of toxicity, although the infection may invade locally, producing necrosis. These infections tend to be relatively indolent, spreading slowly to contiguous areas. Localized infections are relatively free of pain and edema. Perhaps because of the lack of edema, gas that is limited to the wound and the immediately surrounding tissue may be more evident than in gas gangrene. In these localized infections, gas is never found intramuscularly. Cellulitis, perirectal abscesses, and diabetic foot ulcers are typical infections from which clostridial species can be isolated. If inadequately treated, these localized infections advance by extension through subcutaneous tissue and fascial planes into muscle and may produce severe systemic disease with signs of toxemia.

A localized form of suppurative myositis has been described in heroin addicts. These patients develop local pain and tenderness in discrete areas (particularly the thigh and forearm), with the subsequent appearance of fluctuance and crepitance that require surgical drainage. The unusual aspect of these infections is that they remain localized without systemic signs of toxicity. Moreover, the affected local areas are not necessarily sites of trauma or heroin injection. Pathologic examination reveals subcutaneous abscesses, purulent myositis, and fasciitis from which clostridia are recovered in pure culture; on occasion, mixed infections involving aerobes and anaerobes are found. Wound botulism has been reported in association with the injection of black tar heroin.

**SPREADING CELLULITIS AND FASCIITIS WITH SYSTEMIC TOXICITY** This condition involves diffuse spreading cellulitis and fasciitis, without myonecrosis and with only mild inflammation in muscle. Patients present with the abrupt onset of a syndrome that progresses rapidly (within hours) through the fascial planes. In cases with suppuration and gas in soft tissues as well as overwhelming toxemia, the infection is rapidly fatal. On physical examination there is subcutaneous crepitation but little localized pain. Surgery is of no proven value because there are no discretely involved tissues amenable to resection, as may be the case in myonecrosis. However, in rapidly advancing fasciitis, incision of the affected area is still the cornerstone of therapy. The initial local lesion may be quite innocuous and arises from an area involved by tumor or other infection and not by injury. The systemic toxic effects include hemolysis and injury of capillary membranes. Usually, this infection is fatal within 48 h, despite intensive therapy involving antitoxin and exchange transfusion. This syndrome is seen most commonly in patients with carcinoma, especially of the sigmoid or the
Myonecrosis, especially of the extremities. They present with a rapidly worsening course that includes hemoglobinuria, hemoglobinemia, and sepsis.

**GAS GANGRENE (CLOSTRIDIAL MYONECROSIS)** Gas gangrene is characterized by rapid and extensive necrosis of muscle accompanied by gas formation and systemic toxicity and occurs when bacteria invade healthy muscle from adjacent traumatized muscle or soft tissue. The infection originates in a wound contaminated with clostridia. Although >30% of deep wounds are infected with clostridia, the incidence of clostridial myonecrosis is quite low. These infections occur in both military and civilian settings.

An essential factor in the genesis of gas gangrene appears to be trauma, particularly involving deep muscle laceration. The entity of clostridial myonecrosis is relatively uncommon after simple, through-and-through bullet wounds without shattering of bone and is relatively common following sharpshilet fragmentation wounds, particularly when deep muscle is involved. In civilian cases, gas gangrene can follow trauma, surgery, or intra-muscular injection. The trauma need not be severe; however, the wound must be deep, necrotic, and without communication to the surface.

The incubation period of gas gangrene is usually short: almost always <3 days and frequently <24 h. Some 80% of cases are caused by *C. perfringens*, while *C. novyi*, *C. septicum*, and *C. histolyticum* cause most of the remaining cases. Typically, gas gangrene begins with the sudden onset of pain in the region of the wound, which helps to differentiate it from spreading cellulitis. Once established, the pain increases steadily in severity but remains localized to the infected area and spreads only if the infection spreads. Soon after pain develops, local swelling and edema—accompanied by a thin, often hemorrhagic exudate—appear. Patients frequently develop marked tachycardia, but elevation in temperature may be only minimal. Gas is usually not obvious at this early stage and may be completely absent. Foulness of the wound exudate may be noted. The skin is tense, white, often marbled with blue, and cooler than normal. The symptoms progress rapidly; swelling, edema, and toxemia increase, and a profuse serous discharge, which may have a peculiar sweetish smell, appears. Gram’s staining of the wound exudate shows many gram-positive rods with relatively few inflammatory cells.

At surgery, muscle may appear pale because of the intensity of edema, but it does not contract when probed with a scalpel. When dissected, the muscle is beefy red and nonviable and can progress to become black, friable, and gangrenous. It is important to establish a diagnosis early, preferably by frozen-section biopsy of muscle.

Despite hypotension, renal failure, and (often) body crepitation, patients with myonecrosis frequently have a heightened awareness of their surroundings until just before death, when they lapse into toxic bronzing of the skin. As in myonecrosis, the mental status of severely ill patients is characterized by increased alertness and apprehension.

**Bacteremia and Clostridial Sepsis** The relatively common entity of transient clostridial bacteremia can arise in any hospitalized patient but is most common with a predisposing focus in the gastrointestinal tract, biliary tract, or uterus. Fever frequently resolves within 24 to 48 h without therapy. Despite the finding of clostridial bacteremia following septic abortions and the frequent isolation of clostridia from the lochia, most of the patients involved do not have evidence of sepsis.

In one series of 60 patients with clostridial bacteremia, half had an infected site that could be associated with the bacteremia, while the other half had a totally unrelated illness, such as tuberculous pneumonia, meningitis, or benign gastroenteritis. By the time blood culture reports are returned, patients frequently are completely well and sometimes have been discharged. Therefore, when a blood culture is positive for clostridia, the patient must be assessed clinically rather than simply treated on the basis of the culture result.

Clostridial sepsis is an uncommon but almost invariably fatal illness following clostridial infection—primarily that of the uterus, colon, or biliary tract. This entity must be differentiated from transient clostridial bacteremia, which is much more common. *C. perfringens* causes the majority of cases of both sepsis and transient bacteremia.

The relatively common entity of transient clostridial sepsis originates from the female genital tract and follow septic abortion. Introduction of a foreign body is a common antecedent event. In the uterus, residual necrotic fetal and placental tissues and traumatized endometrium may allow the growth of clostridia. Only a small fraction of cases of septic abortion (1%) are followed by serious sepsis. In these patients, sepsis, fever, and chills begin from 1 to 3 days after the attempted abortion. The initial signs are malaise, headache, severe myalgias, abdominal pain, nausea, vomiting, and occasionally diarrhea. Frequently, a bloody or brown vaginal discharge is noted. Patients may rapidly develop oliguria, hypotension, jaundice, and hemoglobinuria. The hemolysis, which is secondary to *C. perfringens* α toxin, causes a characteristic bronzing of the skin. As in myonecrosis, the mental status of severely ill patients is characterized by increased alertness and apprehension.

Local examination of the pelvis reveals foul cervical discharge, occasionally with gas. Frequently, laceration marks around the cervix or perforation of the cervical segment is evident. If the infection involves...
the myometrium or has spread to the adnexa, extreme tenderness, guarding, and an adnexal mass may be found.

Laboratory studies in patients with sepsis reveal an elevated white blood cell count and may show pink, hemoglobin-tinted plasma. Anemia is proportional to the degree of hemolysis, and the hematocrit may be extremely low. Platelet counts may be reduced, and there is often evidence of disseminated intravascular coagulation (DIC). Oliguria or anuria, increasingly refractory hypotension, and hemorrhage and bruising may develop.

Clostridia may enter the bloodstream from the gastrointestinal or biliary tract. This occurrence is associated with ulcerative lesions or obstruction of the small or large intestine, necrotic or infiltrating malignancy, bowel surgery, or various abdominal catastrophes. The patient may present with an acute febrile illness, with chills and fever but no other signs of localized infection. Intravascular hemolysis occurs in as many as half of such cases. Biliary or gastrointestinal symptoms, if present, may be the only clue to the etiology. Positive blood cultures provide the definitive clue to the diagnosis.

Patients with malignant disease can also develop rapidly fatal clostridial sepsis, particularly from a gastrointestinal focus. The most common species in this setting is *C. septicum*. Characteristic signs and symptoms include fever, tachycardia, hypotension, abdominal pain or tenderness, nausea, vomiting, and (preterminally) coma. The tachycardia may be out of proportion to the fever. Only ~20 to 30% of patients develop hemolysis. A striking feature of this syndrome is the rapidity of death, which frequently occurs in <12 h.

**DIAGNOSIS** The diagnosis of clostridial disease, in association with positive cultures, must be based primarily on clinical findings. Because of the presence of clostridia in many wounds, their mere isolation from any site, including the blood, does not necessarily indicate severe disease. Smears of wound exudates, uterine scrapings, or cervical discharge may show abundant large gram-positive rods as well as other organisms. Cultures should be placed in selective media and incubated anaerobically for identification of clostridia. The diagnosis of clostridial myonecrosis can be established by frozen-section biopsy of muscle.

The urine of patients with severe clostridial sepsis may contain protein and casts, and some patients may develop severe uremia. Profound alterations of circulating erythrocytes are seen in severely toxemic patients. Patients have hemolytic anemia, which develops extremely rapidly, along with hemoglobinemia, hemoglobinuria, and elevated levels of serum bilirubin. Spherocytosis, increased osmotic and mechanical red blood cell fragility, erythropagocytosis, and met-hemoglobinemia have been described. DIC may develop in patients with severe infection. In patients with severe sepsis, Wright’s or Gram’s staining of a smear of peripheral blood or Buffy coat may demonstrate clostridia.

X-ray examination sometimes provides an important clue to the diagnosis by revealing gas in muscles, subcutaneous tissue, or the uterus. However, the finding of gas is not pathognomonic for clostridial infection. Other anaerobic bacteria, frequently mixed with aerobic organisms, may produce gas.

swr questions on efficacy, but several knowledgeable authors believe that hyperbaric oxygen therapy has contributed to dramatic clinical improvement. Such therapy may, however, be associated with untoward effects due to oxygen toxicity and high atmospheric pressure. Some centers without hyperbaric chambers have reported acceptable mortality rates; thus expert surgical and medical management and control of complications are probably the most important factors in the treatment of gas gangrene. Fasciectomy should not be delayed for hyperbaric oxygen therapy.

127 MENINGOCOCCAL INFECTIONS
David S. Stephens, Robert S. Munford, Lee M. Wetzler

DEFINITION Neisseria meningitidis is the etiologic agent of two life-threatening diseases: meningococcal meningitis and fulminant meningococcemia. Meningococci also cause pneumonia, septic arthritis, pericarditis, urethritis, and conjunctivitis. Most cases are potentially preventable by vaccination.

ETIOLOGIC AGENT Meningococci are gram-negative aerobic diplococci. Unlike the other neisseriae, they have a polysaccharide capsule. They are transmitted among humans—their only known habitat—via respiratory secretions. Colonization of the nasopharynx or pharynx is much more common than invasive disease.

MICROBIOLOGY AND CLASSIFICATION On the basis of genome sequencing, N. meningitidis is categorized as a β-proteobacterium related to Bordetella, Burkholderia, Kingella, and Methylomonas and—more distantly—to Vibrio, Haemophilus, and Escherichia coli. Meningococci are traditionally classified by serologic typing systems based on structural differences in capsule (serogroup), major outer-membrane protein (OMP) porins (serotype), other OMPS (serosubtype), and lipooligosaccharide (LOS; immunotype). Thus, the meningococcal strain designation B:2b:P1.5:L3,7,9 reflects the serogroup (B), serotype (2b), serosubtype (P1.5), and immunotype (L3,7,9).

Meningococci are classified into serogroups according to the antigenicity of their capsular polysaccharides, which reflects structural differences in these carbohydrates. Five serogroups (A, B, C, Y, and W-135) are responsible for >90% of cases of meningococcal disease worldwide. Serogroup A strains, which caused most of the large epidemics of meningococcal disease during the first half of the twentieth century, are now associated with recurring epidemics in sub-Saharan Africa and other locales in the developing world. Serogroups B and C cause most cases of sporadic and epidemic meningococcal disease in industrialized countries. In the United States and Canada during the 1990s, serogroup B was the most common cause of sporadic disease, while serogroup C was a more frequent cause of outbreaks. Serogroup Y has recently been isolated from almost one-third of cases of meningococcal disease in the United States. In general, patients with serogroup Y disease are older and more likely to be African American or to have a chronic underlying illness than are patients with disease caused by other serogroups. Serogroups Y and W-135 are isolated more often than the other serogroups from patients with pneumonia.

One limitation of the serogroup classification is that the genes for capsule biosynthesis can be transferred from one strain to another, with consequent changes in the capsule structure of the recipient strain and therefore in its serogroup. Other methods for tracking meningococcal strains have thus become increasingly useful. Meningococcal serotypes and subtypes are defined by antigenic differences in specific OMPS, whereas multilocus enzyme electrophoresis classifies bacteria into electrophoretic types (ETs). Other techniques for establishing strain identity or nonidentity are pulsed-field gel electrophoresis and amplification of bacterial genomic sequences by polymerase chain reaction (PCR). These techniques are used for the identification of the strains associated with outbreaks of disease. For example, the virulent III-1 clonal complex of serogroup A was first recognized in Nepal in 1983 to 1984; it spread to Mecca, then to sub-Saharan Africa, and subsequently to temperate Africa. The serogroup B ET-5 complex was first identified in Norway in the 1970s and later caused outbreaks in Europe, Cuba, and South and North America (most recently, in the Pacific Northwest). Serogroup C ET-24 (the ET-37 complex) has caused sporadic cases and outbreaks in Canada and the United States; in some analyses, it has been associated with high rates of mortality and morbidity.

EPIDEMIOLOGY Meningococcal disease occurs worldwide as isolated (sporadic) cases, institution- or community-based outbreaks, and large epidemics. Despite effective antibiotics and partially effective vaccines, N. meningitidis is still a leading global cause of meningitis and rapidly fatal sepsis, often in otherwise-healthy individuals.

N. meningitidis is unique among the major bacterial agents of meningitis in that it causes epidemic as well as endemic (sporadic) disease. In all, 300,000 to 500,000 cases of meningococcal disease occur worldwide each year,numbers that frequently are increased by large epidemics. The annual incidence of meningococcal disease is 1 to 2 cases per 100,000 population for sporadic disease, 5 to 10 per 100,000 for hypersporadic disease (localized outbreaks and case clusters), and 10 to >1000 per 100,000 for pandemic and epidemic disease (e.g., serogroup A epidemics). The African meningitis belt (i.e., sub-Saharan Africa) continues to have high levels of sporadic disease and major outbreaks. In the largest meningococcal epidemic outbreak recorded, >300,000 cases and 30,000 deaths occurred in sub-Saharan Africa in 1996 to 1997 due to serogroup A N. meningitidis. Large serogroup B epidemics and/or outbreaks of serogroup A or C meningococcal disease have also occurred in Europe, the United States, Canada, China, Nepal, Mongolia, New Zealand, Cuba, Brazil, Chile, Saudi Arabia, and South Africa since 1980. In 2000, 2001, and 2002, worldwide epidemics of serogroup W-135 meningococcal disease occurred in association with the Muslim pilgrimage to Mecca (the Hajj) and in the meningitis belt of sub-Saharan Africa.

In the United States, the attack rate for sporadic meningococcal disease is ~1 case per 100,000 persons per year. Disease attack rates are highest among infants 3 to 9 months of age (10 to 15 cases per
Meningococcal colonization of the nasopharynx (asymptomatic carriage) can persist for months. In nonepidemic periods, ~10% of healthy individuals are colonized. Factors that predispose individuals to colonization with *N. meningitidis* include residence in the same household with a person who has meningococcal disease or is a carrier, household or institutional crowding, active or passive exposure to tobacco smoke, and a recent history of a viral upper respiratory infection. These factors have also been associated with an increased risk of meningococcal disease.

**PATHOGENESIS** (Fig. 127-1) Meningococci that colonize the upper respiratory tract are internalized by nonciliated mucosal cells and may traverse them to enter the submucosa, from which they can make their way into the bloodstream. While meningococcal colonization occurs often in healthy humans, bloodstream infection is an infrequent event that is not essential for the organisms’ survival and spread. The production of human disease has no obvious evolutionary advantage for either pathogen or host. Although some strains of *N. meningitidis* are thought to cause more severe disease in humans than do other strains, the basis for this difference is not understood. Meningococci may undergo important phenotypic changes when they adapt to growth in vivo; presumed virulence traits include the antiphagocytic capsule polysaccharide, an ability to sialylate LOS so that it mimics host-cell carbohydrate moieties, the secretion of IgA protease, and mechanisms for iron acquisition. The ET-5 strain of serogroup B *N. meningitidis* has been associated with high case-fatality rates in some populations but not in others; this discrepancy suggests that host factors also contribute importantly to disease pathogenesis.

A meningococcus that enters the bloodstream from the nasopharynx and survives host defenses generally has one of two fates. If multiplication occurs slowly, the bacteria eventually may seed local sites, such as the meninges and/or (less commonly) the joints or the pericardium. More rapid multiplication in the bloodstream is associated with the clinical features of meningococcemia, with petechiae, purpura, disseminated intravascular coagulation (DIC), and shock, which usually causes symptoms before local sites become infected. Thus compartmentalization of bacterial growth and host inflammation either in the blood or at a local site (usually the meninges) can occur.

**Outer-Membrane Components Associated with Virulence** Invasive meningococcal strains are characterized by the expression of capsular polysaccharide and other outer-membrane structures, including LOS (endotoxin). Outer-membrane blebbing, meningococcal autolysis, molecular mimicry, genome plasticity, horizontal DNA exchange, and phase and/or antigenic variation are all important in meningococcal virulence.

**Capsule** The polysaccharide capsule is a major—if not the major—virulence factor of *N. meningitidis*. As stated above, meningococci isolated from the blood or cerebrospinal fluid (CSF) of patients with invasive meningococcal disease most often express capsules of serogroups A, B, C, Y, and W-135. Isolates from asymptomatic nasopharyngeal carriers are nongroupable or express B, Y, X, Z, or 29E capsular serogroups. Capsules impart antiphagocytic and antibacterial properties to the meningococcus and thus enhance meningococcal survival during invasion of the bloodstream or CSF. Capsules also provide protective properties (e.g., preventing desiccation and phagocytic killing) and antiadherent properties; these properties promote meningococcal transmission, spread, and survival externally and within intracellular compartments such as phagocytic vacuoles.

Except in serogroup A, the major meningococcal capsular polysaccharides associated with invasive disease are composed of sialic acid (N-acetyl neuraminic acid, NANA) derivatives. The serogroup B capsule is composed of (α2→8)-linked NANA, the serogroup C capsule of (α2→9)-linked NANA, the serogroup Y capsule of alternating D-glucose and NANA, and the serogroup W-135 capsule of D-galactose and NANA. The differences in sialic acid capsule composition are derived from the distinct polysialyltransferases encoded by the fourth gene of the capsule biosynthesis operon, which is also used as a basis for capsule-specific PCR diagnosis. A four-gene operon encoding the capsule transport apparatus (ctr) is conserved among different serogroups and is also used in PCR diagnosis. The serogroup A capsule is composed of repeating units of (α2→3)-linked N-acetyl-mannosamine-1-phosphate and is encoded by a four-gene biosynthesis cassette unique for this serogroup.

**Outer-Membrane Proteins** Meningococci isolated from sites of colonization or invasive disease are piliated. Pili are complex outer-membrane, protein-based organelles that facilitate adhesion—the first step in meningococcal host-cell interactions. Meningococci express two major OMPs, PorA and PorB. Human opsonins and bactericidal antibodies induced during meningococcal disease have been shown to recognize PorA and PorB. Vaccines based on PorA-containing outer-membrane vesicles are under development. Another OMP, Opc, is involved in cell attachment and is also a target of bactericidal antibodies. Meningococci encounter iron-restricted environments during infection. The majority of host iron is presented intracellularly as he-
Lipooligosaccharide Meningococcal LOS is structurally related to the lipopolysaccharide (LPS) expressed by many gram-negative bacilli. However, LOS does not have repeating O-antigen subunits of sugars. The lipid A moiety of LOS, which has been classically termed endotoxin (as opposed to the bacterial exotoxins), is the portion that mediates the induction of inflammatory cytokines often seen in disease. The effect of lipid A is due to an interaction with the innate immune receptor Toll-like receptor 4 (TLR4) in association with the membrane protein MD2. TLR4 and MD2 are found mainly on macrophages/monocytes, dendritic cells, and other phagocytes. The morbidity and mortality of meningococcal bacteremia and meningitis have been directly correlated with the amount of circulating meningococcal endotoxin.

**Other Virulence Mechanisms** The outer-membrane components of N. meningitidis (e.g., pili, LOS, Opa proteins, Opc, capsule) vary in expression or structure at high frequencies ($10^{-2}$ to $10^{-4}$ per cell per generation). Variation is the result of genetic switches that turn on or off, regulate the amount of a component, or alter the structure of a component. Genetic events leading to phase and structural variation allow immune escape and create variability in the structures that are important in pathogenesis (on and off expression of attachment ligands, protection against serum killing, invasion determinants). The serogroup B capsule provides an example of how meningococci downregulate the human immune response through the expression of host-like antigens. The $O$-$2\rightarrow8$-linked polysialic acid capsule of serogroup B meningococci is identical to structures on the human neural cell adhesion molecule N-CAM. Meningococci are also characterized by frequent vesiculation (blebbing) of the outer membrane, and the amount of blebbing may vary between strains. Blebs may contribute to the rapid initiation of the inflammatory and clotting cascades. They may also be related to the natural autolysis of meningococci that results in DNA release and facilitates genetic transformation.

Specific disease manifestations of meningococcal infections have specific virulence and pathogenic mechanisms as described below for fulminant meningococcemia and meningitis.

**Fulminant Meningococcemia (Purpura Fulminans)** Fulminant meningococcemia is perhaps the most rapidly lethal form of septic shock experienced by humans. It differs from most other forms of septic shock by the prominence of hemorrhagic skin lesions (petechiae, purpura; see Fig. 46-5) and the consistent development of DIC.

The dominant proinflammatory molecule in the meningococcal cell wall is the endotoxin or LOS, and the outer membrane that contains it is poorly tethered to the underlying peptidoglycan. This structural peculiarity seems to account for the fact that meningococci shed LOS-containing membrane blebs as they grow. The bacteria can multiply to very high concentrations in the blood. The concentrations of endotoxin detected in the blood of patients with fulminant meningococcemia are 10-1000-fold higher than those found in the blood of patients with bacteremia due to other gram-negative bacteria. The bacteria and endotoxin-containing blebs stimulate monocytes, neutrophils, and endothelial cells, which then release cytokines and other mediators that can activate many distant targets, including other leukocytes, platelets, and endothelial cells. In addition, meningococci can invade the vascular endothelium. When activated, the endothelium produces molecules that can be procoagulant as well as adhesive for leukocytes.

Patients with fulminant meningococcemia usually have extremely high blood levels of both proinflammatory mediators—i.e., tumor necrosis factor (TNF), interleukin (IL) 1, interleukin $\gamma$, and IL-8—and anti-inflammatory mediators—i.e., IL-1 receptor antagonist (IL-1Ra), soluble IL-1 receptors, soluble TNF receptors, and IL-10. The plasma of patients with meningococcal shock can decrease the responses of normal leukocytes to stimuli such as LOS; the implication is that anti-inflammatory mediators predominate in the blood late in infection.

**Figure 127-2** The pathogenesis of fibrin deposition in patients with fulminant meningococcemia. PAI-1, plasminogen activator inhibitor 1. (Adapted from M Levi et al: *Eur J Clin Invest* 27:3, 1997.)

Procoagulant, antifibrinolytic forces are also active in the blood of patients with fulminant meningococcemia (Fig. 127-2). Monocytes express large amounts of tissue factor. Fibrinopeptide A and thrombin-antithrombin levels are high, reflecting active clotting, while antithrombin and fibrinogen levels are low. Although the tissue factor-regulated ("extrinsic") arm of coagulation predominates, the contact system (factors XII and XI, prekallikrein, high-molecular-weight kininogen) is also activated. Striking deficiencies of antithrombin and proteins C and S can occur; studies have found a strong negative correlation between protein C activity and both the size of purpuric skin lesions and the mortality rate. Plasminogen levels are decreased, while plasmin-antiplasmin complexes and plasminogen activator inhibitor 1 (PAI-1) levels in the blood are very high. PAI-1 levels have been correlated with mortality risk.

Fibrin deposition is therefore favored both by the procoagulant tendency (promoted through activation of tissue factor and deficiencies of proteins C and S and antithrombin) and by an antifibrinolytic tendency (favored by excessive PAI-1). Both platelets and leukocytes doubtless contribute to the formation of microthrombi and to the vascular injury that ensues. Thrombosis of small- to mid-sized arteries can produce peripheral necrosis and gangrene necessitating limb or digit amputation.

**Meningitis** Meningococcal bacteremia can result in the seeding of the meninges, pericardium, and large joints. Up to one-third of patients with meningococcal disease present with meningitis or other closed-space infections without signs of sepsis. How meningococci traverse the blood-brain barrier and enter the CSF or reach other closed sites is unclear. Meningococci have been shown to invade endothelial cells both experimentally and in vivo. The choroid plexus is also a potential site of meningococcal entry into the CSF. Meningococcal pili may bind CD46, a complement-regulatory protein that is expressed by the choroid plexus and meningeal epithelia. Upon meningococcal entry into the CSF, a vigorous local inflammatory response ensues, probably triggered by endotoxin-containing meningococcal membranes. Both bacterial growth and the inflammatory response occur within the CSF, where levels of endotoxin, IL-6, TNF, IL-1$\beta$, IL-1Ra, and IL-10 exceed the concentrations found in plasma by 1000-fold. The inflammatory response is largely confined to the subarachnoid space and contiguous structures. The inflammatory cytokines TNF and IL-1 released in meningococcal bacteremia may also enhance the permeability of the blood-brain barrier. Meningitis and other closed-space infections (e.g., arthritis, pericarditis) are the result of bacterial survival and multiplication at these sites. For example, meningitis and its sequelae are due to the induction of local inflammatory cytokines and other mediators (e.g., nitric oxide), leukocyte infiltration across the blood-brain barrier, breakdown of the blood-brain barrier with edema,
release of metalloproteases, induction of cellular apoptosis, coagulation of vessels, and ischemia.

Patients who develop meningitis without meningococccemia may be individuals in whom meningococci do not grow rapidly in or have been cleared from the blood; may have antibodies or phagocytes that slow meningococcal growth; or may lack the (unknown) factors that allow _Neisseria meningitidis_ to multiply rapidly in vitro. If disease is recognized early, the prognosis of patients with meningococcal meningitis is substantially better than that of patients with fulminant meningococcemia.

**HOST DEFENSE MECHANISMS** Preventing meningococcal growth in blood requires bactericidal and opsonic antibodies, complement, and phagocytes (Fig. 127-3). The major bactericidal antibodies are IgM and IgG, which (except for serogroup B) bind to the capsular polysaccharide. Immunity to meningococci is therefore serogroup specific. Antibodies to other surface (subcapsular) antigens may confer cross-serogroup protection. PorA, PorB, Opc, and LOS appear to be major targets of cross-reactivity and of serogroup B bactericidal antibodies. Infants are protected from meningococcal disease during the first months of life by passively transferred maternal IgG antibodies. As maternal antibody levels wane, the attack rate increases, peaking from 3 to 9 months of age. Disease incidence declines as protective antibodies are induced by colonization with nonpathogenic bacteria that have cross-reactive antigens. In addition to _Neisseria lactamica_, which frequently colonizes young children, some enteric bacteria have antigens that cross-react with those of meningococci. One theory relates the occurrence of some cases of meningococcal disease to the presence of high levels of IgA antibodies to meningococci, since these antibodies can block the bactericidal activity of IgM.

Complement is required for bactericidal activity and for efficient opsonophagocytosis. Individuals deficient in any of the late complement components (C5 to C9) cannot assemble the membrane-attack complex (MAC). PorA, PorB, Opc, and LOS appear to be major targets of cross-reactivity and of serogroup B bactericidal antibodies. Infants are protected from meningococcal disease during the first months of life by passively transferred maternal IgG antibodies. One theory relates the occurrence of some cases of meningococcal disease to the presence of high levels of IgA antibodies to meningococci, since these antibodies can block the bactericidal activity of IgM.

Complement is required for bactericidal activity and for efficient opsonophagocytosis. Individuals deficient in any of the late complement components (C5 to C9) cannot assemble the membrane-attack complex (MAC) needed to kill _Neisseria_. These persons typically develop less severe meningococcal disease than complement-sufficient individuals, do so at an older age, and tend to have disease due to uncommon serogroups (W-135, X, Y, Z, and 29E). Although only one-half of individuals with known late-complement-component deficiency ever experience meningococcal disease, some affected persons have several episodes. Deficiency of each of the terminal complement components is inherited in an autosomal recessive fashion. Proporin deficiency, in contrast, is X-linked; some affected males develop overwhelming meningococcal disease, an observation indicating that the alternative complement pathway is also needed for antimeningococcal host defense. Disease onset in properdin-deficient individuals typically occurs in the teens or twenties. There is also recent evidence that inherited differences in the mannose-binding lectin (MBL) pathway of complement activation may influence the risk of acquiring meningococcal disease in childhood. Alleles that decrease MBL synthesis have been associated with increased risk in the few studies reported to date. Activation of the classic pathway of complement by antigen-antibody complexes or of the alternative pathway by LOS or capsular polysaccharide is important for producing and maintaining C3b (Fig. 127-3). Without C3b, neither bactericidal lysis nor phagocytosis can proceed effectively. When C3b is generated, meningococcal growth is probably checked by the MAC, which produces bacterial lysis, and by robust phagocytosis. Most IgG antibodies to the meningococcal polysaccharide are of the IgG2 isotype; a phagocytic cell defect (the FcγRIIA R131 allele) that impairs the phagocytosis of IgG2-coated particles has been associated with more severe meningococcal disease. This allele has also been associated with a more severe clinical course in patients with late-complement-component deficiency; thus effective phagocytosis may contribute to the relatively mild meningococcal disease usually observed in these individuals.

The available studies of gene polymorphism—disease associations are summarized in Figs. 127-1 and 127-3. In individuals who lack bactericidal antibodies, protection from acquiring meningococcal bacteremia may be provided, at least in part, by innate immune mechanisms such as the MBL pathway for activating complement, complement factor C4b, and the TLR4 pathway for LOS recognition. Other genes may influence meningococcal survival in vivo (FcγRIIA (CD32)), while still others seem to regulate the host inflammatory (IL-1β, IL-1Ra, TNF, angiotensin-converting enzyme) and clotting (PAI-1) responses to invading meningococci. Although many of these associations await confirmation in other populations of patients, in sum they point to important genetic influences on the acquisition and severity of meningococcal disease. This conclusion is supported by the over-representation of ABO blood group nonsecretors among patients with meningococcal disease and by the striking variability in meningococcal disease incidence among different racial groups.

**CLINICAL MANIFESTATIONS** _Upper Respiratory Tract Infections_ Although many patients who develop meningococcal meningitis or meningococcemia report having had throat soreness or other upper respiratory symptoms during the preceding week, it is uncertain whether these symptoms are due to infection with meningococci. Meningococcal pharyngitis is rarely diagnosed. Adult patients with _N. meningitidis_ bacteremia more often have clinically apparent disease of the respiratory tract (pneumonia, sinusitis, tracheobronchitis, conjunctivitis) than do younger patients.

**Meningococcemia** Patients with meningococcal disease may have both meningococcemia and meningitis. These conditions have a wide clinical spectrum, with many overlapping features.

Approximately 10 to 30% of patients with meningococcal disease have meningococcemia without clinically apparent meningitis. Although meningococcal bacteremia may occasionally be transient and asymptomatic, in most individuals it is associated with fever, chills, nausea, vomiting, and myalgias. Prostration is common. The most distinctive feature is rash. Erythematous macules rapidly become petechial and, in severe cases, purpuric (see Fig. 46-5). Although the lesions are typically found on the trunk and lower extremities, they may also occur on the face, arms, and mucous membranes. The petechiae may coalesce into hemorrhagic bullae or may undergo necrosis and ulcerate. Patients with severe coagulopathy may develop ischemic extremities or digits, often with a sharp line of demarcation between normal and ischemic tissue.

In many patients with fulminant meningococcemia, the CSF may be normal and the CSF culture negative. Indeed, the absence of meningitis in a patient with meningococcemia is a poor prognostic sign; it suggests that the bacteria have multiplied so rapidly in the blood that meningococcal disease has not yet occurred or had time to elicit in-
flammon in the CSF. Most of these patients also lack evidence of an acute-phase response; i.e., the erythrocyte sedimentation rate is normal, and the C-reactive protein concentration in blood is low.

The Waterhouse-Friderichsen syndrome is a dramatic example of DIC-induced microthrombosis, hemorrhage, and tissue injury. Although overt adrenal failure is infrequently documented in patients with fulminant meningococcal meningitis, patients may have partial adrenal insufficiency and be unable to mount the normal hypercortisolemic response to severe stress or cosynotropin stimulation. Almost all patients who die from fulminant meningococcal meningitis have adrenal hemorrhages at autopsy.

Chronic meningococcal meningitis (Fig. 127-4) is a rare syndrome of episodic fever, rash, and arthralgias that can last for weeks to months. The rash may be maculopapular; it is occasionally petechial. Splenomegaly may develop. If untreated or if treated with glucocorticoids, chronic meningococcal meningitis may evolve into meningitis, fulminant meningococcal meningitis, or (rarely) endocarditis.

Meningitis (See also Chap. 360) Patients with meningococcal meningitis have usually been sick for 24 h before they seek medical attention. Common presenting symptoms include nausea and vomiting, headache, neck stiffness, lethargy, and confusion. The symptoms and signs of meningococcal meningitis cannot be distinguished from those elicited by other meningeal pathogens. Many patients with meningococcal meningitis have concurrent meningococcal meningitis, however, and petechial or purpuric skin lesions (Fig. 46-5) may suggest the correct diagnosis. CSF findings are consistent with those of purulent meningitis: hypoglycorrhachia, an elevated protein concentration, and a neutrophilic leukocytosis. A Gram’s stain of CSF is usually positive (see “Diagnosis,” below); when this finding is unaccompanied by CSF leukocytosis, the diagnosis for normal recovery is often poor.

Other Manifestations Arthritis occurs in ~10% of patients with meningococcal disease. When arthritis develops during the first few days of the patient’s illness, it usually reflects direct meningococcal invasion of the joint. Arthritis that begins later in the course is thought to be due to immune complex deposition. Primary meningococcal pneumonia occurs principally in adults, often in military populations, and is often due to serogroup Y. While meningococcal pericarditis is occasionally seen, endocarditis due to N. meningitidis is now exceedingly rare. Primary meningococcal conjunctivitis can be complicated by meningococcemia; systemic therapy is therefore warranted when this condition is diagnosed. Meningococcal urethritis has been reported in individuals who practice oral sex.

Complications Patients with meningococcal meningitis may develop cranial nerve palsies, cortical venous thrombophlebitis, and cerebral edema. Children may develop subdural effusions. Permanent sequelae can include mental retardation, deafness, and hemiparesis. The major long-term morbidity of fulminant meningococcemia is the loss of skin, limbs, or digits that results from ischemic necrosis and infarction.

DIAGNOSIS Few clinical clues help the physician distinguish the patient with early meningococcal disease from patients with other acute systemic infections. The most useful clinical finding is the petechial or purpuric rash (see Fig. 46-5), but it must be differentiated from the petechial lesions seen with gonococccemia (see Fig. 128-1), Rocky Mountain spotted fever (see Fig. 158-1), hypersensitivity vasculitis (see Fig. 46-4), endemic typhus, and some viral infections. In one case series, one-half of the adults with meningococcal bacteremia had neither meningitis nor a rash.

The definitive diagnosis is established by recovering N. meningitidis, its antigens, or its DNA from normally sterile body fluids, such as blood, CSF, or synovial fluid, or from skin lesions. Meningococci grow best on Mueller-Hinton or chocolate blood agar at 35°C in an atmosphere that contains 5 to 10% CO₂. Specimens should be plated without delay. N. meningitidis bacteria are oxidase-positive, gram-negative diplococci that typically utilize maltose and glucose.

A Gram’s stain of CSF reveals intra- or extracellular organisms in ~85% of patients with meningococcal meningitis. The latex agglutination test for meningococcal polysaccharides is less sensitive. PCR amplification of DNA in buffy coat or CSF samples is more sensitive than either of these tests; like the latex agglutination test, this method is unaffected by prior antibiotic therapy. Early nasopharyngeal specimens should be cultured on Thayer-Martin medium, which suppresses the competing oral flora. Throat or nasopharyngeal cultures are recommended only for research or epidemiologic purposes, since a positive result merely confirms the carrier state and does not establish the existence of systemic disease.

TREATMENT (Table 127-1) A third-generation cephalosporin, such as cefotaxime (2 g intravenously every 4 h) or ceftriaxone (2 g intravenously every 12 h), is preferred for initial therapy. One of these cephalosporins in combination with other agents may cover other bacteria (such as Streptococcus pneumoniae and Haemophilus influenzae) that can cause the same syndromes (Chap. 360). Penicillin G (18 to 24 million units intravenously per day) remains an acceptable alternative for confirmed invasive meningococcal disease in most countries. However, the prevalence of meningococci with reduced susceptibility to penicillin has been increasing, and high-level penicillin resistance has been reported. Other options include meropenem (1 g intravenously every 8 h). In the patient who is allergic to β-lactam drugs, chloramphenicol (75 to 100 mg/kg per day) is a suitable alternative; chloramphenicol-resistant meningococci have been reported from Vietnam and France. The newer fluoroquinolones gatifloxacin, moxifloxacin, and gemifloxacin have excellent in vitro activity against N. meningitidis, with measurable CNS penetration, and appear promising in animal models. Patients with meningococcal meningitis should be given antimicrobial therapy for at least 5 days. While glucocorticoid therapy for meningitis in adults is controversial, many experts administer dexamethasone, beginning if possible before antibiotic therapy is initiated; the schedule is 10 mg intravenously 15 to 20 min before the first antibiotic dose and then every 6 h for 4 days.

Patients with fulminant meningococcemia often experience diffuse leakage of fluid into extravascular spaces, shock, and multiple-organ dysfunction (Chaps. 253 and 254). Myocardial depression may be prominent. Supportive therapy, although never studied in randomized, placebo-controlled trials, is recommended. Standard measures include vigorous fluid resuscitation (often requiring several liters over the first 24 h), elective ventilation, and pressors. Some authorities recommend early hemodialysis or hemofiltration. Fresh-frozen plasma is often given to patients who are bleeding extensively or who have severely deranged clotting parameters. Many European experts have adminis-
The attack rate for meningococcal disease is also high among military recruits, pilgrims on the Hajj, and individuals traveling to sub-Saharan Africa during the dry months (June to December) or to other areas with epidemic meningococcal disease. The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends vaccination of incoming college freshmen who will live in dormitories. In general, the vaccine should be given only to persons >2 years of age.

New meningococcal capsular oligosaccharide and polysaccharide conjugate vaccines (C; A and C, A, C, Y, W-135) are being developed; some are currently undergoing clinical trials, and some are now in use in Europe and Canada. These vaccines are based on the approach used for the highly successful H. influenzae type b conjugate vaccines. Covalent linkage of the polysaccharide to a carrier protein converts the polysaccharide to a thymus-dependent antigen enhancing IgG anticapsular antibodies and memory B cells. Because levels of antibody in mucosal secretions are much higher after the administration of a conjugate vaccine than after vaccination with an unconjugated preparation, a major benefit of these vaccines may be the introduction of herd immunity. Memory response to meningococcal polysaccharide also appears to be an important effect of the conjugate vaccines. Meningococcal conjugate vaccines are not yet licensed in the United States. However, in the United Kingdom, serogroup C conjugate vaccines introduced in 2000 have had a marked impact on the incidence of serogroup C disease in the population vaccinated. If conjugate meningococcal vaccines prove to be capable of providing durable antibody or memory responses (particularly in infants and young children), their integration into the routine childhood immunization schedule would appear warranted. Vaccines for serogroup B meningococcal disease remain elusive; none of the group B vaccines studied in clinical trials has proven to be broadly effective, but these products have a role in the control of serogroup B epidemics. The identification of new meningococcal protective antigens and the development of better meningococcal vaccines are areas of continued research and hold promise for the prevention of diseases due to N. meningitidis.

Screening tests for complement-component deficiency should be conducted in patients who have a history of meningococcal or disseminated gonococcal disease; in patients who have a recurrence; in patients whose first case occurs at ≥15 years of age; in patients with cases caused by serogroups other than A, B, or C; and in family members of patients found to have a complement deficiency.

Antimicrobial Chemoprophylaxis The attack rate for meningococcal disease among household or other close contacts of cases is >400-fold greater than that in the population as a whole. Close contacts of cases should receive chemoprophylaxis with rifampin, ciprofloxacin, ofloxacin, or azithromycin (Table 127-1). A single intramuscular injection of ceftriaxone is also effective. Close contacts include persons who live in the same household, day-care center contacts, and anyone directly exposed to a patient’s oral secretions. Casual contacts are not at increased risk. Chemoprophylaxis should be administered as soon as possible after the case is identified.

Isolation Precautions The CDC recommends that patients with meningococcal disease who are hospitalized be placed in respiratory isolation for the first 24 h.
Outbreak Control  An organization- or community-based outbreak of meningococcal disease is defined as the occurrence of three or more cases within ≤3 months in persons who have a common affiliation or reside in the same area but who are not close contacts of one another; in addition, the primary disease attack rate must exceed 10 cases per 100,000 persons, and the case strains of *N. meningitidis* must be of the same molecular type. Mass vaccination should be considered when such outbreaks occur, and mass chemoprophylaxis may be used to control school- or other institution-based outbreaks. Consultation with public health authorities is recommended when such campaigns are contemplated.

FURTHER READING

**DEFINITION** Gonorrhea is a sexually transmitted infection of epithelium and commonly manifests as cervicitis, urethritis, proctitis, and conjunctivitis. If untreated, infections at these sites can lead to local complications such as endometritis, salpingitis, tuboovarian abscess, Bartholinitis, peritonitis, and periretinitis in the female; periurethritis and epididymitis in the male; and ophthalmitis neonatorum in the newborn. Disseminated gonococcerca is an uncommon event whose manifestations include skin lesions, tenosynovitis, arthritis, and (in rare cases) endocarditis or meningitis.

*Neisseria gonorrhoeae* is a gram-negative, nonmotile, non-spore-forming organism that grows in pairs (diplococci). Each individual organism is shaped like a coffee bean, with adjacent concave sides seen on Gram’s stain. Gonococci, like all other *Neisseria* spp., are oxidase positive. They are distinguished from other neisseriae by their ability to grow on selective media and to utilize glucose but not maltose, sucrose, or lactose.

**EPIDEMIOLOGY** The incidence of gonorrhea has declined significantly in the United States, but there were still ~362,000 newly reported cases in 2002. Gonorrhea remains a major public health problem worldwide, is a significant cause of morbidity in developing countries, and may play a role in enhancing transmission of HIV.

Gonorrhea predominantly affects young, nonwhite, unmarried, less educated members of urban populations. The number of reported cases probably represents half of the true number of cases—a discrepancy resulting from underreporting, self-treatment, and nonspecific treatment without a culture-proven diagnosis. The number of reported cases of gonorrhea in the United States rose from ~250,000 in the early 1960s to a high of 1.01 million in 1978. The peak recorded incidence of gonorrhea in modern times was reported in 1975, with 468 cases per 100,000 population in the United States. This peak was attributable to the interaction of several variables, including improved accuracy of diagnosis, changes in patterns of contraceptive use, and changes in sexual behavior. The incidence of the disease has since gradually declined and is currently estimated at 120 cases per 100,000, a figure that is still the highest among industrialized countries. A further decline in the overall incidence of gonorrhea in the United States over the past decade may reflect increased condom use resulting from public health efforts to curtail HIV transmission. Presently, the attack rate in the United States is highest in the 20- to 24-year age group, in which 75% of all cases occur. With adjustment for sexual experience, the risk is highest among sexually active 15- to 19-year-old women. In terms of ethnicity, rates are highest among African Americans and lowest among persons of Asian or Pacific Island descent.

The incidence of gonorrhea is highest in developing countries. The exact incidence of any of the sexually transmitted diseases (STDs) is difficult to ascertain in developing countries because of limited surveillance and variable diagnostic criteria. For example, in Kenya, it was estimated in 1987 that 10% of all live births were adversely affected by STDs, and gonococcal ophthalmitis neonatorum reportedly affected 4% of all live-born infants. The median prevalence of gonorrhea in unselected populations of pregnant women has been estimated at 10% in Africa, 5% in Latin America, and 4% in Asia. Studies in Africa have clearly demonstrated that nonulcerative STDs such as gonorrhea are an independent risk factor for the transmission of HIV (Chap. 173).

Gonorrhea is transmitted from males to females more efficiently than in the opposite direction. The rate of transmission to a woman following a single unprotected sexual encounter with an infected man is on the order of 40 to 60%. Oropharyngeal gonorrhea occurs in ~20% of women who practice fellatio with infected partners. Transmission in either direction by cunnilingus is rare.

There exists in any population a small minority of individuals who have high rates of new-partner acquisition. These “core-group members” or “high-frequency transmitters” are vital in sustaining STD transmission at the population level. Another instrumental factor in sustaining gonorrhea in the population is the large number of infected individuals who are asymptomatic or have minor symptoms that are ignored. These persons, unlike symptomatic individuals, do not cease sexual activity and therefore continue to transmit the disease. This situation underscores the importance of contact tracing and empirical treatment of sex partners of index cases.

**PATHOGENESIS, IMMUNOLOGY, AND ANTIMICROBIAL RESISTANCE** ■ Outer-Membrane Proteins ■ PILI Fresh clinical isolates of *N. gonorrhoeae* initially form piliated (fimbriated) colonies distinguishable on translucent agar. Pilius expression is rapidly switched off with unselected subculture because of rearrangements in pilus genes. This change is a basis for phase variation of gonococci. Piliated strains adhere better to cells derived from human mucosal surfaces and are more virulent in organ culture models and human inoculation experiments than nonpiliated variants. In a fallopian tube explant model, pilus mediates gonococcal attachment to nonciliated columnar epithelial cells. This event initiates gonococcal phagocytosis and transport through these cells to intercellular spaces near the basement membrane or directly into the subepithelial tissue. Damage to nearby ciliated columnar epithelial cells, which is caused by the release of cytokines, results in loss of cilia and sloughing of ciliated cells and diminishes the integrity of the fallopian tube. Nonpiliated gonococci cause epithelial damage at a much slower rate. CD46 (membrane cofactor protein) is present on urogenital epithelial cells in both men and women and has been determined to be a receptor for PilC; this subunit is located at the tip of the pilus molecule.
and is critical in mediating adherence. Pili are also essential for genetic competence and transformation of *N. gonorrhoeae*, which permit horizontal transfer of genetic material between different gonococcal lineages in vivo.

**Opacity-Associated Protein** Another gonococcal surface protein that is important in adherence to epithelial cells is opacity-associated protein (Opa, formerly called protein II). Opa contributes to intergonococcal adhesion, which is responsible for the opaque nature of gonococcal colonies on translucent agar and the organism’s adherence to a variety of eukaryotic cells, including polymorphonuclear leukocytes (PMNs). Certain Opa variants promote invasion of epithelial cells, and this effect has been linked with the ability of Opa to bind vitronectin, glycosaminoglycans, and several members of the carcinoembryonic antigen–related cell adhesion molecule (CEACAM, previously known as CD66) receptor family. Each strain of *N. gonorrhoeae* possesses as many as 11 different *opa* genes, but usually no more than three types are expressed at any given time. Isolates from normally sterile sites such as the fallopian tube and synovial fluid usually fail to express Opa, while isolates from mucosal sites usually form opaque colonies. Female commercial sex workers with antibodies to Opa may be less likely to develop pelvic inflammatory disease (PID) than women without such antibodies. *N. gonorrhoeae* Opa proteins that bind CEACAM 1, which is expressed by primary CD4+ T lymphocytes, suppress the activation and proliferation of these lymphocytes. This phenomenon may serve to explain the transient decrease in CD4+ T-lymphocyte counts associated with gonococcal infection.

**Porin** Porin (previously designated protein I) is the most abundant gonococcal surface protein, accounting for >50% of the organism’s total outer-membrane protein. Porin molecules exist as trimers that provide anion aqueous channels through the otherwise-hydrophobic outer membrane. Porin shows stable interstrain antigenic variation and forms the basis for gonococcal serotyping. Two main serotypes have been identified: Por1A strains are often associated with disseminated gonococcal infection (DGI), while Por1B strains usually cause local genital infections only. DGI strains are generally resistant to the killing action of normal human serum, do not incite a significant local inflammatory response, and therefore may not cause symptoms at genital sites. These characteristics may be related to the ability of Por1A strains to bind to complement-downregulatory molecules, resulting in a diminished inflammatory response. Porin can translocate to the cytoplasmic membrane of host cells—a process that could initiate gonococcal endocytosis and invasion. In addition, porin is an immunologic target of bactericidal and opsonophagocytic antibodies that may arise in response to immune stimulation resulting from infection or immunization with porin-containing vaccine candidates.

**Other Outer-Membrane Proteins** Other notable outer-membrane proteins include H.8, a lipoprotein that is present in high concentration on the surface of all gonococcal strains and is an excellent target for antibody-based diagnostic testing. Transferrin–binding proteins (Tbp1 and Tbp2) and lactoferrin-binding protein are required for scavenging iron from transferrin and lactoferrin in vivo. Transferrin and iron have been shown to increase attachment of iron-deprived *N. gonorrhoeae* to human endometrial cells. Studies with volunteers have demonstrated that gonococci deficient in transferrin- and lactoferrin-binding proteins cannot establish infection in men. IgA1 protease is produced by *N. gonorrhoeae* and may protect the organism from the action of mucosal IgA.

**Lipo-oligosaccharide** Gonococcal lipo-oligosaccharide (LOS) consists of a lipid A and a core oligosaccharide that lacks the repeating O-carbohydrate antigenic side chain seen in other gram-negative bacteria (Chap. 105). Gonococcal LOS possesses marked endotoxic activity and immune modulatory activity in the context of other gonococcal outer membrane proteins. LOS core sugars undergo a high degree of antigenic variation under different conditions of growth; this variation reflects genetic regulation and expression of glycosyltransferase genes that dictate the carbohydrate structure of LOS. These phenotypic changes may affect interactions of *N. gonorrhoeae* with elements of the humoral immune system (antibodies and complement) and may also influence direct binding of organisms to both professional phagocytes and nonprofessional phagocytes (epithelial cells). For example, gonococci that are sialylated at their LOS sites bind complement factor H and downregulate the alternative pathway of complement. LOS sialylation may also mask bactericidal antibody–binding epitopes on LOS and porin and may decrease opsonophagocytosis and inhibit the oxidative burst in PMNs. While sialylation of LOS confers on the bacteria the ability to attenuate the inflammatory response and evade the innate immune system, experiments in male volunteers suggest that sialylated gonococci may be less virulent than the local cytokine effect than their unmodified counterparts. This difference could be explained by the observation that the unsialylated terminal lactosamine residue of LOS binds to an asialoglycoprotein receptor on male epithelial cells that would otherwise facilitate binding and subsequent gonococcal invasion of these cells.

**Host Factors** In addition to gonococcal structures that interact with epithelial cells, host factors seem to be important in mediating entry of gonococci into nonphagocytic cells. Activation of phosphatidylinerine-specific phospholipase C and acidic sphingomyelinase by *N. gonorrhoeae*, which results in the release of diacylglycerol and ceramide, is a requirement for the entry of *N. gonorrhoeae* into epithelial cells. Ceramide accumulation within cells leads to apoptosis, which may disrupt epithelial integrity and facilitate entry of gonococci into subepithelial tissue. Release of chemotactic factors as a result of complement activation contributes to inflammation, as does the toxic effect of LOS in provoking the release of inflammatory cytokines.

The importance of humoral immunity in host defenses against neisserial infections is best illustrated by the predisposition of persons deficient in terminal complement components (C5 through C9) to recurrent bacteremic gonococcal infections and to recurrent meningococcal meningitis or meningococcemia. Gonococcal porin induces T cell–proliferative responses in persons with urogenital gonococcal disease. A significant increase in porin–specific interleukin (IL) 4–producing CD4+ as well as CD8+ lymphocytes is seen in individuals with mucosal gonococcal disease. A portion of these lymphocytes that show a porin–specific Th2-type response could traffic to mucosal surfaces and play a role in immune protection against the disease. Few data clearly indicate that protective immunity is acquired from a previous gonococcal infection, although bactericidal and opsonophagocytic antibodies to porin and LOS may offer partial protection. On the other hand, women who are infected and acquire high levels of antibody to another outer-membrane protein, Rmp (reduction modifiable protein, formerly called protein III), may be especially likely to become reinfected with *N. gonorrhoeae* because Rmp antibodies block the effect of bactericidal antibodies to porin and LOS. Rmp shows little, if any, interstrain antigenic variation; therefore, Rmp antibodies potentially may block antibody-mediated killing of all gonococci. The mechanism of blocking has not been fully characterized, but Rmp antibodies noncompetitively inhibit binding of porin and LOS antibodies because of the proximity of these structures in the gonococcal outer membrane. Less well understood is how blocking antibody may divert complement binding to the gonococcal surface or otherwise hasten inactivation of complement. In male volunteers who have no history of gonorrhea, the net effect of these events may influence the outcome of experimental challenge with *N. gonorrhoeae*. Because Rmp bears extensive homology to enterobacterial OmpA and meningococcal class 4 proteins, it is possible that these blocking antibodies result from prior exposure to cross-reacting proteins from these species and also play a role in first-time infection with *N. gonorrhoeae*.

**Gonococcal Resistance to Antimicrobial Agents** It is no surprise that *N. gonorrhoeae*, with its remarkable capacity to alter its antigenic structure and adapt to changing environmental conditions, has become resistant to numerous antibiotics. The first effective agents against gonorrhea were the sulfonamides, which were introduced in the 1930s. Within a
decade, antibiotic resistance emerged, resulting in treatment failures in one-third of patients. Penicillin was then employed as the drug of choice for the treatment of gonorrhea. By 1965, 42% of gonococcal isolates had developed low-level resistance to penicillin G. To prevent treatment failures, the Centers for Disease Control and Prevention (CDC) at that time recommended doubling the dose of penicillin for the treatment of gonorrhea. Resistance due to the production of penicillinase arose later.

Gonococci become fully resistant to antibiotics either by chromosomal mutations or by acquisition of R factors (plasmids). Two types of chromosomal mutations have been described. The first type, which is drug specific, is a single-step mutation leading to high-level resistance. The second type involves mutations at several chromosomal loci that combine to determine the level as well as the pattern of resistance. Strains with mutations in chromosomal genes were first observed in the late 1950s. As recently as 1997, strains with chromosomal resistance (CMRNG) accounted for resistance to penicillin, tetracycline, or both in ~20% of strains surveyed in the United States.

β-Lactamase (penicillinase)–producing strains of *N. gonorrhoeae* (PPNG) carrying plasmids with the Pe determinants were seen simultaneously in the United States, England, western Africa, and the Philippines in the late 1970s. PPNG strains have since spread worldwide and by the early 1980s accounted for >50% of all gonococcal isolates in some parts of the developing world. The average prevalence of PPNG in the United States dropped by two-thirds after most penicillin use was discontinued and is now on the order of 4%, with higher rates reported from certain areas. *N. gonorrhoeae* strains with plasmidborne tetracycline resistance (TRNG) can mobilize some β-lactamase plasmids, and PPNG and TRNG occur together, sometimes along with CMRNG. Penicillin, ampicillin, and tetracycline are no longer reliable agents for the treatment of gonorrhea and should not be used. Third-generation cephalosporins have remained highly effective as single-dose therapy for gonorrhea. Even though the minimal inhibitory concentrations (MICs) of ceftriaxone for certain strains may reach 0.015 to 0.125 mg/L (higher than MICs of 0.0001 to 0.008 mg/L for fully susceptible strains), these levels are greatly exceeded in blood, the urethra, and the cervix when the routinely recommended ceftriaxone and cefixime regimens are administered (see below). These regimens almost always result in an effective cure.

Quinolone-containing regimens are also recommended for treatment of gonococcal infections; the fluoroquinolones offer the advantage of antichlamydial activity when administered for 7 days. Serum concentrations following therapeutic dosages of the quinolones exceed the MIC for *N. gonorrhoeae* by ~100-fold. However, quinolone-resistant *N. gonorrhoeae* (QRNG) appeared soon after these agents were first used to treat gonorrhea, particularly in Southeast Asia. QRNG strains have been reported recently in the United States, mostly in the far western states. Alterations in DNA gyrase and topoisomerase IV have been implicated as mechanisms of fluoroquinolone resistance.

Resistance to spectinomycin, which is used as an alternative agent, has been reported, but resistance to this agent is usually not associated with resistance to other antibiotics. Therefore, spectinomycin can be reserved for use against multiresistant strains of *N. gonorrhoeae*. Nevertheless, outbreaks caused by strains resistant to spectinomycin have been documented in Korea and England when the drug was used as a primary agent to treat gonorrhea.

**CLINICAL MANIFESTATIONS ▶ Gonococcal Infection in Males**

Acute urethritis is the most common clinical manifestation of gonorrhea in males. The usual incubation period following exposure is 2 to 7 days, although the interval can be longer and some men remain asymptomatic. Strains of the Por1A serotype, with nutritional requirements for arginine, hypoxanthine, and uracil (i.e., the AHU auxotroph), tend to cause a greater proportion of cases of mild and asymptomatic urethritis than Por1B strains. Urethral discharge and dysuria, usually without urinary frequency or urgency, are the major symptoms. The discharge initially is scant and mucoid but becomes profuse and purulent within a day or two. The clinical manifestations of gonococcal urethritis are usually more severe and overt than those of nongonococcal urethritis, including urethritis caused by *Chlamydia trachomatis* (Chap. 160); however, exceptions are common, and it is often impossible to differentiate the causes of urethritis on clinical grounds alone. The majority of cases of urethritis seen in the United States today are not caused by *N. gonorrhoeae* and/or *C. trachomatis*. Although a number of other organisms may be responsible, most cases do not have a specific etiologic agent identified. Most symptomatic males with gonorrhea seek treatment and cease to be infectious. The remaining men, who are largely asymptomatic, accumulate in number over time and constitute about two-thirds of all the infected men at any point in time. Together with men incubating the organism (who shed the organism but are asymptomatic), they serve as the source of spread of infection. Prior to the antibiotic era, symptoms of urethritis persisted for about 8 weeks. Epididymitis is now an uncommon complication, and gonococcal prostatitis occurs rarely, if at all. Other unusual local complications of gonococcal urethritis include edema of the penis due to dorsal lymphangitis or thrombophlebitis, submucous inflammatory “soft” infiltration of the urethral wall, periurethral abscess or fistulae, inflammation or abscess of Cowper's gland, and seminal vesiculitis. Balanitis may develop in uncircumcised men. After a decline in gonococcal infections among homosexual men early in the era of AIDS, a disturbing increase in gonorrhea was observed among young homosexual men in the 1990s, probably related to decreased condom use. The clinical features of anorectal and pharyngeal gonorrhea are discussed below.

**Gonococcal Infections in Females ▶ GONOCOCCAL CERVICITIS**

Mucopurulent cervicitis is the most common STD diagnosis in American women and may be caused by *N. gonorrhoeae*, *C. trachomatis*, and other organisms. Cervicitis may coexist with candidal or trichomonal vaginitis. *N. gonorrhoeae* primarily infects the cervical os but can also infect more peripheral areas of the cervix where columnar epithelium meets stratified squamous epithelium. Except in rare instances, the vaginal mucosa, which is lined by stratified squamous epithelium, does not become infected. Bartholin's glands occasionally become infected.

Women infected with *N. gonorrhoeae* usually develop symptoms. However, the women who either remain asymptomatic or have only minor symptoms may delay in seeking medical attention. These symptoms may include scant discharge from the vagina that may issue forth from the inflamed cervix (not vaginitis or vaginosis per se) and dysuria (often without urgency or frequency) that may be associated with gonococcal urethritis. Although the incubation period of gonorrhea is less well defined in women than in men, symptoms usually develop within 10 days of infection and are more acute and intense than those of chlamydial cervicitis.

The physical examination may reveal a mucopurulent discharge (mucopus) issuing from the cervical os. The examiner may check for mucopurulent discharge by swabbing a sample of mucus from the endocervix and observing its color against the white background of the swab; yellow or green mucus suggests mucopus. However, only 35% of women with gonococcal cervicitis actually have a mucopurulent discharge defined by these criteria. Because Gram’s stain is not sensitive for the diagnosis of gonorrhea in women, specimens should be submitted for culture or a nonculture assay (see below). Edematous and friable cervical ectopy as well as endocervical bleeding induced by gentle swabbing are more often seen in chlamydial cervicitis.

128 Gonococcal Infections 857

* N. gonorrhoeae may be recovered from the urethra and rectum of women with cervicitis, but these are rarely the sole infected sites. Urethritis in women may produce symptoms of internal dysuria, which is often attributed to “cystitis.” Pyuria in the absence of bacteriuria seen on Gram’s stain of unspun urine, accompanied by urine cultures that fail to yield >10^6 colonies of bacteria usually associated with urinary tract infection, signifies the possibility of urethritis due to *C. trachomatis*. Urethral infection with *N. gonorrhoeae* may also occur in this
context, but in this instance urethral cultures will usually be positive. Compression of the urethra through the anterior vaginal wall against the symphysis pubis may express urethral exudate.

**Complications of Gonococcal Cervicitis** Gonococcal infection may extend deep enough to produce dyspareunia and lower abdominal or back pain. In such cases, it is imperative to consider a diagnosis of PID and to administer treatment for that disease (Chap. 115). Ascending infection of the genital tract follows ~20% of cases of gonococcal cervicitis and may result in acute endometritis accompanied by abnormal menstrual bleeding, midline lower abdominal pain and tenderness, and dyspareunia. Spread to the fallopian tubes results in acute salpingitis, whose symptoms may be accompanied by signs of cervical motion tenderness and abnormal adnexal mass on pelvic examination. Patients may be febrile, and leukocytosis and an elevated erythrocyte sedimentation rate or C-reactive protein level may be detected. Co-infection with *C. trachomatis* may increase the risk of PID, which is the clinical counterpart of endometritis and salpingitis. Tubal scarring leading to infertility is the most devastating sequela of salpingitis; the increased risk of ectopic pregnancy is also significant. Prompt and appropriate antibiotic therapy for gonococcal salpingitis (prior to the development of an adnexal mass) can prevent tubal infertility in nearly all cases. Bilateral tubal damage occurs in ~20% of women with an adnexal mass. More than half of women with tubal infertility give no history of PID. Those women with “silent salpingitis” may report abdominal or pelvic discomfort (such as dysmenorrhea or dyspareunia) that may be attributed to other diagnoses (such as endometriosis). Spread of infection to the pelvis may result in pelvic peritonitis characterized by nausea and vomiting. Spread of gonococci—or, more commonly, of *Chlamydia*—via the peritoneal cavity to the upper abdomen may result in acute proctitis manifested by anorectal pain or pruritus, tenesmus, purulent rectal discharge, and rectal bleeding. Among homosexual men, the frequency of gonococcal infection, including rectal infection, fell by ≥80% throughout the United States in the early 1980s, but a resurgence of gonorrhea among homosexual men was documented in several cities during the 1990s. Gonococcal isolates from the rectum of homosexual men tend to be more resistant than other gonococcal isolates to antimicrobials. Gonococcal isolates with a mutation in mtrR (multiple transferable resistance repressor) or in the promoter region of the gene that encodes for this transcriptional repressor develop increased resistance to antimicrobial hydrophobic agents such as bile acids and fatty acids in feces and thus are found with increased frequency in homosexual men. The mutation, which curtails the production of a DNA-binding protein called MtrR, results in derepression of the expression of other *mtr* genes that encode the production of an energy-dependent efflux pump, thereby resulting in increased resistance to hydrophobic agents. This situation may have been responsible for higher rates of failure of treatment for rectal gonorrhea with older regimens consisting of penicillin or tetracyclines.

**Pharyngeal Gonorrhea** Pharyngeal gonorrhea is usually mild or asymptomatic, although symptomatic pharyngitis does occasionally occur with cervical lymphadenitis. The mode of acquisition is oral-genital sexual exposure, with fellatio being a more efficient means of transmission than cunnilingus. It is important to solicit a sexual history as part of the evaluation of pharyngitis so that appropriate cultures for *N. gonorrhoeae* can be performed. Acute HIV infection should also be considered in the differential diagnosis of pharyngitis in persons with appropriate risk factors. Most cases resolve spontaneously, and transmission from the pharynx to sexual contacts is rare. Pharyngeal infection almost always coexists with genital infection. Swabs from the pharynx should be plated directly onto gonococcal selective media. Because pharyngeal colonization with *N. meningitidis* needs to be differentiated from that with other *Neisseria* species, the diagnosis of pharyngeal gonorrhea is more expensive and difficult than that of anogenital gonorrhea.

**Ocular Gonorrhea in Adults** Ocular gonorrhea in an adult usually results from autoinoculation from an infected genital site. As in genital infection, the manifestations range from severe to occasionally mild or asymptomatic disease. The variability in clinical manifestations may result from differences in the ability of the infecting strain to elicit an inflammatory response. Infection may result in a markedly swollen eyelid, severe hypemia and chemosis, and a profuse purulent discharge. The massively inflamed conjunctiva may be draped over the cornea and limbus. Lytic enzymes from the infiltrating PMNs occasionally cause corneal ulceration and rarely cause perforation.

Prompt recognition and treatment of this condition are of paramount importance. Gram’s stain and culture of the purulent discharge establish the diagnosis. Genital cultures should also be performed.

**Gonorrhea in Pregnant Women, Neonates, and Children** Gonorrhea in pregnancy can have serious consequences for both the mother and the infant. Therefore, early detection and eradication of the disease in the mother are extremely important. Recognition of gonorrhea early in pregnancy also identifies a population at risk for other STDs, particularly chlamydial infection and syphilis. These women should be monitored closely for these infections throughout pregnancy. The incidence of gonorrhea in pregnancy ranges from rare to ~10%, depending upon the population surveyed. Salpingitis and PID can occur during the first trimester and are associated with a high rate of fetal loss. In the second and third trimesters, the relative impermeability of the cervical mucus (under the influence of progesterone) and the obliteration of the intratunical cavity (resulting from the attachment of the chorion to the endometrial decidua by around the twelfth week of gestation) pose physical barriers that usually prevent ascending infection. Pharyngeal infection, most often asymptomatic, may be more common during pregnancy because of altered sexual practices. Acquisition of gonococcal infection late in pregnancy can adversely affect labor and delivery as well as the well-being of the fetus. Prolonged rupture of the membranes, premature delivery, chorioamnionitis, funisitis (infection of the umbilical cord stump), and sepsis in the infant (with *N. gonorrhoeae* detected in the gastric aspirate of the newborn during delivery) are common complications of maternal gonococcal infection at term. Hazards to the fetus include spontaneous abortion, perinatal death, premature delivery, perinatal distress, and premature
rupture of membranes. Other microorganisms and conditions, including *Mycoplasma hominis*, *Ureaplasma urealyticum*, *C. trachomatis*, and bacterial vaginosis, have been associated with similar complications.

The most common form of gonorrhea in neonates is ophthalmia neonatorum, which results from exposure to infected cervical secretions during parturition. Ocular neonatal instillation of a prophylactic agent (e.g., 1% silver nitrate eyedrops or ophthalmic preparations containing erythromycin or tetracycline) is a cost-effective measure for the prevention of ophthalmia neonatorum but is not effective for its treatment, which requires systemic antibiotics. The clinical manifestations are acute and begin 2 to 5 days after birth. A small inoculum of organisms, low virulence of the infecting strain, or partial suppression by maternal antibodies can result in a more indolent course. Therefore, gonococcal infection must be ruled out by culture in every case of conjunctivitis in infants. An initial nonspecific conjunctivitis with a serosanguineous discharge is followed by tense edema of both eyelids, chemosis, and a profuse, thick, purulent discharge. Corneal ulcerations that result in nebulae or perforation may lead to anterior synechiae, anterior staphyloma, panophthalmitis, and blindness. Infections described at other mucosal sites in infants, including vaginitis, rhinitis, and anorectal infection, are likely to be asymptomatic. Pharyngeal colonization has been demonstrated in 35% of infants with gonococcal ophthalmia, and coughing is the most prominent symptom in these cases. Septic arthritis (see below) is the most common manifestation of systemic infection or DGI in the newborn. The primary focus of DGI in most of these cases is uncertain. The onset usually comes at 3 to 21 days of age, and polycyclic involvement is common. Sepsis, meningitis, and pneumonia are seen in rare instances.

Any STD in children beyond the neonatal period raises the possibility of sexual abuse. In most cases of abuse, the perpetrator is a male assailant known to the child. Gonococcal vulvovaginitis is the most common manifestation of gonococcal infection in children beyond infancy. Anorectal and pharyngeal infections are common in these children and are frequently asymptomatic. The urethra, Bartholin’s and Skene’s glands, and the upper genital tract are rarely involved. All children with gonococcal infection should also be evaluated for chlamydial infection, syphilis, and possibly HIV infection. All cases of suspected and confirmed child abuse should be reported to the appropriate social service agency in the county where the child resides.

**Gonococcal Arthritis (DGI)**

DGI or gonococcal arthritis results from gonococcal bacteremia. In the 1970s, DGI occurred in ~0.5 to 3% of persons with untreated gonococcal mucosal infection. The lower incidence at present is probably attributable to a decline in the prevalence of particular strains that are likely to disseminate and has resulted in fewer cases that present in the bacteremic stage of the disease (see below). DGI strains resist the bactericidal action of human serum and generally do not incite inflammation at genital sites, probably because of limited generation of chemotactic factors. These strains are often of the Por1A serotype, are highly susceptible to penicillin, and have special growth requirements (i.e., the AHU auxotype) that makes the organism more fastidious and more difficult to isolate. Menstruation is a risk factor for dissemination, and approximately two-thirds of cases of DGI are in women. In about half of affected women, symptoms of DGI begin within 7 days of onset of menses. Complement deficiencies, especially of the components involved in the assembly of the membrane attack complex (C5 through C9), predispose to neisserial bacteremia. Up to 13% of patients with DGI have complement deficiencies, and persons with more than one episode of DGI should be screened with an assay for total hemolytic complement activity. The clinical manifestations of DGI have sometimes been classified into two stages: a bacteremic stage, which is less common today, and a joint-localized stage with supplicative arthritis. A clear-cut progression usually is not evident. Patients in the bacteremic stage have higher temperatures, and their fever is more frequently accompanied by chills. Painful joints are common and often occur in conjunction with tenosynovitis and skin lesions. Polyarthralgias usually include the knees, elbows, and more distal joints; the axial skeleton is generally spared. Skin lesions are seen in ~75% of patients and include papules and pustules, often with a hemorrhagic component (Fig. 128-1). These lesions are usually on the extremities and number between 5 and 40. The differential diagnosis of the bacteremic stage of DGI includes Reiter’s syndrome, acute rheumatoid arthritis, sarcoidosis, erythema nodosum, drug-induced arthritis, and viral infections (e.g., hepatitis B and acute HIV infection). The distribution of joint symptoms in Reiter’s syndrome differs from DGI (Fig. 128-2), as do the skin and genital manifestations (Chap. 305).

Suppurative arthritis involves one or two joints, most often (in decreasing order of frequency) the knees, wrists, ankles, and elbows. The occurrence of arthritis in the absence of signs and symptoms of the bacteremic stage has led to the suggestion that these are separate syndromes. Other joints, such as the small joints of the hands and feet and the sternoclavicular and temporomandibular joints, are occasionally involved. Most patients who develop gonococcal septic arthritis do so without prior polyarthralgias or skin lesions; in the absence of symptomatic genital infection, this disease cannot be distinguished from septic arthritis caused by other pathogens. The differential diagnosis of acute arthritis in young adults is discussed in Chap. 314. Rarely, osteomyelitis complicates septic arthritis involving small joints of the hand.

Although it has been postulated that the initial arthritis and skin lesions are due to direct tissue invasion by *N. gonorrhoeae*, the organism has been recovered from <5% of skin lesions cultured. This low isolation rate has been attributed to either a small inoculum of infecting organisms or the fastidious growth requirements of *N. gonorrhea.*

---

**FIGURE 128-1** Disseminated gonococcosis in the skin is seen as hemorrhagic papules and pustules with purpuric centers in a centrifugal distribution.

**FIGURE 128-2** Distributions of joints with arthritis in 102 patients with disseminated gonococcal infection and 173 patients with Reiter’s syndrome. “Sternal” includes the sternoclavicular joints. “SI” denotes the sacroiliac joint. (Reprinted with permission from M Kousa et al: Sex Transm Dis 5:57, 1978; with permission.)
N. gonorrhoeae strains that disseminate. Gonococcal antigens have been identified in "sterile" skin lesions by immunofluorescent staining techniques. There is also evidence that immune-mediated or hypersensitivity phenomena caused by gonococcal antigens account for skin lesions. Other manifestations of noninfectious dermatitis, such as nodular lesions, urticaria, and erythema multiforme, have been described. Gonococcal endocarditis, although rare today, was relatively common in the preantibiotic era, causing about one-quarter of reported cases of endocarditis. Another unusual complication of DGI is meningitis.

**Gonococcal Infection in HIV-Infected Persons** The association between gonorrhea and the acquisition of HIV has been demonstrated in several well-controlled studies, mainly in Kenya and Zaire. The nonulcerative STDs enhance the transmission of HIV by three- to fivefold, possibly because of increased viral shedding in persons with urethritis or cervicitis (Chap. 173). HIV has been detected by polymerase chain reaction (PCR) more commonly in ejaculates from HIV-positive men with gonococcal urethritis than in those from HIV-positive men with nongonococcal urethritis. PCR positivity diminishes by twofold following appropriate therapy for urethritis. Not only does gonorrhea enhance the transmission of HIV, it may also increase the individual's risk for acquisition of HIV. A proposed mechanism is the significantly greater number of CD4 + lymphocytes and dendritic cells that can be infected by HIV in endocervical secretions of women with nonulcerative STDs than in those of women with ulcerative STDs.

**Laboratory Diagnosis** A rapid diagnosis of gonococcal infection in men may be obtained by Gram's staining of urethral exudates. The detection of gram-negative intracellular diplococci is usually highly specific and sensitive in diagnosing gonococcal urethritis in symptomatic males but is only ~50% sensitive in diagnosing gonococcal cervicitis. Samples should be collected with Dacron or rayon swabs. Part of the sample should be inoculated onto a plate of modified Thayer-Martin or other gonococcal selective medium for culture. It is important to process all samples immediately because gonococci do not tolerate drying. If plates cannot be incubated immediately, they can be held safely for several hours at room temperature in candle extinction jars prior to incubation. If processing is to occur within 6 h, transport of specimens may be facilitated by the use of nonnutritive swab transport systems such as Stuart or Amies medium. For longer holding periods (e.g., when specimens for culture are to be mailed), culture media with self-contained CO2-generating systems (such as the JEMBEC or Gono-Pak systems) may be used. Specimens should also be obtained for the diagnosis of chlamydial infection.

PMNs are often seen in the endocervix on a Gram's stain, and an abnormally increased number [≥30 PMNs per field in five 1000X oil-immersion (microscopic) fields] establishes the presence of an inflammatory discharge. Unfortunately, the presence or absence of gram-negative intracellular diplococci in cervical smears does not accurately predict which patients have gonorrhea, and the diagnosis in this setting should be made by culture or another suitable nonculture diagnostic method. The sensitivity of a single endocervical culture is ~80 to 90%, with the precise figure depending on the quality of the medium and the adequacy of the clinical specimen. The yield can be enhanced by culture of a second cervical specimen. If a history of rectal sex is elicited, a rectal wall swab (uncontaminated with feces) should be cultured. A presumptive diagnosis of gonorrhea cannot be made on the basis of gram-negative diplococci in smears from the pharynx, where other Neisseria species are components of the normal flora.

Nucleic acid probe tests are sometimes substituted for culture for the direct detection of N. gonorrhoeae in urogenital specimens. A common assay employs a nonisotopic chemiluminescent DNA probe that hybridizes specifically with gonococcal 16S ribosomal RNA. Studies assessing the utility of the nucleic acid probe system in high-risk outpatients undergoing screening for STDs have revealed that it is at least as sensitive as conventional culture techniques and may be a cost-effective alternative to culture, especially in high-risk males. A disadvantage of non-culture-based assays in general is that specimens submitted in probe-transport systems cannot be cultured subsequently. Therefore, a culture-confirmed test is not possible, and formal antimicrobial susceptibility testing, if needed, cannot be performed. Low-cost point-of-care tests are under development for use in resource-poor settings, where specific diagnosis often gives way to syndromic management. Nucleic acid amplification tests (NAATs, including Roche Amplicor, Gen-Probe APTIMA, and BDProbeTec) have been cleared by the U.S. Food and Drug Administration (FDA) and offer the advantage of detecting in urine samples with a sensitivity similar to that of culture and other non-NAATs on urethral or cervical swab samples.

Because of the legal implications, the preferred method for the diagnosis of gonococcal infection in children is a standardized culture. Two positive NAATs, each targeting a different nucleic acid sequence, may be substituted for culture of the cervix or the urethra as legal evidence of infection; however, cervical specimens are not recommended for prepubertal girls. Nonculture tests for gonococcal infection have not been approved by the FDA for use with specimens obtained from the pharynx and rectum of infected children. Cultures should be obtained from the pharynx and anus of both girls and boys, the vagina of girls, and the urethra of boys. For boys with a urethral discharge, a metnal specimen of the discharge is adequate for culture. Presumptive colonies of N. gonorrhoeae should be identified definitively by at least two independent methods (e.g., biochemical, enzyme substrate, or serologic).

Blood should be cultured in suspected cases of DGI. The use of Isolator blood culture tubes may enhance the yield. The probability of positive blood cultures decreases after 48 h of illness. Synovial fluid should be inoculated into blood culture broth medium and plated onto chocolate agar rather than selective medium because this fluid is not likely to be contaminated with commensal bacteria. Gonococci are infrequently recovered from early joint effusions containing <20,000 leukocytes/µL but may be recovered from effusions containing >80,000 leukocytes/µL. The organisms are seldom recovered from blood and synovial fluid of the same patient.

### Treatment

Although clinical isolates of N. gonorrhoeae vary in their antimicrobial susceptibility patterns in different parts of the world, they remain susceptible to a wide variety of agents. Because failure of treatment can lead to continued transmission and the emergence of antibiotic resistance, the importance of adequate treatment with a regimen that the patient will adhere to cannot be overemphasized. Thus highly effective single-dose regimens have been developed for the treatment of uncomplicated gonococcal infections. The 2002 CDC treatment guidelines for gonococcal infections are summarized in Table 1-1; the recommendations for uncomplicated gonorrhea apply to HIV-infected as well as HIV-uninfected patients.

The third-generation cephalosporins cefixime (given orally) and ceftriaxone (given intramuscularly), both as a single dose, have been the mainstay of therapy with this class of antibiotics for uncomplicated gonococcal infection of the urethra, cervix, rectum, or pharynx. The recent discontinuation of cefixime production in the United States has prompted further examination of alternative oral options for urogenital and pharyngeal gonococcal infections. To be considered as a recommended treatment for uncomplicated gonorrhea, an antimicrobial regimen should cure >95% of urogenital infections. (The therapeutic efficacy for anorectal infection is typically comparable to that for urogenital infection.) Studies documenting efficacy should have sufficient sample size so that the lower limit of the confidence interval (CI) of the cure rate is also >95%. The available data do not demonstrate that any single-dose oral antimicrobial regimen other than cefixime or a fluoroquinolone (see below) meets these efficacy criteria for urogenital gonococcal infection; published data on the efficacy of alternative oral regimens in treating pharyngeal gonococcal infection are even more
limited. Single doses of ciprofloxacin, ofloxacin, or levofloxacin are effective first-line regimens. Other quinolones, such as gatifloxacin, norfloxacin, and lomefloxacin, are probably efficacious for treating uncomplicated gonorrhea, but data regarding their use are also limited, and they offer no advantage over the other recommended quinolones. Because of resistance to fluoroquinolones in several parts of Asia and the Pacific (including Hawaii), these agents should not be used to treat gonorrhea acquired in these regions. Several states, including California, are now recommending the curtailment of quinolone treatment for gonorrhea infection altogether, and in these regions ceftriaxone should be used.

Because co-infection with *C. trachomatis* occurs frequently, initial treatment regimens must incorporate an agent (e.g., azithromycin or doxycycline) effective against chlamydial infection. Routine dual therapy without testing for *Chlamydia* can be cost-effective for populations where chlamydial infection accompanies 10 to 30% of gonococcal infections. Pregnant women with gonorrhea should receive concurrent treatment with a macrolide antibiotic for possible chlamydial infection; doxycycline should not be used during pregnancy. A single 1-g dose of azithromycin, which is effective therapy for uncomplicated chlamydial infections, results in an acceptably low cure rate (93%) for gonococcal infections and should not be used alone.

Uncomplicated gonococcal infections in penicillin-allergic persons who cannot tolerate quinolones may be treated with a single dose of spectinomycin.

Persons with uncomplicated infections who receive a recommended regimen need not return for a test of cure. Cultures for *N. gonorrhoeae* should be performed if symptoms persist after therapy with an established regimen, and any gonococcal isolated should be tested for antimicrobial susceptibility.

Symptomatic gonococcal pharyngitis is more difficult to eradicate than genital infection. Few regimens result in cure rates of >90%. Persons who cannot tolerate cephalosporins or quinolones can be treated with spectinomycin, but this agent results in a cure rate of ≤52%. Therefore, persons given spectinomycin should have a pharyngeal culture performed 3 to 5 days after treatment as a test of cure.

Treatments for gonococcal epididymitis and PID are discussed in Chap. 115. Ocular gonococcal infections in older children and adults should be managed with a single dose of ceftriaxone combined with saline irrigation of the conjunctivae (both undertaken expeditiously), and patients should undergo a careful ophthalmologic evaluation that includes a slit-lamp examination.

DGI may require higher dosages and longer durations of therapy (Table 128-1). Hospitalization is indicated if the diagnosis is uncertain, if the patient has localized joint disease that requires aspiration, or if the patient cannot be relied on to comply with treatment. Open drainage is necessary only occasionally—e.g., for management of hip infections that may be difficult to drain percutaneously. Nonsteroidal anti-inflammatory agents may be indicated to alleviate pain and hasten improvement of affected joints. Gonococcal meningitis and endocarditis should be treated in the hospital with high-dose intravenous ceftriaxone (1 to 2 g every 12 h); therapy should continue for 10 to 14 days for meningitis and for at least 4 weeks for endocarditis. All persons who experience more than one episode of DGI should be evaluated for complement deficiency.

<sup>a</sup> True failure of treatment with a recommended regimen is rare and should prompt an evaluation for reinfection or consideration of an alternative diagnosis. In cases of quinolone failure, the isolate should be tested for drug resistance if possible.

<sup>b</sup> Quinolones should not be used for infections acquired in Asia or the Pacific, including Hawaii and California. The use of quinolones is also inadvisable for treating infections acquired in other areas where the prevalence of quinolone-resistant *N. gonorrhoeae* (QRNG) is >1%, or in areas that are reporting increasing numbers of QRNG strains.

<sup>c</sup> Cefixime, a first-line recommendation for treatment of uncomplicated gonococcal infection (or continuation therapy for DGI), is currently unavailable in the United States.

<sup>+</sup> Plus lavage of the infected eye with saline solution (once).

<sup>f</sup> Prophylactic regimens are discussed in the text.

<sup>h</sup> Hospitalization is indicated if the diagnosis is uncertain, if the patient has frank arthritis with an effusion, or if the patient cannot be relied on to adhere to treatment.

<sup>i</sup> All initial regimens should be continued for 24 to 48 h after clinical improvement begins, at which time therapy may be switched to one of the continuation regimens to complete a full week of antimicrobial treatment.

<sup>j</sup> Hospitalization is indicated to exclude suspected meningitis or endocarditis.

### Prevention and Control

Condoms, if properly used, provide effective protection against the transmission and acquisition of gonorrhea as well as other infections that are transmitted to and from genital mucosal surfaces. Spermicidal preparations used with a diaphragm or cervical sponges impregnated with nonoxynol 9 offer some protection against gonorrhea and chlamydial infection. However, the frequent use of preparations that contain nonoxynol 9 is associated with mucosal disruption that paradoxically may enhance the risk of HIV infection.
in the event of exposure. All patients should be instructed to refer sex partners for evaluation and treatment. All sex partners of persons with gonorrhea should be evaluated and treated for N. gonorrhoeae and C. trachomatis infections if their last contact with the patient took place within 60 days before the onset of symptoms or the diagnosis of infection in the patient. If the patient’s last sexual encounter was >60 days before onset of symptoms or diagnosis, the patient’s most recent sex partner should be treated. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms. Greater emphasis must be placed on prevention by public health education, individual patient counseling, and behavior modification. Sexually active persons, especially adolescents, should be offered screening for STDs. For males, a NAAT on urine or a urethral swab may be used for screening. Preventing the spread of gonorrhea may help reduce the transmission of HIV. No effective vaccine for gonorrhea is yet available, but efforts to test a porin vaccine candidate are under way.

The gram-negative coccus Moraxella catarrhalis is a component of the normal bacterial flora of the upper airways and has been increasingly recognized as a cause of otitis media, sinusitis, and bronchopulmonary infection. Over the past several decades, this organism has been variously designated as Micrococcus catarrhalis, Neisseria catarrhalis, and Branhamella catarrhalis.

**BACTERIOLOGY AND IMMUNITY** On Gram’s staining, M. catarrhalis organisms appear as gram-negative cocci, sometimes occurring in pairs and retaining the side-by-side kidney-bean configuration of Neisseria (Fig. 129-1). These cocci tend to retain crystal violet during the decolorizing step and may be confused with Staphylococcus aureus.

**M. catarrhalis** colonies grow well on blood or chocolate agar but may be overlooked because of their resemblance to Neisseria spp. (a major component of the normal pharyngeal flora). Moraxella is readily distinguishable from Neisseria spp. by biochemical tests.

Strains of M. catarrhalis show a surprising degree of homogeneity in terms of their outer-membrane proteins. Antibody to some of these proteins is generally present in serum of children >4 years old; however, colonizing or disease-causing isolates may survive in serum despite this naturally present antibody and complement. Bactericidal antibody emerges after natural infection and may be directed against one or more conserved outer-membrane proteins—a property of potential value in vaccine development. The presence of certain outer-membrane proteins is associated with virulence in mice, and antibody may be protective. Antibody to lipooligosaccharide may also provide some degree of protection. These and other bacterial constituents are under investigation for use as vaccines.

**EPIDEMIOLOGY** With repeated cultures and the use of selective media, M. catarrhalis can be isolated from the upper respiratory tract or saliva of 50% of healthy schoolchildren and of up to 7% of healthy adults. When conventional microbiologic techniques are used, Moraxella can be isolated from sputum of about 10% of persons who have chronic bronchitis and 25% of those who have bronchiectasis in the absence of acute infection. Investigators in both the northern and southern hemispheres have reported a striking seasonal variation in the isolation of this organism from clinical specimens, with a peak in late winter/early spring and a nadir in late summer/early fall. Direct contact has not been shown to contribute to community-acquired infection, but nosocomial spread of infection has been documented occasionally.

**CLINICAL MANIFESTATIONS** Otitis Media and Sinusitis M. catarrhalis has repeatedly been shown to be the third most common bacterial isolate from middle-ear fluid of children who have otitis media, being surpassed only by Streptococcus pneumoniae and nontypable Haemophilus influenzae. Recent studies have shown that this organism is also a prominent isolate from sinus cavities in acute and chronic sinusitis.

**Pulmonary Tracheobronchitis and Pneumonia** M. catarrhalis causes acute exacerbations of chronic bronchitis (increased production and/or purulence of sputum), purulent tracheobronchitis (the latter also involving fever and leukocytosis), and pneumonia; acquisition of a new bacterial strain is often responsible. The great majority of infected persons are >50 years old and have a long history of cigarette smoking and underlying chronic obstructive pulmonary disease (COPD); many have lung cancer as well. In one study, 76% of affected persons had COPD (severe in many cases), and one-third of those with COPD had lung cancer; most patients also had clinical evidence of malnutrition. In one extensive series of cases, M. catarrhalis pneumonia did not occur in otherwise-healthy hosts.

Symptoms of M. catarrhalis infection have been regarded as modest in severity. Both cough and the amount and purulence of sputum are usually increased above baseline. Chills are reported in one-quarter
of patients, pleuritic pain in one-third, and malaise in 40%. Most patients have peak temperatures of <38.3°C (<101°F), and peripheral white blood cell counts are <10,000/μL in nearly one-quarter of cases. Microscopic examination of a good sputum specimen following Gram’s staining regularly reveals profuse organisms, and quantitative culture yields ~2 × 10^9 colony-forming units per milliliter. The radiologic appearance is variable; in one study, 43% of subjects had segmental or lobar infiltrates, and the remainder had a mixed pattern of subsegmental, segmental, interstitial, and diffuse involvement. These clinical, laboratory, and radiographic findings do not differ from those of pneumococcal or Haemophilus pneumonia in an older patient population. However, a far lesser degree of bloodstream infection occurs in M. catarrhalis infection; in one series, none of 25 patients with M. catarrhalis pneumonia had bacteremia. Nevertheless, pneumonia due to M. catarrhalis is a marker for severe underlying disease: nearly half of patients die within 3 months of onset.

Other Syndromes Local extension causing empyema is very uncommon, and, as might be inferred from the low rate of bacteremia, metastatic complications of M. catarrhalis pneumonia, such as septic arthritis, are exceedingly rare. As of 1995, 58 cases of bacteremic infection due to M. catarrhalis had been reported, mainly in children <10 years old or adults >60 years old; most of these patients had severe underlying lung disease and/or were immunocompromised. The syndromes reported have included bacteremia with no apparent focus, pneumonia, endocarditis, and meningitis. A petechial or purpuric rash, reminiscent of that observed in meningococcal sepsis and associated with disseminated intravascular coagulation, has been described in a few cases.

DIAGNOSIS Microscopic examination of Gram-stained sputum yields characteristic findings (Fig. 129-1). The presence of many polymorphonuclear leukocytes without epithelial cells indicates that the sputum sample is of good quality; since most patients with Moraxella infection have chronic lung disease, it is usually not difficult to obtain a good specimen. Large numbers of Moraxella organisms are seen as gram-negative cocci, often lining up side by side and thus resembling pairs of kidneys.

TREATMENT Treatment of M. catarrhalis infection with a penicillin/clavulanic acid combination seems highly appropriate. Penicillin resistance first appeared in isolates in the mid-1970s and is now found in 94% of clinical isolates. Resistance is mediated by two closely related ß-lactamases, BRO-1 and BRO-2, which are present in 90% and 10% of resistant isolates, respectively. These enzymes are active against penicillin, amoxicillin, and amoxicillin but less so against cephalosporins, especially third-generation cephalosporins, and they bind avidly to clavulanic acid and sulbactam. Thus a ß-lactam/ß-lactamase inhibitor combination offers an effective mode of treatment. Cephalosporins, especially those of the second and third generations, are effective alternatives. Isolates in the United States are also nearly uniformly susceptible to tetracycline, newer macrolides, ketolides, trimethoprim-sulfamethoxazole (TMP-SMX), quinolones, and chloramphenicol. A 5-day course of therapy has been shown to cure respiratory infection, although a longer course is required in sinuses.

Treatment of sinusitis or otitis media is empirical, as appropriate specimens are usually obtained only in research studies. In the treatment of pneumonia during the period between the identification of gram-negative cocci in a Gram-stained specimen and the final identification of the organisms by culture, the severity of the condition and the potential presence of other infecting organisms should guide antibiotic selection. For example, an exacerbation of bronchitis caused by M. catarrhalis might be treated with tetracycline or TMP-SMX; however, in a patient with pneumonia, the possibility that pneumo-

* Some of these isolates would now be distinguished as a new species, Moraxella lincolnii. Note: CSF, cerebrospinal fluid.

Source: Adapted from a summary of CDC experience (Graham et al.).

**OTHER MORAXELLA SPECIES**

Other Moraxella species cause a wide range of infections, including bronchitis, pneumonia, empyema, endocarditis, meningitis, conjunctivitis, endophthalmitis, urinary tract infection, septic arthritis, and wound infection. In a report on all Moraxella isolates submitted to the Centers for Disease Control and Prevention (CDC) between 1953 and 1980, certain clinical associations were apparent (Table 129-1). M. osloensis and M. nonliquefaciens, the most commonly isolated species, were cultured from a wide range of normally sterile body sites, including blood, cerebrospinal fluid, and joints. M. osloensis was the Moraxella species most frequently isolated from blood; M. nonliquefaciens tended to be isolated from the ears, nose, or throat (47%) or the sputum (8%) and has since been implicated as a cause of conjunctivitis and keratitis. M. urethralis was isolated most often from urine and the genital tract and probably represents the Moraxella species implicated previously in urethritis. More than half of isolates of M. phenylpyruvica and M. atlantae were obtained from normally sterile sites. A recent study found Moraxella spp., including M. catarrhalis, in 35% of infected wounds following cat bites and in 10% of those following dog bites. The clinical features of infections due to Moraxella spp. other than M. catarrhalis and the nature of the hosts in which they occur have not been fully characterized.

**FURTHER READING**

HAEMOPHILUS INFLUENZAE

MICROBIOLOGY  
Haemophilus influenzae was first recognized in 1892 by Pfeiffer, who erroneously concluded that the bacterium was the cause of influenza. The bacterium is a small (1- by 0.3-μm) gram-negative organism of variable shape; hence, it is often described as a pleomorphic cocccobacillus. In clinical specimens such as cerebrospinal fluid (CSF) and sputum, it frequently stains only faintly with phosphafranin and therefore can easily be overlooked.

H. influenzae grows both aerobically and anaerobically. Its aerobic growth requires two factors: hemin (X factor) and nicotinamide adenine dinucleotide (V factor). These requirements are used in the clinical laboratory to identify the bacterium. Six major serotypes of H. influenzae have been identified; designated a through f, they are based on antigenically distinct polysaccharide capsules. In addition, some strains lack a polysaccharide capsule and are referred to as nontypable strains. Type b and nontypable strains are the most relevant strains clinically (Table 130-1), although encapsulated strains other than type b can cause disease. H. influenzae was the first free-living organism to have its entire genome sequenced.

The antigenically distinct type b capsule is a linear polymer composed of ribosyl-ribitol phosphate. Strains of H. influenzae type b (Hib) cause disease primarily in infants and children under the age of 6 years. Nontypable strains are primarily mucosal pathogens, although these strains occasionally cause invasive disease.

EPIDEMIOLOGY AND TRANSMISSION  
H. influenzae is an exclusively human pathogen. The organism is spread by airborne droplets or by direct contact with secretions or fomites. Nontypable strains colonize the upper respiratory tract of up to three-fourths of healthy adults. Colonization with nontypable H. influenzae is a dynamic process; new strains are acquired and other strains are replaced periodically.

The widespread use of Hib conjugate vaccines has resulted in striking decreases in the rate of nasopharyngeal colonization by Hib and the incidence of Hib infection (Fig. 130-1). Invasive Hib disease now occurs predominantly in underimmunized children and in infants who have not completed the primary immunization series.

Certain population groups have a higher incidence of invasive Hib disease than the general population. The incidence of meningitis due to Hib has been three to four times higher among black children than among white children in several studies. In some Native American groups, the incidence of invasive Hib disease is 10 times higher than that in the general population. Although this increased incidence has not yet been accounted for, several factors may be relevant, including age at exposure to the bacterium, socioeconomic conditions, and genetic differences in the ability to mount an immune response.

PATHOGENESIS  
Hib strains cause systemic disease by invasion and hematogenous spread to distant sites such as the meninges, bones, and joints. The type b polysaccharide capsule is an important virulence factor affecting the bacterium’s ability to avoid opsonization and cause systemic disease.

Nontypable strains cause disease by local invasion of mucosal surfaces. Otitis media results when bacteria reach the middle ear by way of the eustachian tube. Adults with chronic bronchitis experience recurrent lower respiratory tract infection due to nontypable strains. The incidence of invasive disease caused by nontypable strains is low.

IMMUNE RESPONSE  
Antibody to capsule is important in protection from infection by Hib strains. The level of (maternally acquired) serum antibody to the capsular polysaccharide, which is a polymer of polyribitol ribose phosphate (PRP), declines from birth to 6 months of age and, in the absence of vaccination, remains low until around 2 or 3 years of age. The age at the antibody nadir correlates with that of the peak incidence of type b disease. Antibody to PRP then appears partly as a result of exposure to Hib or cross-reacting antigens. Systemic Hib disease is unusual after the age of 6 years because of the presence of protective antibody. Vaccines in which PRP is conjugated to protein carrier molecules have been developed and are now used widely. These vaccines generate an antibody response to PRP in infants and are effective in preventing invasive infections in infants and children.

Since nontypable strains lack a capsule, the immune response to infection is directed at noncapsular antigens. These noncapsular antigens of H. influenzae have generated considerable interest as targets of the human immune response and as potential vaccine components. The human immune response to nontypable strains appears to be strain-specific, accounting in part for the propensity of these strains to cause recurrent otitis media and recurrent exacerbations of chronic bronchitis in immunocompetent hosts.

CLINICAL MANIFESTATIONS  
Hib  
The most serious manifestation of infection with Hib is meningitis. The age of peak incidence varies somewhat among populations, depending in part on the use of vaccine, but this infection primarily affects infants <2 years of age. The clinical manifestations of meningitis caused by Hib are similar to those of meningitis caused by other bacterial pathogens. Fever and altered central nervous system function are the most common features at presentation. Nuchal rigidity may or may not be evident. Subdural effusion, the most common complication, is suspected when, despite 2 or 3 days of appropriate antibiotic therapy, the infant has seizures, hemiparesis, or continued obtundation. The overall mortality from meningitis caused by Hib is ~5%, and the rate of morbidity is high. Of survivors, 6% have permanent sensorineural hearing loss, and about one-fourth have a significant handicap of some type. If more subtle handicaps are sought, up to half of survivors are found to have some neurologic sequelae, such as partial hearing loss and delay in language development.

Epiglottitis is a life-threatening infection involving cellulitis of the epiglottis and supraglottic tissues. It can lead to acute upper airway obstruction. Its unique epidemiologic features are its occurrence in an older age group (2 to 7 years old) than other Hib infections and its absence among Navajo Indians and Alaskan Eskimos. Sore throat and

fever rapidly progress to dysphagia, drooling, and airway obstruction. Epiglottitis also occurs in adults.

Cellulitis due to Hib occurs in young children. The most common location is on the head or neck, and the involved area sometimes takes on a characteristic bluish-red color. Most patients have bacteremia, and 10% have an additional focus of infection.

Hib causes pneumonia in infants. The infection is clinically indistinguishable from other types of bacterial pneumonia (e.g., pneumococcal pneumonia) except that Hib is more likely to involve the pleura.

Several less common invasive conditions can be important clinical manifestations of Hib infection in children. These include osteomyelitis, septic arthritis, pericarditis, orbital cellulitis, endophthalmitis, urinary tract infection, abscesses, and bacteremia without an identifiable focus. As has already been mentioned, infections due to Hib are unusual among patients older than 6 years.

Nontypable H. influenzae Nontypable H. influenzae is a common cause of community-acquired bacterial pneumonia in adults. Nontypable H. influenzae pneumonia is especially common among patients with chronic obstructive pulmonary disease (COPD) or AIDS. The clinical features of pneumonia due to H. influenzae are similar to those of other types of bacterial pneumonia (including pneumococcal pneumonia). Patients present with fever, cough, and purulent sputum, usually of several days’ duration. Chest radiography reveals alveolar infiltrates in a patchy or lobar distribution. Gram-stained sputum contains a predominance of small, pleomorphic, coccobacillary gram-negative bacteria.

Exacerbations of COPD caused by nontypable H. influenzae are characterized by increased cough, sputum production, and shortness of breath. Fever is low-grade, and no infiltrates are evident on chest x-ray.

Nontypable H. influenzae is one of the three most common causes of childhood otitis media (the other two being Streptococcus pneumoniae and Moraxella catarrhalis). Infants are febrile and irritable, while older children report ear pain. Symptoms of viral upper respiratory infection often precede otitis media. The diagnosis is made by pneumatic otoscopy. An etiologic diagnosis, although not routinely sought, can be established by tympanocentesis and culture of middle-ear fluid.

Nontypable H. influenzae also causes periperal sepsis and is an important cause of neonatal bacteremia. These nontypable strains tend to be of biotype IV and cause invasive disease after colonizing the female genital tract.

Nontypable H. influenzae causes sinusitis in adults and children. In addition, the bacterium is a less common cause of various invasive infections that are reported primarily as small-series descriptions and case reports. These infections include empyema, adult epiglottitis, pericarditis, cellulitis, septic arthritis, osteomyelitis, endocarditis, cholecystitis, intraabdominal infections, urinary tract infections, mastoiditis, aortic graft infection, and bacteremia without a detectable focus.

Diagnosis The most reliable method for establishing a diagnosis of Hib infection is recovery of the organism in culture. The Csf of a patient in whom meningitis is suspected should be subjected to Gram’s staining and culture. The presence of gram-negative coccobacilli in Gram-stained CSF is strong evidence for Hib meningitis. Recovery of the organism from CSF confirms the diagnosis. Cultures of other normally sterile body fluids, such as blood, joint fluid, pleural fluid, pericardial fluid, and subdural effusion, are confirmatory in other infections.

Detection of PRP is an important adjunct to culture in rapid diagnosis. Immunoelectrophoresis, latex agglutination, coagglutination, and enzyme-linked immunosorbent assay are effective in detecting PRP. These assays are particularly helpful when patients have received prior antimicrobial therapy and thus are especially likely to have negative cultures.

Before the early 1980s, nontypable strains of H. influenzae were frequently misidentified as Hib because of their autoagglutination when serotypes were determined in agglutination assays. Since nontypable H. influenzae is primarily a mucosal pathogen, it is a component of a mixed flora; this situation makes etiologic diagnosis challenging. Nontypable H. influenzae infection is strongly suggested by the predominance of gram-negative coccobacilli among abundant polymorphonuclear leukocytes in a Gram-stained sputum specimen from a patient in whom pneumonia or tracheobronchitis is suspected. A sputum culture is helpful when interpreted along with the results of Gram’s staining. Although bacteremia is detectable in a small proportion of patients with pneumonia due to nontypable H. influenzae, most such patients have negative blood cultures.

A diagnosis of otitis media is based on the detection by pneumatic otoscopy of fluid in the middle ear. An etiologic diagnosis requires tympanocentesis but is not routinely sought. An invasive procedure is also required to determine the etiology of sinusitis; thus, treatment is often empirical once the diagnosis is suspected in light of clinical symptoms and sinus radiographs.

Treatment Initial therapy for meningitis due to Hib should consist of a cephalosporin such as ceftriaxone or cefotaxime. For children, the dosage of ceftriaxone is 75 to 100 mg/kg daily given in two doses 12 h apart. The pediatric dosage of cefotaxime is 200 mg/kg daily given in four doses 6 h apart. Adult dosages are 2 g every 12 h for ceftriaxone and 2 g every 4 to 6 h for cefotaxime. An alternative regimen for initial therapy is ampicillin (200 to 300 mg/kg daily in four divided doses) plus chloramphenicol (75 to 100 mg/kg daily in four divided doses). Therapy should continue for a total of 1 to 2 weeks.

Administration of glucocorticoids to patients with Hib meningitis reduces the incidence of neurologic sequelae. The presumed mechanism is reduction of the inflammation induced by bacterial cell-wall mediators of inflammation when cells are killed by antimicrobial agents. Dexamethasone (0.6 mg/kg per day intravenously in four divided doses for 2 days) is recommended for the treatment of Hib meningitis in children >2 months of age.

Invasive infections other than meningitis are treated with the same antimicrobial agents. For epiglottitis, the dosage of ceftriaxone is 50 mg/kg daily, and the dosage of cefotaxime is 150 mg/kg daily, given in three divided doses 8 h apart. Epiglottitis constitutes a medical emergency, and maintenance of an airway is critical. The duration of therapy is determined by the clinical response. A course of 1 to 2 weeks is usually appropriate.

Many infections caused by nontypable strains of H. influenzae, such as otitis media, sinusitis, and exacerbations of COPD, can be treated with oral antimicrobial agents. Approximately 25% of nontypable strains produce β-lactamase and are resistant to ampicillin. Infections caused by ampicillin-resistant strains can be treated with a variety of agents, including trimethoprim-sulfamethoxazole, amoxicillin/clavulanic acid, various extended-spectrum cephalosporins, and newer macrolides (azithromycin and clarithromycin). Fluoroquinolones are highly active against H. influenzae but are not currently recommended for the treatment of children or pregnant women because of possible effects on articular cartilage.

Prevention In the United States, the recommended immunization schedule for the primary series between 2 and 6 months of age, and a booster dose at 12 to 15 months of age. Specific recommendations vary for the different conjugate vaccines. The reader is referred to the recommendations of the American Academy of Pediatrics. Currently, no vaccines are available for the prevention of disease caused by nontypable H. influenzae.
HAEMOPHILUS INFLUENZAE BIOGROUP AEGYPTIUS

*H. influenzae* biogroup aegyptius was formerly called *Haemophilus aegyptius* because of phenotypic characteristics distinct from those of *H. influenzae*. However, later studies involving DNA hybridization and DNA transformation demonstrated that *H. aegyptius* and *H. influenzae* are members of the same species.

*H. influenzae* biogroup aegyptius has long been associated with conjunctivitis. Moreover, this strain is now known to be the cause of Brazilian purpuric fever (BPF), which was first recognized in 1984 in the rural Brazilian town of Promissao. The sharing of many phenotypic and genotypic characteristics by the various strains of *H. influenzae* biogroup aegyptius that cause BPF indicates that these strains represent a clone of *H. influenzae*. The age of peak incidence of BPF is 1 to 4 years, with a range of 3 months to 8 years. The illness can occur sporadically or in outbreaks. Typically, after an episode of purulent conjunctivitis, high fever occurs in association with vomiting and abdominal pain. Within 12 to 48 h after onset, the patient develops pectechiae, purpura, and peripheral necrosis and experiences vascular collapse. The characteristic laboratory features are thrombocytopenia, prolonged prothrombin time, uniformly unrevealing CSF findings, and blood cultures positive for *H. influenzae* biogroup aegyptius. Initial reports cited high mortality (70%), but subsequent studies have indicated that milder forms of the illness exist. Most patients have resolved or resolving purulent conjunctivitis, and culture of the conjunctiva is positive in approximately one-third of cases. BPF has been seen in several towns in Brazil and on two occasions in Australia.

HAEMOPHILUS DUCREYI

*Haemophilus ducreyi* is the etiologic agent of chancroid (Chap. 115), a sexually transmitted disease characterized by genital ulceration and inguinal adenitis. *H. ducreyi* poses a significant health problem in developing countries. Although this infection is less common in the United States, its incidence has increased dramatically in the past several years. In addition to being a cause of morbidity in itself, chancroid is associated with infection with HIV because of the role of genital ulceration in the transmission of HIV.

MICROBIOLOGY  *H. ducreyi* is a highly fastidious coccobacillary gram-negative bacterium whose growth requires X factor (hemin). Although, in light of this requirement, the bacterium has been classified in the genus *Haemophilus*, DNA homology and chemotaxonomic studies have established substantial differences between *H. ducreyi* and other *Haemophilus* species. Taxonomic reclassification of the organism is likely in the future but awaits further study.

The histology of the genital ulcer of chancroid is characterized by perivascular and interstitial infiltrates of macrophages and of CD4+ and CD8+ lymphocytes. The appearance is consistent with a delayed-type hypersensitivity, cell-mediated immune response. The presence of CD4+ cells and macrophages in the ulcer may explain, in part, the facilitation of transmission of HIV in patients with chancroid.

EPIDEMIOLOGY AND PREVALENCE  Chancroid is a common cause of genital ulcers in developing countries. In the United States, chancroid is now endemic in some regions, and several large outbreaks have occurred since 1981. Recurring epidemiologic themes have been apparent in these outbreaks: (1) transmission has been predominantly heterosexual; (2) males have outnumbered females by ratios of 3:1 to 25:1; (3) prostitutes have been important in transmission of the infection; and (4) chancroid has been strongly associated with illicit drug use. The incidence of chancroid in the United States will likely increase in the coming years, and the genital ulcers associated with this infection will continue to play a role in the transmission of HIV.

CLINICAL MANIFESTATIONS  Infection is acquired as the result of a break in the epithelium during sexual contact with an infected individual. An incubation period of 4 to 7 days, the initial lesion—a papule with surrounding erythema—appears. In 2 to 3 days, the papule evolves into a pustule, which spontaneously ruptures and forms a sharply circumscribed ulcer that is generally not indurated (Fig. 130-2). The ulcers are painful and bleed easily; little or no inflammation of the surrounding skin is evident. Approximately half of patients develop enlarged, tender inguinal lymph nodes, which frequently become fluctuant and spontaneously rupture. Patients usually seek medical care after 1 to 3 weeks of painful symptoms.

The presentation of chancroid does not usually include all of the typical clinical features and is sometimes atypical. Multiple ulcers can coalesce to form giant ulcers. Ulcers can appear and then resolve, with inguinal adenitis (Fig. 130-2) and suppuration following 1 to 3 weeks later; this clinical picture can be confused with that of lymphogranuloma venereum. Multiple small ulcers can resemble folliculitis. Other differential diagnostic considerations include the various infections causing genital ulceration, such as primary syphilis, condyloma latum of secondary syphilis, genital herpes, and donovanosis. In rare cases chancroid lesions become secondarily infected with bacteria; the result is extensive inflammation.

DIAGNOSIS  Clinical diagnosis of chancroid is often inaccurate, and laboratory confirmation should be attempted in suspected cases. Gram’s staining of a swab of the lesion may reveal a predominance of characteristic gram-negative coccobacilli, but the presence of other bacteria often makes it difficult to interpret this result. An accurate diagnosis of chancroid relies on cultures of *H. ducreyi* from the lesion. In addition, aspiration and culture of suppurative lymph nodes should be considered. Since the organism can be difficult to grow, the use of selective and supplemented media is necessary. A new multiplex
polymerase chain reaction (PCR) assay has been developed to amplify simultaneously DNA targets from *H. ducreyi*, *Treponema pallidum*, and herpes simplex virus types 1 and 2. When this assay becomes commercially available, it will be a useful diagnostic method with which to identify the etiology of genital ulcers.

**TREATMENT**

The treatment regimen recommended by the Centers for Disease Control and Prevention is a single 1-g oral dose of azithromycin. Alternative regimens include ceftriaxone (250 mg intramuscularly in a single dose), ciprofloxacin (500 mg orally twice a day for 3 days), or erythromycin base (500 mg orally three times a day for 7 days). Isolates from patients who do not respond promptly to treatment should be tested for antimicrobial susceptibility. In patients with HIV infection, healing may be slow and longer courses of treatment may be necessary. Clinical treatment failure in HIV-seropositive patients may reflect co-infection, especially with herpes simplex virus. Contacts of patients with chancroid should be identified and treated whether or not symptoms are present if they had sexual contact with the patient during the 10 days preceding the patient’s onset of symptoms.

**OTHER HAEMOPHILUS SPECIES**

*Haemophilus* species are often recovered as components of the flora of the normal human upper respiratory tract. However, these bacteria are infrequent causes of infection because of their low pathogenic potential. *Haemophilus* species have fastidious growth requirements and are generally rather slow-growing. The species implicated in human infections include *H. parainfluenzae*, *H. aphrophilus*, and *H. paraphrophilus*. Most strains produce β-lactamase and are thereby resistant to ampicillin. Other strains are sensitive to ampicillin, and this agent has been used successfully to treat many infections. Alternative agents with good activity against most *Haemophilus* species include trimethoprim-sulfamethoxazole, third-generation cephalosporins, tetracycline, chloramphenicol, and aminoglycosides. Endocarditis caused by ampicillin-sensitive strains should be treated with ampicillin plus an aminoglycoside.

**FURTHER READING**

of patients with native-valve endocarditis due to *Haemophilus* species report a history of cardiac valvular disease, 60% have been ill for <2 months before presentation, and 50% are anemic at presentation. Some 19% to 50% of these patients develop congestive heart failure. Mortality rates as high as 30% to 50% have been reported in older series, 19% to 50% of these patients develop congestive heart failure. Mortality rates as high as 30% to 50% have been reported in older series.

### Treatment

**Haemophilus species**
- Ceftriaxone (2 g/d)
- **Alternative Agents**
  - Fluoroquinolones, ampicillin/sulbactam
  - Ampicillin ± aminoglycoside can be used if organism does not produce β-lactamase.
  - Limited data exist on efficacy of regimens other than semisynthetic penicillins or third-generation cephalosporins.

**Actinobacillus actinomycescomitans**
- Ceftriaxone (2 g/d)
- **Alternative Agents**
  - Semisynthetic penicillins (e.g., mezlocillin), TMP-SMX, fluoroquinolones, azithromycin
  - Ceftriaxone, ampicillin/sulbactam

**Cardiobacterium hominis**
- Penicillin (16–18 MIU/d in 6 divided doses) ± gentamicin (5–6 mg/kg/d in 3 divided doses)
- **Alternative Agents**
  - Ceftriaxone, ampicillin/sulbactam

**Eikenella corrodens**
- Ampicillin (2 g q4h)
- **Alternative Agents**
  - Ceftriaxone, fluoroquinolones

**Kingella kingae**
- Ceftriaxone (2 g/d) or ampicillin/sulbactam (3 g of ampicillin q8h)
- **Alternative Agents**
  - Fluoroquinolones, vancomycin, clindamycin, macrolides, TMP-SMX

### Note

- TMP-SMX, trimethoprim-sulfamethoxazole.
- Fluoroquinolones are not recommended for treatment of children <17 years of age.
- Susceptibility testing should be performed to guide therapy.

### Other Gram-negative Bacteria

**Achromobacter xylosodan**
- Previously known as *Alcaligenes xylosodans*, this gram-negative bacillus is probably part of the endogenous intestinal flora and has been isolated from water sources. Immunosuppressed hosts appear to be at increased risk for infection with this organism. Nosocomial sources to which outbreaks of infection with *A. xylosodans* have been attributed include contaminated intravenous fluids, pressure transducers, and disinfectants. Clinical illness has been associated with isolates from many sites, including blood (often in the setting of infected intravascular devices), urine, respiratory secretions, cerebrospinal fluid, peritoneal and pleural fluids, and

*See Table 131-1.*
endocarditic prosthetic valves. Community-acquired bacteremia with A. xylosidans usually occurs in the setting of pneumonia. Metastatic skin lesions are present in one-fifth of cases. The reported mortality rate is 67%, similar to rates for other bacteremic gram-negative pneumonias.

**TREATMENT**

In vitro susceptibility testing of all clinically relevant isolates is essential to the selection of appropriate therapy.

**AGROBACTERIUM RADIOBACTER (TUMEFACIENS)** This organism has been associated with intravascular catheter–related infections in immunocompromised hosts, especially individuals infected with HIV. Clinically important infections associated with *A. radiobacter* include prostatic-joint and prosthetic-valve infections, bacteremia, peritonitis, and urinary tract infections.

**TREATMENT**

Antibiotic sensitivity testing is essential in the choice of therapy.

**CAPNOCYTOPHAGA SPECIES** This genus of fusiform, long, thin, gram-negative cocacobacilli is facultatively anaerobic and requires an atmosphere enriched in carbon dioxide for optimal growth. *C. ochracea*, *C. gingivalis*, and *C. sputigena* are inhabitants of the healthy human oral cavity and have been isolated from the female genital tract. Their isolation has also been reported from blood, cerebrospinal fluid, and respiratory fluids (including pleural collections). These organisms have been associated with sepsis in immunocompromised hosts; particularly at risk are neutropenic patients with acute myelogenous leukemia or acute lymphocytic leukemia. In the immunocompetent host, these three species probably play a role in localized juvenile periodontitis; however, they have been isolated from many other sites as well, usually as part of a polymicrobial infection. In vitro sensitivity testing of these organisms is difficult because they are slow-growing and fastidious.

*C. canimorsus* and *C. cynodegmi* are endogenous to the canine mouth. Patients infected with these species frequently have a history of dog bites or of exposure to dogs without scratches or bites. Asplenia, glucocorticoid therapy, and alcohol abuse are predisposing conditions for asplenic patients sustaining dog-bite injuries. Patients with suspected infection due to *C. canimorsus* should be treated empirically, because identification of this organism and determination of its antibiotic sensitivity can take many days. Other drugs to which *C. canimorsus* is reportedly susceptible include clindamycin, imipenem, quinolones, and third-generation cephalosporins.

**CHROMOBACTERIUM VIOLACEUM** This organism is rarely a human pathogen but reportedly has been responsible for life-threatening infections with severe sepsis and metastatic abscesses, particularly in children. A slender, slightly curved, gram-negative rod that is facultatively anaerobic, *C. violaceum* inhabits tropical water and soil and causes infection after contamination of skin wounds. Patients with defective neutrophil function (e.g., those with chronic granulomatous disease) are infected by this organism with unusual frequency. The mortality rate in the United States from infection with *C. violaceum* has been reported at >60%.

**TREATMENT**

*C. violaceum* is generally susceptible to ciprofloxacin (500 mg every 12 h orally or 400 mg every 12 h intravenously), trimethoprim-sulfamethoxazole (TMP-SMX), gentamicin, and chloramphenicol.

**CHRYSEOBACTERIUM SPECIES** *C. meningosepticum* and *C. indologenes* were previously classified as *Flavobacterium* species. *C. meningosepticum* is a ubiquitous organism and an important cause of nosocomial infections. It has been associated with outbreaks due to contaminated fluids, such as disinfectants, arterial catheter flush solutions, and aerosolized antibiotics, and with sporadic infections due to indwelling devices, vials, sink traps, feeding tubes, and other fluid-associated apparatus. Patients with nosocomial *C. meningosepticum* infection usually have underlying immunosuppression (e.g., related to malignancy). *C. meningosepticum* has been reported to cause meningitis (primarily in neonates), sepsis, endocarditis, bacteremia, soft tissue infections, and pneumonia. *C. indologenes* has caused bacteremia, sepsis, and pneumonia, typically in immunocompromised patients with indwelling devices.

**TREATMENT**

Antibiotic treatment should be based on susceptibility results because of the high likelihood that a *C. meningosepticum* isolate will produce β-lactamase. Early reports suggested that vancomycin might be efficacious, but more recent data refute this conclusion.

**PLESIOMONAS SHIGELLOIDES** This freshwater organism is a cause of acute diarrhea (Chap. 113) and occasionally of serious extraintestinal disease. *P. shigelloides* is transmitted to humans via contaminated water or food. This motile, facultatively anaerobic gram-negative rod most often produces mild, watery diarrhea. Severe extraintestinal infections have been reported, most commonly in immunocompromised hosts, and include bacteremia, cellulitis, neonatal sepsis and meningitis, and septic arthritis.

**AEROMONAS SPECIES** Five species of *Aeromonas* are known to be associated with disease in humans, but more than 85% of these *Aeromonas* infections are caused by *A. hydrophila*, *A. caviae*, and *A. veronii* biovar sobria. *Aeromonas* proliferates in potable and fresh water and in soil. It remains controversial whether *Aeromonas* is a cause of bacterial gastroenteritis. Although many case reports have associated *Aeromonas* with gastroenteritis, no clear outbreaks with a single isolate have been documented, no conclusive animal model exists, and asymptomatic colonization of the intestinal tract with *Aeromonas* occurs frequently. However, rare cases of hemolytic-uremic syndrome following bloody diarrhea have been shown to be secondary to the presence of *Aeromonas*. In addition, identification of an enterotoxin (different from the Shiga-like toxin produced by *Escherichia coli* O157:H7) in these cases supports the hypothesis that *Aeromonas* causes gastroenteritis.
**Aeromonas** causes sepsis and bacteraemia in infants with multiple medical problems and in immunocompromised hosts, particularly those with cancer or hepatobiliary disease. Aeromonas infection and sepsis can occur in trauma patients with myonecrosis or in burn patients exposed to Aeromonas by environmental contamination of their wounds from fresh water or soil sources. Mortality ranges from 25% among immunocompromised adults with sepsis to >90% among patients with myonecrosis. Aeromonas can produce skin lesions resembling the ecthyma gangrenosum lesions seen in *Pseudomonas aeruginosa* infection. These lesions are hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration. Aeromonas wound infections can occur in healthy adults who sustain minor trauma with environmental contamination, usually water-related; after severe trauma and crush injuries with sepsis and environmental contamination, usually water-borne; after minor trauma with environmental contamination, usually water-borne; or in those with myonecrosis. Aeromonas can cause skin lesions resembling the ecthyma gangrenosum lesions seen in *Pseudomonas aeruginosa* infection. These lesions are hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration. Aeromonas wound infections can occur in healthy adults who sustain minor trauma with environmental contamination, usually water-related; after severe trauma and crush injuries with sepsis and environmental exposure, usually to soil; and in nosocomial infections related to catheters, surgical incisions, or use of leeches. Other clinical manifestations include meningitis, peritonitis, pneumonia, and ocular infections.

**MICROBIOLOGY**

64 serogroups. The species *Legionella pneumophila* causes 80 to 90% of human infections and includes at least 14 serogroups; serogroups 1, 4, and 6 are most commonly implicated in human infections. To date, 17 species other than *L. pneumophila* have been associated with human infections, among which *L. micdadei* (Pittsburgh pneumonia agent), *L. bozemanii*, *L. dumoffii*, and *L. longbeachae* are the most common.

Members of the Legionellaceae are aerobic gram-negative bacilli that do not grow on routine microbiologic media. Buffered charcoal yeast extract (BCYE) agar is the medium used to grow *Legionella*. Antibiotics added to the medium suppress the growth of competing flora from nonsterile sites, and dyes color the colonies and assist in identification.

The direct fluorescent antibody (DFA) test can definitively identify a number of individual species. In *L. pneumophila*, lipopolysaccharide is a prominent constituent of the outer membrane, and the serogroup-specific antigen and antibodies detected by immunofluorescence are directed primarily at the lipopolysaccharide. Both polyclonal and monoclonal DFA reagents are commercially available. The monoclonal antibody reagent is less cross-reactive but is specific for *L. pneumophila*.

**TREATMENT**

Treatment should be guided by antimicrobial susceptibility testing. *Aeromonas* species are generally susceptible to fluoroquinolones (e.g., ciprofloxacin at a dosage of 500 mg every 12 h orally or 400 mg every 12 h intravenously), TMP-SMX (at a trimethoprim dosage of 10 mg/kg per day in 3 or 4 divided doses), third-generation cephalosporins, ciprofloxacin at a dosage of 500 mg every 12 h orally or 400 mg every 12 h intravenously, aminoglycosides. However, resistance is increasing.

**DEFINITION**

*Legionellosis* refers to the two clinical syndromes caused by bacteria of the genus *Legionella*. Pontiac fever is an acute, febrile, self-limited illness that has been serologically linked to *Legionella* species, whereas *Legionnaires’ disease* is the designation for pneumonia caused by these species.

**HISTORY**

Legionnaires’ disease was first recognized in 1976, when an outbreak of pneumonia took place at a hotel in Philadelphia during the American Legion Convention. The causative agent proved to be a newly discovered bacterium, *Legionella pneumophila*, that was isolated from lung specimens obtained from the victims at autopsy.

**MICROBIOLOGY**

The family Legionellaceae comprises 41 species with 64 serogroups. The species *L. pneumophila* causes 80 to 90% of human infections and includes at least 14 serogroups; serogroups 1, 4, and 6 are most commonly implicated in human infections. To date, 17 species other than *L. pneumophila* have been associated with human infections, among which *L. micdadei* (Pittsburgh pneumonia agent), *L. bozemanii*, *L. dumoffii*, and *L. longbeachae* are the most common.

Members of the Legionellaceae are aerobic gram-negative bacilli that do not grow on routine microbiologic media. Buffered charcoal yeast extract (BCYE) agar is the medium used to grow *Legionella*. Antibiotics added to the medium suppress the growth of competing flora from nonsterile sites, and dyes color the colonies and assist in identification.

The direct fluorescent antibody (DFA) test can definitively identify a number of individual species. In *L. pneumophila*, lipopolysaccharide is a prominent constituent of the outer membrane, and the serogroup-specific antigen and antibodies detected by immunofluorescence are directed primarily at the lipopolysaccharide. Both polyclonal and monoclonal DFA reagents are commercially available. The monoclonal antibody reagent is less cross-reactive but is specific for *L. pneumophila*.

**ECOLOGY AND TRANSMISSION**

The natural habitats for *L. pneumophila* are aquatic bodies, including lakes and streams. *L. longbeachae* can be isolated from soil. *Legionella* can survive under a wide range of environmental conditions; for example, the organisms can live for years in refrigerated water samples. Natural bodies of water contain only small numbers of *Legionella*. However, once the organisms enter human-constructed aquatic reservoirs (such as water-distribution systems), they can grow and proliferate. Factors known to enhance colonization by and amplification of legionellae include warm temperatures (25° to 42°C), stagnation, and scale and sediment. *L. pneumophila* can form microcolonies within biofilms; its eradication from water-distribution systems requires disinfectants that can penetrate the biofilm. The presence of symbiotic microorganisms, including algae, amebas, ciliated protozoa, and other water-dwelling bacteria, promotes the growth of *L. pneumophila*. *Legionella* can invade and multiply within free-living protozoa.

Hot-water tanks colonized with *L. pneumophila* are significantly more likely than uncolonized tanks to be cooler, to have a vertical configuration, to be older, and to have higher concentrations of calcium and magnesium. Vertical tanks, especially those that are electric-coil–heated rather than gas-heated, have a pronounced temperature stratification and thick sediment accumulation at the bottom. The source of *Legionella* is water. Early investigations that implicated cooling towers antedated the discovery that the organism could also exist in potable-water distribution systems. It is now known that, in most previously reported outbreaks, cases of Legionnaires’ disease continued to occur despite disinfection of cooling towers and the potable water supply was the actual source. Koch’s postulates have been fulfilled in epidemiologic studies using molecular fingerprinting methods to link potable water sources (rather than cooling towers) to *Legionella* infection in humans. Community-acquired Legionnaires’ disease has also been linked to colonization of residential and industrial water supplies.

Multiple modes of transmission of *Legionella* to humans exist, including aerosolization, aspiration, and direct instillation into the lung during respiratory tract manipulations. Aspiration is the predominant
mode of transmission, but it is unclear whether Legionella enters the lung via oropharyngeal colonization or directly via the drinking of contaminated water. Nasogastic tubes have been linked to nosocomial Legionnaires’ disease in several reports; microaspiration of contaminated water was the hypothesized mode of transmission. Surgery with general anesthesia is a known risk factor that is consistent with aspiration. Especially compelling is the reported 30% incidence of postoperative Legionella pneumonia among patients undergoing head and neck surgery at a hospital with a contaminated water supply; aspiration is a recognized sequela in such cases. Studies of patients with hospital-acquired Legionnaires’ disease have shown that these individuals underwent endotracheal intubation significantly more often and for a significantly longer duration than patients with nosocomial pneumonia of other etiologies.

Aerosolization of Legionella by devices filled with tap water, including nebulizers and humidifiers, has been implicated in disease causation. An ultrasonic mist machine in the produce section of a grocery store was implicated in a community outbreak. Pontiac fever has been linked to Legionella-containing aerosols from water-using machinery, a cooling tower, air-conditioners, and whirlpools.

**Epidemiology**

The incidence of Legionnaires’ disease depends on the degree of contamination of the aquatic reservoir, the immune status of the persons exposed to water from that reservoir, the intensity of exposure, and the availability of specialized laboratory tests on which the correct diagnosis can be based.

Numerous prospective studies have ranked Legionella among the top four microbial causes of community-acquired pneumonia (with Streptococcus pneumoniae, Haemophilus influenzae, and Chlamydia pneumoniae usually ranked first, second, and third, respectively), accounting for 3 to 15% of cases. On the basis of a multihospital study of community-acquired pneumonia in Ohio, it is estimated that only 3% of sporadic cases of Legionnaires’ disease are correctly diagnosed. Legionella is responsible for 10 to 50% of nosocomial pneumonias when a hospital’s water system is colonized with the organisms. One situation in which the diagnosis of Legionnaires’ disease should be considered is that in which the presenting patient has been hospitalized within 10 days before the onset of symptoms.

The most common risk factors for Legionnaires’ disease are cigarette smoking, chronic lung disease, advanced age, and immunosuppression (including receipt of glucocorticoids). However, in a large prospective study of community-acquired pneumonia, 28% of patients with Legionnaires’ disease did not have these classic risk factors. Surgery is a prominent predisposing factor in hospital-acquired infection, with transplant recipients at highest risk. Hospital-acquired cases are now being recognized among neonates and children with immunosuppression or underlying pulmonary disease.

Pontiac fever occurs in epidemics. The high attack rate (>90%) reflects airborne transmission.

**Pathogenesis and immunity**

Legionella enters the lungs through aspiration or direct inhalation. Attachment of the bacteria to host cells is mediated by type IV pili, heat-shock protein Hsp60, and the major outer-membrane protein. Legionella binds to complement CR1 and CR3 integrin receptors on the surface of the host cell. Because the organisms possess pili that may mediate adherence to respiratory tract epithelial cells, conditions that impair mucociliary clearance, including cigarette smoking, lung disease, or alcoholism, predispose to Legionnaires’ disease.

Cell-mediated immunity is the primary mechanism of host defense against Legionella, as it is against other intracellular pathogens, including Mycobacterium tuberculosis, Listeria, and Toxoplasma. Alveolar macrophages readily phagocytose Legionella. The attachment of the bacteria to phagocytes is mediated via Fc receptors and complement receptors, which attach to the bacterial major outer-membrane protein. Binding to these receptors promotes phagocytosis but fails to trigger an oxidative burst. The L. pneumophila phagosome resists acidification and evades fusion with late endocytic compartments and lysosomes. Although many Legionella organisms are killed, some proliferate intracellularly until the cells rupture; the bacteria are then phagocytosed again by newly recruited phagocytes, and the cycle begins anew.

Two general types of bacterial virulence genes required for intracellular growth have been identified: those that affect trafficking of the bacterial phagosome (establishment factors) and those that affect replication after trafficking (maintenance factors). Establishment factor mutants exhibit severe intracellular-growth defects because they cannot alter phagosome trafficking to inhibit fusion with lysosomes. Genes of the L. pneumophila chromosome that harbor this phenotype, referred to as dot (defective organelle trafficking) or icm (intracellular multiplication) genes, play an essential role in redirecting phagosome trafficking and establishing an intracellular site for bacterial growth. The Dot/Icm apparatus is hypothesized to be a translocase that exports effector molecules into host cells. Legionella does not require this transporter for growth once a replicative niche has been established. Among the L. pneumophila maintenance factors is the macrophage infectivity potentiation protein (Mip), which is exported to the bacterial surface and is involved in establishing intracellular infection. L. pneumophila Mip mutants have macrophage uptake and replicative phagosome formation kinetics that are similar to those of wild-type bacteria. However, these activities are delayed once the replicative phagosome is established.

Legionnaires’ disease is more common and its manifestations are more severe among patients with depressed cell-mediated immunity, including transplant recipients, patients infected with HIV, and patients receiving glucocorticoids. The disease also occurs with unusual frequency among patients with hairy cell leukemia (which is characterized by monocyte deficiency and dysfunction) but not among patients with other types of leukemia.

The role of neutrophils in immunity appears to be minimal: neutropenic patients are not predisposed to Legionnaires’ disease. Although L. pneumophila is susceptible to oxygen-dependent microbiologic systems in vitro, it resists killing by neutrophils.

The humoral immune system is active against Legionella. Typespecific IgM and IgG antibodies are measurable within weeks of infection. In vitro, antibodies promote killing of Legionella by phagocytes (neutrophils, monocytes, and alveolar macrophages). Immunized animals develop a specific antibody response, with subsequent resistance to Legionella challenge. However, antibodies neither enhance lysis by complement nor inhibit intracellular multiplication within phagocytes.

Some L. pneumophila strains are clearly more virulent than others, although the precise factors mediating virulence remain uncertain. For example, although multiple strains may colonize water-distribution systems, only a few cause disease in patients exposed to water from these systems. At least one surface epitope of L. pneumophila serogroup 1 is associated with virulence. L. pneumophila serogroup 6 is more commonly involved in hospital-acquired Legionnaires’ disease and is more likely to be associated with a poor outcome.

**Pathology**

The consistent pathologic features of Legionnaires’ disease are confined to the lungs. Multifocal pneumonia with patchy lobular inflammation and extensive multilobar consolidation has been observed. Visible abscesses with central necrosis were seen in 20% of autopsied cases in one study. On histologic examination, fibrinopurulent pneumonia with intense alveolitis and bronchiolitis is evident. Lesions of longer standing can have a nodular appearance with a central area of necrosis surrounded by macrophages and other cells. The alveoli are filled with fibrin, neutrophils, and alveolar macrophages. The direct fluorescent stain is not only specific but also the most sensitive option for visualization of the organism in tissues. Polyclonal DFA stains but not monoclonal DFA stain can be used for formalinized specimens. Culture is the preferred method for diagnosis based on clinical specimens.
CLINICAL AND LABORATORY FEATURES

Pontiac Fever

Pontiac fever is an acute, self-limiting, flulike illness with a 24- to 48-h incubation period. Pneumonia does not develop. Malaise, fatigue, and myalgias are the most frequent symptoms, occurring in 97% of cases. Fever (usually with chills) develops in 80 to 90% of cases and headache in 80%. Other symptoms (seen in fewer than 50% of cases) include arthralgias, nausea, cough, abdominal pain, and diarrhea. Modest leukocytosis with a neutrophilic predominance is sometimes detected. Complete recovery takes place within only a few days without antibiotic therapy; a few patients may experience lassitude for many weeks thereafter. The diagnosis is established by antibody seroconversion.

Legionnaires’ Disease (Pneumonia)

Legionnaires’ disease is often included in the differential diagnosis of “atypical pneumonia,” along with infection due to C. pneumoniae, Chlamydia psittaci, Mycoplasma pneumoniae, Coxiella burnetii, and some viruses. The clinical similarities among these types of pneumonia include a relatively nonproductive cough and a low incidence of grossly purulent sputum. However, the clinical manifestations of Legionnaires’ disease are usually more severe than those of most “atypical” pneumonias, and the course and prognosis of Legionnaires pneumonia more closely resemble those of bacteremic pneumococcal pneumonia than those of pneumococcal pneumonia due to other “atypical” pathogens. Patients with community-acquired Legionnaires’ disease are significantly more likely than patients with pneumonia of other etiologies to be admitted to an intensive care unit on presentation.

The incubation period for Legionnaires’ disease is 2 to 10 days. The symptoms and signs may range from a mild cough and a slight fever to stupor with widespread pulmonary infiltrates and multisystem failure. Nonspecific symptoms—malaise, fatigue, anorexia, and headache—are seen early in the illness. Myalgias and arthralgias are uncommon but are prominent in a few patients. Upper respiratory symptoms, including coryza, are rare.

The mild cough of Legionnaires’ disease is only slightly productive. Sometimes the sputum is streaked with blood. Chest pain—either pleuritic or nonpleuritic—can be a prominent feature and, when coupled with hemoptysis, can lead to an incorrect diagnosis of pulmonary embolism. Shortness of breath is reported by one-third to one-half of patients.

Gastrointestinal difficulties are often pronounced; abdominal pain, nausea, and vomiting affect 10 to 20% of patients. Diarrhea (watery rather than bloody) is reported in 25 to 50% of cases. The most common neurologic abnormalities are confusion or changes in mental status; however, the multifunctional neurologic symptoms reported range from headache and lethargy to encephalopathy. Patients with Legionnaires’ disease virtually always have fever. Temperatures in excess of 40.5°C (104.9°F) were recorded in 20% of the cases in one series. Relative bradycardia has been overemphasized as a useful diagnostic finding; it occurs primarily in older patients with severe pneumonia. Chest examination reveals rales early in the course and evidence of consolidations as the disease progresses. Abdominal examination may reveal generalized or local tenderness.

Although the clinical manifestations often considered classic for Legionnaires’ disease (Table 132-1) may suggest the diagnosis, prospective comparative studies have shown that clinical manifestations are generally nonspecific and that Legionnaires’ disease is not readily distinguishable from pneumonia of other etiologies. In a review of 13 studies of community-acquired pneumonia, clinical manifestations that occurred significantly more often in Legionnaires’ disease included diarrhea, neurologic findings (including confusion), and a temperature of >39°C. Hyponatremia, elevated values in liver function tests, and hematuria also occurred more frequently in Legionnaires’ disease. Other laboratory abnormalities include creatine phosphokinase elevation, hyponatremia, serum creatinine elevation, and proteinuria.

Extrapulmonary Legionellosis

Since the portal of entry for Legionella is the lung in virtually all cases, extrapulmonary manifestations usually result from bloodstream dissemination from the lung. In a prospective survey of patients with Legionnaires’ disease diagnosed by isolation of the organism from sputum, Legionella was isolated from the blood by a special culture method in 38% of cases.

Legionella has been identified in lymph nodes, spleen, liver, or kidneys in autopsied cases of Legionnaires’ disease. The most common extrapulmonary site of legionellosis is the heart; numerous reports have described myocarditis, pericarditis, postcardiotomy syndrome, and prosthetic-valve endocarditis. Most cases have been hospital-acquired. In some patients who have not had overt evidence of pneumonia, the organisms may have gained entry through a postoperative sternal wound exposed to contaminated tap water or through a mediastinal-tube insertion site. Sinusitis, peritonitis, pyelonephritis, skin and soft tissue infection, septic arthritis, and pancreatitis have been seen predominantly in immunosuppressed patients.

Chest Radiographic Abnormalities

Virtually all patients with Legionnaires’ disease have abnormal chest radiographs showing pulmonary infiltrates at the time of clinical presentation. In a few cases of hospital-acquired disease, fever and respiratory tract symptoms have preceded the appearance of the infiltrate on chest radiography. Findings on chest radiography are useful for assessing the severity of illness in that they identify multilobar involvement and permit monitoring of disease progression. However, these findings are nonspecific and do not serve to distinguish Legionnaires’ disease from pneumonias of other etiologies. Pleural effusion is evident in 28 to 63% of cases on hospital admission. In immunosuppressed patients, especially those receiving glucocorticoids, distinctive rounded nodular opacities may be seen; these lesions may expand and cavitate (Fig. 132-1). Likewise, pulmonary abscesses can occur in immunosuppressed hosts. The progression of infiltrates and pleural effusion on chest radiography despite appropriate antibiotic therapy within the first week is common, and radiographic improvement lags behind clinical improvement by several days. Complete clearing of infiltrates requires 1 to 4 months.

DIAGNOSIS

The diagnosis of Legionnaires’ disease requires special microbiologic tests (Table 132-2). The sensitivity of bronchoscopy specimens is approximately the same as that of sputum samples for culture on selective media; if sputum is not available, bronchoscopy specimens may yield the organism. Bronchoalveolar lavage fluid gives higher yields than bronchial wash specimens. Thoracentesis should be performed if pleural effusion is found, and the fluid should be evaluated by DFA staining, culture, and the antigen assay designed for use with urine.

Staining

Gram’s staining of material from normally sterile sites, such as pleural fluid or lung tissue, occasionally suggests the diagnosis; efforts to detect Legionella in sputum by Gram’s staining typically reveal numerous leukocytes but no organisms. When they are visualized, the organisms appear as small, pleomorphic, faint, gram-negative bacilli. L. micdadei organisms can be detected as weakly or partially acid-fast bacilli in clinical specimens. Modified acid-fast staining substitutes 1% sulfuric acid for the traditional 3% hydrochloric acid; the less aggressive decolorizer increases the yield of L. micdadei. Legionella-infected patients have occasionally been treated empirically with
IgG and IgM testing of both acute- and convalescent-phase sera. A single titer of Serogroup 1 only.

The definitive method for diagnosis of Legionnaires’ disease is isolation of the organism from respiratory secretions or other specimens. Multiple selective BCYE media are required for maximal sensitivity. Colonies grow slowly, requiring 3 to 5 days to become grossly visible. When culture plates are overgrown with other microflora, pre-treatment of the specimen with acid or heat can markedly improve the yield. L. pneumophila is often isolated from sputum that is not grossly or microscopically purulent; sputum containing more than 25 epithelial cells per high-power field (a finding that classically suggests contamination) may still yield L. pneumophila.

Antibody Detection Antibody testing of both acute- and convalescent-phase sera is necessary. A fourfold rise in titer is diagnostic; 12 weeks are often required for the detection of an antibody response. A single titer of 1:128 in a patient with pneumonia constitutes presumptive (but not definitive) evidence for Legionnaires’ disease. Serology is of use primarily in epidemiologic studies. The specificity of serology for Legionella species other than L. pneumophila is uncertain; there is cross-reactivity with Legionella spp. and some gram-negative bacilli.

Urinary Antigen The assay for Legionella soluble antigen in urine (Binax, Portland, ME) is rapid, relatively inexpensive, easy to perform, second only to culture in terms of sensitivity, and highly specific. Its use in every clinical laboratory is recommended. The test is available only for L. pneumophila serogroup 1, which, as has been mentioned, causes about 80% of Legionella infections. Cross-reactivity with other L. pneumophila serogroups and other Legionella species has been detected in up to 22% of urine samples from patients with culture-proven cases. Antigen in urine is detectable 3 days after the onset of clinical disease, and urinary antigen positivity persists for several weeks. The test is not affected by antibiotic administration.

Molecular Methods Polymerase chain reaction (PCR) with DNA probes is theoretically more sensitive and specific than other methods, but the results have been disappointing to date. PCR has proved useful in the identification of Legionella from environmental water specimens.

### TREATMENT

Since Legionella is an intracellular pathogen, antibiotics that can reach intracellular concentrations exceeding the minimal inhibitory concentration are most likely to be efficacious in the clinical setting. The dosages for various drugs used in the treatment of Legionella infection are listed in Table 132-3.

The newer macrolides (especially azithromycin) and respiratory tract quinolones (levofloxacin, gemifloxacin, moxifloxacin) are now the antibiotics of choice and are effective as monotherapy. Compared with erythromycin, the newer macrolides have superior in vitro activity, display greater intracellular activity, and reach higher concentrations in respiratory secretions and in lung tissue. The pharmacokinetics of the newer macrolides and quinolones also allow once- or twice-daily dosing. Finally, the large fluid volume required for intravenous administration, symptomatic ototoxicity, and gastrointestinal side effects have rendered erythromycin obsolete for the treatment of Legionella infection. Quinolones are the preferred antibiotics for transplant recipients because both macrolides and rifampin interact with transplant physiology.

Pertussis is an acute infection of the respiratory tract caused by *Bordetella pertussis*. The name *pertussis* means “violent cough,” which aptly describes the most consistent and prominent feature of the illness. The inspiratory sound made at the end of an episode of paroxysmal coughing gives rise to the common name for the illness, “whooping cough”; however, this feature is variable, being uncommon in infants ≤6 months of age and frequently absent in older children and adults. The Chinese name for pertussis is “the 100-day cough,” which accurately describes the clinical course of the illness. The identification of *B. pertussis* was first reported by Bordet and Gengou in 1906, and vaccines were produced over the following two decades.

**MICROBIOLOGY** Six species have been identified in the genus *Bordetella*: *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, *B. avium*, *B. holmesii*, and *B. hinzii*. *B. pertussis* infects only humans and is the most important *Bordetella* species causing human disease. *B. parapertussis* causes an illness in humans that is similar to pertussis but is typically milder; coinfections with *B. parapertussis* and *B. pertussis* have been documented. *B. bronchiseptica* is an important pathogen of domestic animals that causes kennel cough in dogs, atrophic rhinitis and pneumonia in pigs, and pneumonia in cats. Both respiratory infection and opportunistic infection are occasionally reported in humans. *B. avium* is an important cause of respiratory illness in turkeys. The remaining two species, *B. hinzii* and *B. holmesii*, have been recognized as unusual causes of bacteremia. Both of these species have been isolated from patients with sepsis, most often from those who are immunocompromised.

*Bordetella* species are gram-negative pleomorphic aerobic bacilli that share common genotypic characteristics. *B. pertussis* and *B. parapertussis* are the most similar of the species but differ in that *B. parapertussis* does not express the gene coding for pertussis toxin. *B. pertussis* is a slow-growing fastidious organism that requires selective medium and forms small glistening bifurcated colonies. Suspicious colonies are presumptively identified as *B. pertussis* by direct fluorescent antibody testing or by agglutination with species-specific antiserum. *B. pertussis* is further differentiated from other *Bordetella* species by biochemical and motility characteristics.

*B. pertussis* produces a wide array of toxins and biologically active products that are important in its pathogenesis and in immunity. Most of these virulence factors are under the control of a single genetic locus that regulates their production, resulting in antigenic modulation and phase variation. Although these processes occur both in vitro and in hospital-acquired pneumonia. Studies have shown that neither a high degree of outward cleanliness nor routine application of maintenance measures decreases the frequency or intensity of *Legionella* colonization. Thus, engineering guidelines and building codes, although routinely advocated as preventive measures, have little impact on *Legionella* colonization.

Disinfection of the water supply is now feasible. Two methods have proven reliable and cost-effective. The superheat-and-flush method requires heating of the water so that the distal-outlet temperature is 70 to 80°C and flushing of the distal outlets with hot water for at least 30 min. This method is ideal for emergency situations. A commercial copper and silver ionization method has proved effective in numerous hospitals. Hyperchlorination is no longer recommended because of its expense, carcinogenicity, corrosive effects on piping, and unreliable efficacy.

**FURTHER READING**

vivo, their importance in the pathobiology of the organism is unknown; they may play a role in intracellular persistence and person-to-person spread. The organism’s most important virulence factor is pertussis toxin, which is composed of a B oligomer–binding subunit and an enzymatically active A protomer that ADP-ribosylates a guanine nucleotide-binding regulatory protein (G protein) in target cells, producing a variety of biologic effects. Pertussis toxin has important mitogenic activity, affects the circulation of lymphocytes, and serves as an adhesin for bacterial binding to respiratory ciliated cells. In animal models, the toxin’s effects include histamine sensitization, lymphocytosis promotion, and insulin secretion. Another virulence factor is filamentous hemagglutinin, a component of the cell wall and a bacterial adhesin. Pertactin is an outer-membrane protein and another important adhesin. Fimbriae are bacterial appendages that also play a role in bacterial attachment; they are the major antigens against which agglutinating antibodies are directed. These agglutinating antibodies have historically been the primary means of serotyping B. pertussis strains. Other virulence factors include tracheal cytotoxin, which causes respiratory epithelial damage; adenylate cyclase toxin, which impairs host immune-cell function; dermonecrotic toxin, which may contribute to respiratory mucosal damage; and lipooligosaccharide, which has properties similar to those of other gram-negative bacterial endotoxins.

PATHOGENESIS Infection with B. pertussis is initiated by attachment of the organism to the ciliated epithelial cells of the nasopharynx. Attachment is mediated by surface adhesins (e.g., pertactin and filamentous hemagglutinin), which bind to the integrin family of cell-surface proteins, probably in conjunction with pertussis toxin. The role of fimbriae in adhesion or maintenance of infection has not been fully delineated. At the site of attachment, the organism multiplies, producing a variety of other toxins that cause local mucosal damage (tracheal cytotoxin, dermonecrotic toxin). Impairment of host defense by B. pertussis is mediated by pertussis toxin and adenylate cyclase toxin. There is local cellular invasion, with intracellular bacterial persistence; however, systemic dissemination does not occur. Systemic manifestations (lymphocytosis) result from the effects of the toxins.

The pathogenesis of the clinical manifestations of pertussis is poorly understood. It is not known what causes the paroxysmal cough that is the hallmark of pertussis. A pivotal role for pertussis toxin has been proposed. Proponents of this position point to the efficacy of an acellular pertussis vaccine in adolescents and adults, the incidence of pertussis in the placebo group was 3.7 to 4.5 cases per 1000 person-years. Although this prospective cohort study yielded a lower estimate than the studies of cough illness, its results still translate to between 600,000 and 800,000 cases of pertussis in adults annually in the United States. Severe morbidity and mortality, however, are virtually restricted to infants. In Canada, there were 10 deaths from pertussis between 1991 and 1998; all those who died were infants ≤6 months of age. Although school-age children are the source of infection for most households, adults are the likely source for high-risk infants and may serve as the reservoir of infection between epidemic years. In developing countries, pertussis remains an important cause of infant morbidity and mortality. The World Health Organization estimated that in 1995 over 40 million people worldwide were infected by B. pertussis and that 355,000 children died of pertussis.

CLINICAL MANIFESTATIONS Pertussis is a prolonged coughing illness with clinical manifestations that vary by age (Table 133–1). Classic pertussis is most often seen in preschool and school-age children, although it is not uncommon among adolescents and adults. After an incubation

### EPIEIDEMIOLOGY

Pertussis is a highly communicable disease, with attack rates of 80 to 100% among unimmunized household contacts and 20% within households in well-immunized populations. The infection has a worldwide distribution, with cyclical outbreaks every 3 to 5 years (a pattern that has persisted despite widespread immunization). Pertussis occurs in all months; however, in North America, pertussis activity peaks in the summer and autumn.

Before the institution of widespread immunization programs, pertussis was one of the most common infectious causes of morbidity and death. In the United States prior to the 1940s, between 115,000 and 270,000 cases of pertussis were reported annually, with an average yearly rate of 150 cases per 100,000 population. With universal childhood immunization, the number of reported cases fell by >95%, with even more dramatic decreases in mortality. Only 1010 cases of pertussis were reported in 1976. Since that time, however, rates have slowly increased. In 2000, more than 7800 cases of pertussis were reported in the United States.

Although thought of as a disease of childhood, pertussis can affect people of all ages and is increasingly being identified as a cause of prolonged coughing illness in adolescents and adults. In unimmunized populations, pertussis incidence peaks in the preschool years, and well over half of children have the disease before reaching adulthood. In highly immunized populations such as those in North America, the peak incidence is among infants <1 year of age who have not completed the three-dose primary immunization series. Recent trends, however, show an increasing incidence of pertussis among adolescents and adults. In the United States in 2000, 24% of patients were <7 months of age, 36% were adolescents, and 20% were adults. The figures for adolescents and adults are probably underestimates because of a greater degree of underrecognition and underreporting in these age groups. A number of studies of prolonged coughing illness suggest that pertussis may be the etiologic agent in 12 to 30% of adults with cough that does not improve within 2 weeks. In a recent study of the efficacy of an acellular pertussis vaccine in adolescents and adults, the incidence of pertussis in the placebo group was 3.7 to 4.5 cases per 1000 person-years. Although this prospective cohort study yielded a lower estimate than the studies of cough illness, its results still translate to between 600,000 and 800,000 cases of pertussis in adults annually in the United States. Severe morbidity and mortality, however, are virtually restricted to infants. In Canada, there were 10 deaths from pertussis between 1991 and 1998; all those who died were infants ≤6 months of age. Although school-age children are the source of infection for most households, adults are the likely source for high-risk infants and may serve as the reservoir of infection between epidemic years. In developing countries, pertussis remains an important cause of infant morbidity and mortality. The World Health Organization estimated that in 1995 over 40 million people worldwide were infected by B. pertussis and that 355,000 children died of pertussis.

### IMMUNITY

Both humoral and cell-mediated immunity are thought to be important in pertussis. Antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae are all protective in animal models. Pertussis agglutinins were correlated with protection in early studies of whole-cell pertussis vaccines. Serologic correlates of protection conferred by acellular pertussis vaccines have not been established, although antibody to pertactin, fimbriae, and (to a lesser degree) pertussis toxin correlated best with protection in two acellular pertussis vaccine efficacy trials. The duration of immunity after whole-cell pertussis vaccination is short-lived, with little protection remaining after 10 to 12 years. Data on the duration of protection after acellular pertussis vaccination are still being collected. Although immunity after natural infection has been said to be lifelong, recent epidemiologic evidence suggests that it may not be and that subsequent episodes of clinical pertussis are prevented by intermittent subclinical infection.

</table>
period averaging 7 to 10 days, an illness develops that is indistinguishable from the common cold and is characterized by coryza, lacrimation, mild cough, low-grade fever, and malaise. After 1 to 2 weeks, this *catarrhal phase* evolves into the *paroxysmal phase*: the cough becomes more frequent and spasmodic with repetitive bursts of 5 to 10 coughs, often within a single expiration. Posttussive vomiting is frequent, with a mucous plug occasionally expelled at the end of an episode. The episode may be terminated by an audible whoop, which occurs upon rapid inspiration against a closed glottis at the end of a paroxysm. During a spasm, there may be impressive neck-vein distension, bulging eyes, tongue protrusion, and cyanosis. Paroxysms may be precipitated by noise, eating, or physical contact. Between attacks, the patient’s appearance is normal but increasing fatigue is evident. The frequency of paroxysmal episodes varies widely, from several per hour to 5 to 10 per day. Episodes are often worse at night and interfere with sleep. Weight loss is not uncommon as a result of the illness’s interference with eating. Most complications occur during the paroxysmal stage. Fever is uncommon and suggests bacterial superinfection.

After 2 to 4 weeks, the coughing episodes become less frequent and less severe—changes heralding the onset of the *convalescent phase*. This phase can last from 1 to 3 months and is characterized by a gradual resolution of the coughing episodes. For 6 months to a year, intercurrent viral infections may be associated with a recrudescence of paroxysmal cough.

Not all individuals who develop pertussis have classic disease. The clinical manifestations in adolescents and adults are more often atypical. In a German study of pertussis in adults, more than two-thirds had paroxysmal cough and more than one-third had whoop. Adult illness in North America differs from this experience: the cough may be severe and prolonged but is less frequently paroxysmal, and a whoop is uncommon. Vomiting with cough is the best predictor of a diagnosis of pertussis as the cause of a prolonged cough in adults. Other features predictive of this diagnosis are a cough at night and exposure to other individuals with a prolonged coughing illness.

**Complications** Complications are frequently associated with pertussis and are more common among infants than among older children or adults. Subconjunctival hemorrhages, abdominal and inguinal hernias, pneumothoraces, and facial and truncal petechiae can result from increased intrathoracic pressure generated by severe fits of coughing. Weight loss can follow decreased caloric intake. In a series of more than 1100 children <2 years of age who were hospitalized with pertussis, 27.1% had apnea, 9.4% had pneumonia, 2.6% had seizures, and 0.4% had encephalopathy; 10 children (0.9%) died. Pneumonia is reported in <5% of adolescents and adults and increases in frequency after 50 years of age. In contrast to the primary *B. pertussis* pneumonia that develops in infants, pneumonia in adolescents and adults with pertussis is usually caused by a secondary infection with encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. Pneumothorax, severe weight loss, inguinal hernia, rib fracture, carotid artery aneurysm, and cough syncope have all been reported in adolescents and adults with pertussis.

**Diagnosis** If the classic symptoms of pertussis are present, clinical diagnosis is not difficult. However, particularly in older children and adults, it is difficult to differentiate infections caused by *B. pertussis* and *B. parapertussis* from other respiratory tract infections on clinical grounds. Therefore, laboratory confirmation should be attempted in all cases. Lymphocytosis (absolute lymphocyte count, >10 × 10^9/L) is common among young children (in whom it is unusual with other infections) but not among adolescents and adults. Culture of nasopharyngeal secretions remains the “gold standard” of diagnosis; the best specimen is collected by nasopharyngeal aspiration, in which a fine flexible plastic catheter attached to a 10-mL syringe is passed into the nasopharynx and withdrawn while gentle suction is applied. Since *B. pertussis* is highly sensitive to drying, secretions should be inoculated without delay onto appropriate media (Bordet-Gengou or Regan-Lowe) or the catheter should be flushed with a phosphate-buffered saline solution. An alternative is a nasopharyngeal culture with a calcium alginate swab; again, inoculation of culture plates should be immediate or an appropriate transport medium (such as Regan-Lowe charcoal medium) should be used. Cultures become positive by day 5 of incubation, and *B. pertussis* and *B. parapertussis* can be differentiated by agglutination with specific antisera or by direct immunofluorescence.

Nasopharyngeal cultures in untreated pertussis remain positive for a mean of 3 weeks after the onset of illness; these cultures become negative within 5 days of the institution of appropriate antimicrobial therapy. Since much of the period during which the organism can be recovered from the nasopharynx falls into the catarrhal phase, when the etiology of the infection is not suspected, there is only a small window of opportunity for culture-proven diagnosis. Cultures from infants and young children are more frequently positive than those from older children and adults; this difference may reflect earlier presentation of the former age group for medical care. The increasing availability of the polymerase chain reaction for pertussis in diagnostic laboratories is enhancing the sensitivity of the organism’s detection. This method may further laboratory confirmation but does not solve problems related to the long delays in specimen procurement that often are encountered in pertussis cases. Direct fluorescent antibody tests of nasopharyngeal secretions for direct diagnosis may still be available in some laboratories but should not be used because of poor sensitivity and specificity.

As a result of the difficulties with laboratory diagnosis of pertussis in adolescents, adults, and any patient who has been symptomatic for >4 weeks, increasing attention is being given to serologic diagnosis. Enzyme immunoassays detecting IgA and IgG antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae have been developed and assessed for reproducibility. Two- or fourfold increases in antibody titer are suggestive of pertussis, although cross-reactivity of some antigens (such as filamentous hemagglutinin and pertactin) among *Bordetella* species makes it difficult to depend diagnostically on seroconversion involving a single type of antibody. Late presentation for medical care and prior immunization also complicate serologic diagnosis because the first sample obtained may in fact be a convalescent-phase specimen. Proposed criteria for serologic diagnosis based on a single serum specimen call for comparison of the patient’s antibody levels with established population values; for example, a patient with serologically confirmed pertussis might be required to have a titer greater than two or three standard deviations above the mean titer for a normal population. However, at present, no antibody test is widely or commercially available, and no specific serologic criteria are universally accepted.

**Differential Diagnosis** A child presenting with paroxysmal cough, posttussive vomiting, and whoop is likely to have an infection caused by *B. pertussis* or *B. parapertussis*; lymphocytosis increases the likelihood of a *B. pertussis* etiology. Viruses such as respiratory syncytial virus and adenovirus have been isolated from patients with clinical pertussis but probably represent coinfection. In adolescents and adults, among whom paroxysmal cough and whoop are frequently absent, the differential diagnosis of a prolonged coughing illness is more extensive. Pertussis should be suspected in anyone with a cough that does not improve within 14 days, a paroxysmal cough of any duration, or any respiratory symptoms after contact with a laboratory-confirmed case of pertussis. Other etiologies to consider include infections caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenovirus, influenza virus, and other respiratory viruses. Use of angiotensin-converting enzyme (ACE) inhibitors, reactive airway disease, and gastroesophageal reflux disease are well-described noninfectious causes of prolonged cough in adults.

**Treatment**

**Antibiotics** The purpose of antibiotic therapy for pertussis is to eradicate the infecting bacteria from the nasopharynx; therapy does not

A wide variety of acellular pertussis vaccines have been developed, although not all are available in every country. All acellular pertussis vaccines currently available contain pertussis toxoid. Only one monovalent pertussis toxoid vaccine has been licensed in the United States; the remainder of the fully developed vaccines contain filamentous hemagglutinin as well as toxoid. At least four acellular pertussis vaccines also contain pertactin, and two products also contain one or more types of fimbriae. All of the licensed acellular pertussis vaccines have undergone phase 3 efficacy testing. Although differences in study design make direct comparisons difficult, an effort to standardize case definitions and the similarity of some of the studies, which used common vaccine arms to allow “bridging” of the data between studies, have permitted some general conclusions. Even though some would still disagree, most experts have concluded that two-component acellular pertussis vaccines are more effective than monocomponent vaccines and that the addition of pertactin further increases efficacy. The further addition of fimbriae appears to provide some additional protective efficacy against milder disease. In two studies, protection against pertussis by vaccines correlated best with the production of antibody to pertactin, fimbriae, and pertussis toxin.

The development of acellular pertussis vaccines has sparked interest in the potential for control of pertussis in adolescents and adults and in the possibility that pertussis control in those groups will enhance the protection of infants too young to be immunized. Whole-cell pertussis vaccine is contraindicated in individuals ≥7 years of age because of their poor toleration of possible adverse events. However, adult formulations of acellular pertussis vaccines, both alone and in combination with adult-formulation diphtheria-tetanus toxoid, have been demonstrated to be safe, immunogenic, and efficacious in clinical trials in adolescents and adults and are now recommended for routine immunization of adolescents in several countries. Further epidemiologic studies will help public health authorities and advisory committees determine the role of pertussis immunization in the control of pertussis in adults.

Further Reading

Extraintestinal infections are the predominant presentation of disease caused by gram-negative bacilli (GNB) belonging to medically important genera of the family Enterobacteriaceae (Escherichia, Klebsiella, Proteus, Enterobacter, Serratia, Citrobacter, Morganella, Providencia, and Edwardsiella) and by the genus Acinetobacter from the family Neisseriaceae. However, certain strains of Escherichia coli have evolved to be strictly intestinal pathogens, causing gastroenteritis by a variety of unique pathogenic mechanisms. The virulence traits of intestinal pathogenic E. coli are for the most part distinct from those of extraintestinal pathogenic E. coli and other GNB that cause disease outside the bowel. This difference reflects site-dependent differences in host environments and defense mechanisms.

**E. coli as an Intestinal Pathogen**

Certain strains of *E. coli* are capable of causing intestinal infection. Other important intestinal pathogens are discussed in Chaps. 113, 126, and 137–140.

**Etiology, Epidemiology, and Manifestations**

Intestinal pathogenic strains of *E. coli* are rarely encountered in the fecal flora of healthy hosts and instead appear to be essentially obligate pathogens. These strains have evolved a special ability to cause enteritis, enteroxolysis, and colitis whenever ingested in sufficient quantities by a naive host. At least six distinct “pathotypes” of intestinal pathogenic *E. coli* exist: (1) Shiga toxin–producing *E. coli* (STEC) enterohemorrhagic *E. coli* (EHEC), (2) enterotoxigenic *E. coli* (ETEC), (3) enteropathogenic *E. coli* (EPEC), (4) enteroinvasive *E. coli* (EIEC), (5) enteraggregative *E. coli* (EAEC), and (6) diffusely adherent *E. coli* (DAEC). Organisms of these pathotypes are acquired via the fecal-oral route. Transmission occurs predominantly via contaminated food and water for ETEC, STEC, EIEC, EAEC, and DAEC and by person-to-person spread for EPEC (and occasionally STEC). Humans appear to be the major reservoir (except for STEC), since the host range appears to be dictated by species-specific attachment factors. Although there is some overlap, each pathotype possesses a unique combination of virulence traits that result in a distinctive intestinal pathogenic mechanism (Table 134-1); however, these strains are largely incapable of causing disease outside the intestinal tract. Except in the case of STEC, disease due to this group of pathogens occurs primarily in developing countries.

**Shiga Toxic–Producing E. coli**

STEC strains constitute an emerging group of pathogens that can cause hemorrhagic colitis and the hemolytic-uremic syndrome (HUS). Several large outbreaks resulting from the consumption of undercooked ground beef and other foods have received significant attention from the media. O157:H7 is the most prominent serotype, but O6, O26, O55, O91, O103, O111, O113, and O138 have also been associated with these syndromes. The ability to produce Shiga toxins (Stx1 and/or Stx2) as well as LEED be termed enterohemorrhagic *E. coli* (EHEC).

Domesticated ruminant animals, particularly cattle and young calves, serve as the major reservoir for STEC. Ground beef—the most common food source of STEC strains—is often contaminated during processing. Furthermore, manure from cattle or other animals that is used as fertilizer can contaminate produce (potatoes, lettuce, sprouts, fallen apples) and water (fecal runoff). It is estimated that <10^5 CFU (colony-forming units) of STEC can cause disease. Therefore, not only can low levels of food or environmental contamination (e.g., in water swallowed while swimming) result in disease, but person-to-person transmission (e.g., at day-care centers and in institutions) becomes an important vehicle for secondary spread. Laboratory-associated infections also take place. Both outbreaks and sporadic cases are attributable to this group of pathogens, with a seasonal peak in the summer months.

In contrast to the other pathotypes, STEC causes infections more frequently in developed countries, where the consumption of processed foods is more common than in developing regions. O157 strains are the fourth most commonly reported cause of bacterial diarrhea in the United States (after *Campylobacter*, *Salmonella*, and *Shigella*). Colonization of the colon and perhaps the ileum results in symptoms after an incubation period of 3 or 4 days. Colonic edema and an initial secretory diarrhea may develop into the STEC syndrome’s hallmark, a grossly bloody diarrhea (detected by history or examination) in >90% of cases. Significant abdominal pain and fecal leukocytes are commonly present (70% of cases), but fever is usually absent. Occasionally, *Clostridium difficile*, *Campylobacter*, and *Salmonella* infection present in a similar fashion, as do noninfectious diseases (e.g., inflammatory bowel disease). STEC disease is usually self-limited, lasting 5 to 10 days. This infection can be complicated by HUS, which occurs 2 to 14 days after diarrhea in 2 to 8% of cases, most often affecting the very young and the elderly. It is estimated that >50% of all cases of HUS in the United States are caused by STEC. This complication is probably mediated by the systemic translocation of Shiga toxins. Erythrocytes may serve as carriers of Stx to small-vessel renal and cerebral endothelial cells. The subsequent development of thrombotic microangiopathy (perhaps with direct toxin-mediated effects on various cells) most commonly results in some combination of fever, thrombocytopenia, renal failure, and encephalopathy. Although the mortality rate with dialysis support is <10%, residual renal dysfunction and neurologic sequelae may persist.

**Enterotoxigenic E. coli**

In tropical or developing countries, ETEC is a major cause of endemic diarrhea. After weaning, children experience several episodes of ETEC infection during the first 3 years of life. The incidence of disease diminishes with age, a pattern that correlates with the development of mucosal immunity to colonization factors. In industrialized countries, infection usually follows travel to endemic areas. ETEC is the most common agent of traveler’s diarrhea, causing 25 to 75% of cases. The incidence of infection is decreased by the prudent avoidance of potentially contaminated fluids and foods (Chap. 108). ETEC infection is uncommon in the United States, but outbreaks secondary to consumption of food products imported from endemic areas have occurred. A large inoculum (10^8 to 10^10 CFU) is needed to produce disease. After ingestion of contaminated water or food (particularly items poorly cooked, unpeeled, or unrefrigerated), colonization factor–mediated intestinal adherence occurs over 12 to 72 h. Disease is mediated primarily by heat-labile toxin (LT-1) and/or a heat-stable toxin (STa) that causes net fluid secretion via activation of adenylate cyclase (LT-1) and/or guanylate cyclase (STa) in the jejenum and ileum; the result is watery diarrhea accompanied by cramps. LT-1 consists of an A and a B subunit and is structurally and functionally similar to cholera toxin. Strong binding of the B subunit to
the GM1 ganglioside leads to the intracellular translocation of the A subunit, which functions as an ADP-ribosyltransferase. The mature StA toxin is an 18- or 19-amino-acid secreted peptide whose biologic activity is mediated by binding to the guanylate cyclase C found in the brush-border membrane of intestinal epithelial cells; this binding results in increased intracellular concentrations of cyclic GMP. Characteristically absent are histopathologic changes of the small bowel; mucus, blood, and inflammatory cells in stool; and fever. The disease spectrum ranges from a mild illness to a life-threatening cholera-like illness. Although symptoms are usually self-limited (typically lasting for 3 days), infection may result in significant morbidity and mortality when health care is poor and when small and/or undernourished children are affected.

**Enteropathogenic E. coli** EPEC causes disease primarily in young children, including neonates. The first E. coli pathotype recognized as an agent of diarrheal disease, EPEC was responsible for outbreaks of infantile diarrhea (including some outbreaks in hospital nurseries) in industrialized countries in the 1940s and 1950s. At present, however, infection due to EPEC is uncommon in developed countries. In contrast, EPEC is an important cause of infant diarrhea (both sporadic and epidemic) in developing countries. Breast-feeding diminishes the incidence of EPEC infection. Rapid person-to-person spread may occur. Upon colonization of the small bowel, symptoms develop after a brief incubation period (1 or 2 days). Initial localized adherence leads to a characteristic effacement of microvilli, with the formation of cuplike, actin-rich pedestals. Diarrheal stool often contains mucus but not blood. Although usually self-limited (lasting for 5 to 15 days), EPEC diarrhea may persist for weeks.

**Enteroinvasive E. coli** EIEC, a relatively uncommon cause of diarrhea, is rarely identified in the United States, although a few food-related outbreaks have been described. In developing countries, sporadic disease is infrequently recognized in children and travelers. EIEC shares many genetic and clinical features with Shigella; however, unlike Shigella, EIEC produces disease only at a large inoculum (10⁹ to 10¹⁰ CFU), with onset generally occurring after an incubation period of 1 to 3 days. Initially, enterotoxins are believed to induce secretory small-bowel diarrhea. Subsequently, colonization and invasion of the colonic mucosa, followed by replication therein and cell-to-cell spread, result in the development of inflammatory colitis characterized by fever, abdominal pain, tenesmus, and scant stool containing mucus, blood, and inflammatory cells. Symptoms are usually self-limited (7 to 10 days).

**Enteroaggregative and Diffusely Adherent E. coli** EAEC and DAEC have been described primarily in developing countries and in young children. These strains can cause traveler’s diarrhea. A large inoculum is required for infection. In vitro, the organisms exhibit a diffuse or “stacked-brick” adherence pattern. Clinical disease has been associated with prolonged watery diarrhea.

**DIAGNOSIS** A practical approach to the evaluation of diarrhea is to distinguish noninflammatory from inflammatory cases (Chap. 113). ETEC, EPEC, EAEC, and DAEC are uncommon causes of noninflammatory diarrhea in the United States. Their diagnosis requires specialized assays that are not routinely available and whose use is rarely indicated since these diseases are self-limited. ETEC causes the majority of cases of noninflammatory traveler’s diarrhea; EAEC and DAEC cause a minority of these cases. Definitive diagnosis generally is not necessary in developing countries, and antimicrobial treatment is a reasonable approach. If diarrhea persists despite treatment, *Giardia* or *Cryptosporidium* should be sought. The diagnosis of infection with EIEC, a rare cause of inflammatory diarrhea in the United States, also requires specialized assays. However, evaluation for STEC infection, particularly when bloody diarrhea is reported or observed, is appropriate. Although screening for E. coli strains that do not ferment sorbitol and subsequent serotyping for O157 constitute the most common method presently used to detect STEC, testing for Shiga toxins or toxin genes is more sensitive, specific, and rapid. The latter approach offers another advantage as well: it detects both non-O157 strains and sorbitol-fermenting strains of O157, which otherwise are difficult to identify. DNA-based, enzyme-linked immunosorbent, and cytotoxicity assays are in various stages of development and are likely to emerge as the diagnostic standards in time.

**TREATMENT**

The mainstay of treatment for all diarrheal syndromes is the appropriate replacement of water and electrolytes (Chap. 113). The use of prophylactic antibiotics to prevent traveler’s diarrhea should be discouraged, especially in light of high rates of antibiotic resistance. When stools are free of mucus and blood, early patient-initiated treatment of traveler’s diarrhea with a quinolone decreases the duration of illness, and the use of loperamide may halt symptoms within a few hours (Chap. 113). Although dysentery caused by EIEC is self-limited, treatment hastens the resolution of symptoms, particularly in severe cases. Treatment of STEC infection should be avoided since antibiotics may increase the incidence of HUS (possible via increased release of Stx).

**EXTRAINTESTINAL PATHOGENS**

**GENERAL FEATURES AND PRINCIPLES** Extraintestinal pathogenic *E. coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, *Edwardsiella*, and *Acinetobacter* are components of the normal animal and human colonic flora and/or of the flora of a variety of environmental habitats (including long-term-care facilities and hospitals). In healthy humans, *E. coli* is the predominant gram-negative bacillus in the colonic flora. GNB (primarily *E. coli*, *Klebsiella*, and *Proteus*) only transiently colonize the oropharynx and skin of healthy individuals. In contrast, in long-term-care and hospital settings, a variety of GNB emerge as the dominant colonizing flora of both mucosal and skin surfaces, particularly with antimicrobial use, severe illness, and extended length of stay. Acquisition of the GNB (from various reservoirs) leads to infection.

**Pathogenesis** Multiple bacterial traits are required for various aspects of the pathogenesis of GNB. The possession of specialized virulence genes is what defines pathogens and enables them to infect the host efficiently. As more is learned about these genes, it is becoming clear
that hosts and their cognate pathogens have been coadapting throughout evolutionary history. In fact, it has been speculated that infection is just a point on the spectrum of evolutionary development between microbes and hosts. At one end of this spectrum is a commensal/symbiotic interaction (e.g., mitochondria—formerly bacteria—within eukaryotic cells); at the other end is a lethal outcome that results in a “dead-end relationship” (e.g., Ebola virus). During this host-pathogen “chess match” over time, various and redundant solutions have emerged both in pathogens and in their hosts that enable these partners to maintain their coexistence (Table 134-2).

Extraintestinal pathogenic strains of *E. coli* (ExPEC) and the other genera discussed in this chapter cause infection outside the bowel. All are extracellular pathogens and therefore share certain pathogenic features. Innate defense systems (complement, antimicrobial peptides, professional phagocytes) and humoral immunity are the most critical host-defense components. As a result, both susceptibility to and severity of infection are increased with dysfunction or deficiencies of these components (e.g., neutrophils) (Chap. 104).

A given pathogen usually possesses multiple adhesins for binding to a variety of host cells (e.g., in *E. coli*: type 1 fimbriae, Sfa/Foc, P pili). Nutrient acquisition (e.g., iron via siderophores) requires many genes that are necessary but not sufficient for pathogenesis. The ability to resist the bactericidal activity of complement and professional phagocytes in the absence of antibody [e.g., conferred by capsule or O antigen of lipopolysaccharide (LPS)] is one of the defining traits of an extracellular pathogen. Tissue damage (e.g., hemolysis in the case of *E. coli*) may facilitate spread. Many important virulence genes await identification, and our understanding of many aspects of the pathogenesis of GNB is in its infancy (Chap. 105).

The ability to induce septic shock is another defining feature of these genera. GNB are the most common cause of this dangerous complication. The lipid A moiety of LPS (via interaction with host Toll-like receptors) and probably other bacterial factors as well (including capsule) stimulate a proinflammatory host response, which, if overexuberant, results in shock (Chap. 254).

Lastly, many serotypes exist in most genera of GNB; for example, there are >100 O-specific antigens and >80 capsular antigens in *E. coli*. This antigenic variability, which permits immune evasion and successful recurrent infection by strains of the same species, has also impeded vaccine development (Chap. 107).

### Infectious Syndromes

Depending on both the host and the pathogen, nearly every organ or body cavity can be infected with GNB. *E. coli* and, to a lesser degree, *Klebsiella* and *Proteus* account for the majority of infections and are the most virulent pathogens of this group. However, the other genera are becoming increasingly important, particularly among persons in long-term care and hospitalized patients. This expanding role is in large part due to the innate or acquired resistance of these organisms to antimicrobial agents and to the increasing number of immunocompromised hosts. The mortality rate is significant in many GNB infections and correlates with the severity of illness. Especially problematic are pneumonia and bacteremia from any source complicated by severe sepsis (with or without shock); these conditions have associated mortality rates of 20 to 50%.

#### Diagnosis

Isolation of GNB from ordinarily sterile sites almost always implies infection. Their isolation from nonsterile sites, particularly from soft-tissue and respiratory cultures, requires clinical correlation to differentiate colonization from infection. Results of an assessment of lactose fermentation (described for each genus below) are usually available before final identification of the organism and its antimicrobial susceptibility and may assist in guiding empirical therapy.

### TREATMENT

The antimicrobial resistance of GNB is variable and is influenced by both geographic location and regional antibiotic use. Empirical antimicrobial choices should be based on local susceptibility patterns. Extended-spectrum β-lactamases (ESBLs, class A) and AmpC β-lactamases (class C) are responsible for the majority of multidrug resistance in GNB. The acquisition of ESBLs via transferable plasmids is increasing. To date, ESBLs are most prevalent in *Klebsiella* and *E. coli*, but they have also been described (and are probably underrecognized) in *Enterobacter* and other enteric GNB. Plasmids encoding for ESBLs confer resistance to third-generation cephalosporins and aztreonam and frequently contain linked resistance determinants for aminoglycosides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMX). Up to 50% of strains expressing ESBLs have associated fluoroquinolone resistance. Outbreaks due to strains possessing ESBLs have been associated with extensive institutional use of third-generation cephalosporins, particularly cefazidime. The carbapenems (e.g., imipenem) are the only β-lactam agents that are reliably efficacious against strains expressing an ESBL.

Derepression of inducible chromosomal AmpC β-lactamases, another important resistance mechanism, may be preexisting or may develop during therapy. This determinant confers resistance to second- and third-generation cephalosporins, to aztreonam, and often to β-lactam/β-lactamase inhibitor combinations. Chromosomal AmpC β-lactamases occur in *Enterobacter*, *Serratia*, *Citrobacter*, *Proteus vulgaris*, *Proteus penneri*, *Providencia*, *Morganella*, and *Acinetobacter*. In addition, some strains of *E. coli*, *Klebsiella pneumoniae*, and other Enterobacteriaceae that carry chromosomal AmpC β-lactamases have acquired plasmids that contain AmpC β-lactamases.

Although relevant data are suboptimal or conflicting, combination therapy may increase antibiotic efficacy (particularly for serious infections, such as pneumonia) and diminish the emergence of resistance. Furthermore, drainage of abscesses and removal of infected foreign bodies are often needed for cure.

GNB are commonly involved in polymicrobial infections, in which it is difficult to determine the role of each specific pathogen (Chap. 148). Although some GNB are more pathogenic than others, it is usually prudent, if possible, to design an antimicrobial regimen that includes activity against all of the GNB identified, since each is capable of pathogenicity in its own right.

#### Prevention

Diligent hand hygiene by health care personnel and avoidance of inappropriate antimicrobial use are key in preventing infection and the further development of antimicrobial resistance.

### ESCHERICHIA COLI INFECTIONS / Commensal Strains

Commensal *E. coli* variants, which constitute the major portion of the normal facultative intestinal flora in most humans, for the most part confer benefits (such as resistance to colonization) to their hosts. These strains generally...
lack the specialized virulence traits that enable intestinal and extraintestinal pathogenic \textit{E. coli} strains to cause disease within and outside the gastrointestinal tract, respectively. However, commensal \textit{E. coli} are sometimes involved in extraintestinal infections when an aggravating factor is present, such as a foreign body (e.g., a urinary catheter), host compromise (e.g., local anatomical or functional abnormalities such as urinary or biliary tract obstruction or immunocompromise), or an inoculum that is large or contains a mixture of bacterial species (e.g., fecal contamination of the peritoneal cavity).

**Extraintestinal Pathogenic Strains (ExPEC)** The majority of \textit{E. coli} isolates from symptomatic infections of the urinary tract, bloodstream, cerebrospinal fluid, respiratory tract, and peritoneum (spontaneous bacterial peritonitis) are distinct from commensal and intestinal pathogenic strains of \textit{E. coli} by virtue of their functionally similar virulence factor profiles (Table 134-2) and clonal background. It has recently been proposed that these extraintestinal strains of \textit{E. coli} be termed ExPEC. Evaluation of a limited number of strains has established that ExPEC can also cause surgical wound infection, osteomyelitis, and myositis, but the number of cases evaluated to date is too small for a reliable assessment of proportions. Studies on the nature of \textit{E. coli} strains responsible for other extraintestinal infections are in progress.

Like commensal \textit{E. coli} (but in contrast to intestinal pathogenic \textit{E. coli}), ExPEC strains are often found in the normal intestinal flora and do not cause gastroenteritis in humans. Although acquisition of an ExPEC strain by the host is a prerequisite for ExPEC infection, it is not the rate-limiting step, which instead is entry of a colonizing ExPEC strain from its site of colonization (e.g., the colon, vagina, or oropharynx) into a normally sterile extraintestinal site (e.g., the urinary tract, peritoneal cavity, or lungs). ExPEC strains have acquired genes encoding diverse extraintestinal virulence factors that enable the bacteria to cause infections outside the gastrointestinal tract in both normal and compromised hosts (Table 134-2). These virulence genes are, for the most part, distinct from those that enable intestinal pathogenic strains to cause intestinal disease. All age groups, all types of hosts, and nearly all organs and sites are susceptible to infection by ExPEC. Previously healthy hosts infected with ExPEC can become severely ill and even die; however, adverse outcomes are more prevalent in the presence of coincidental disease and abnormalities in host defenses. \textit{E. coli} is the most common enteric gram-negative species to cause extraintestinal infection in ambulatory, long-term-care, and hospital settings. The diversity and the medical and economic impact of ExPEC infections are evident from a review of the following specific syndromes.

**Infectious Syndromes**

**URINARY TRACT INFECTION (UTI)** The urinary tract is the site most frequently infected by ExPEC. A common infection among ambulatory patients, UTI accounts for 1% of ambulatory care visits in the United States and is second only to lower respiratory tract infection among infections responsible for hospitalization. UTIs are best considered by clinical syndrome (e.g., uncomplicated cystitis, catheter-associated) within the context of specific hosts (e.g., premenopausal women, compromised host; Chap. 269). \textit{E. coli} is the single most prevalent pathogen for all UTI syndrome/host group combinations. Each year in the United States, for example, \textit{E. coli} causes 85 to 95% of an estimated 6 to 8 million episodes of uncomplicated cystitis in premenopausal women, with an estimated $1 million in direct health care costs. Furthermore, 20% of women with an initial infection develop frequent recurrences (0.3 to >20 per year). Except in the first year of life, acceptance of the diagnosis of UTI in males requires clear documentation since such infection is unusual in the absence of a history of instrumentation or anal intercourse.

Uncomplicated urethritis or cystitis occurs most commonly and is characterized by symptoms of dysuria, frequency, and suprapubic pain. Fever and/or back pain suggests progression to pyelonephritis. Pregnant women are at unusually high risk for this complication, which can adversely affect the outcome of pregnancy. As a result, prenatal screening for bacteriuria, with treatment when the results are positive, is the standard of care. Fever may take 5 to 7 days to resolve completely in appropriately treated patients with pyelonephritis but should fall over time. Persistently elevated or increasing fever and neutrophil counts should prompt evaluation for intrarenal or perinephric abscess and/or obstruction. Renal parenchymal damage and loss of renal function occur primarily in the setting of obstruction. Prostatic infection is generally a complication of UTI in men with a history of instrumentation and/or prostatic hypertrophy. The diagnosis and treatment of UTI are detailed in Chap. 269 and are tailored according to the individual host, the nature and site of infection, and the local pattern of antimicrobial susceptibility.

**ABDOMINAL AND PELVIC INFECTION** The abdomen/pelvis is the second most frequent site of extraintestinal infection due to \textit{E. coli}. A wide variety of clinical syndromes occur in this location, including acute peritonitis secondary to fecal contamination, spontaneous bacterial peritonitis, peritoneal dialysis–associated peritonitis, diverticulitis, appendicitis, intraabdominal or visceral abscesses (hepatic, pancreatic, splenic), infected pancreatic pseudocysts, and septic cholangitis and/or cholecystitis. In intraabdominal infections, \textit{E. coli} can be isolated either alone or (as is often the case) along with other facultative and/or anaerobic members of the intestinal flora (Chap. 112).

**PNEUMONIA** \textit{E. coli} is not usually considered a cause of pneumonia (Chap. 239). Indeed, enteric GNB account for only 2 to 5% of cases of community-acquired pneumonia (CAP), in part because these organisms only transiently colonize the oropharynx of a minority of healthy individuals. In contrast, rates of oral colonization with \textit{E. coli} and other GNB increase with the severity of illness and with antibiotic use. Thus, GNB are a common cause of pneumonia among residents of long-term-care institutions and are the most frequent cause (60 to 70% of cases) of hospital-acquired pneumonia (Chap. 116), particularly among postoperative and intensive care patients. Pneumonia is usually acquired by small-volume aspiration but occasionally occurs via hematogenous spread, in which case multifocal nodular infiltrates can be seen. Tissue necrosis, probably due to cytotoxins produced by GNB, is common. Despite significant institutional variation, \textit{E. coli} is generally the third or fourth most commonly isolated gram-negative bacillus in these settings, accounting for 5 to 8% of episodes in both U.S.- and European-based studies. Regardless of the host, pneumonia due to enteric GNB is a serious disease, with high crude and attributable mortality rates (20 to 60% and 10 to 20%, respectively).

**MENINGITIS** (See also Chap. 360) \textit{E. coli} is one of the two leading causes of neonatal meningitis (the other being group B Streptococcus). The majority of responsible strains possess the K1 capsular serotype. Outside this setting, meningitis due to \textit{E. coli} is uncommon, occurring predominantly in the setting of disruption of the meninges due to craniotomy or trauma or in the presence of cirrhosis. In these instances, the meninges are presumably seeded from poorly cleared portal-source episodes of bacteremia or via direct extension from an otogenic or sinus source.

**CELLULITIS/MUSCULOSKELETAL INFECTION** Infections of decubitus ulcers and the lower extremities in diabetic patients (or other hosts with vascular compromise) are usually polymicrobial. \textit{E. coli} contributes frequently to decubitus infections and occasionally to lower-extremity infections in these patients. In addition, \textit{E. coli} may occasionally cause cellulitis or burn-site or surgical-wound infection, particularly when the infection originates close to the perineum. Osteomyelitis secondary to contiguous spread can occur in these settings. Hematogenously acquired osteomyelitis, particularly of vertebral bodies, is more commonly caused by \textit{E. coli} than is generally appreciated; this organism accounts for 10% of cases in some series (Chap. 111). \textit{E. coli} occasionally causes orthopedic device–associated infection or septic arthritis and is a rare cause of hematogenously acquired myositis. Myositis or fasciitis of the upper leg should prompt an evaluation for an abdominal source with contiguous spread.
**ENDOVASCULAR INFECTION** Despite being one of the most common causes of bacteremia, *E. coli* rarely seeds native heart valves and is an uncommon cause of prosthetic-valve endocarditis. Likewise, *E. coli* infections of aneurysms and vascular grafts are uncommon.

**MISCELLANEOUS INFECTIONS** *E. coli* can cause infection in nearly every organ and site. It is responsible for 8% of surgical site infections (superficial, deep tissue, or organ-space—e.g., mediastinitis), occasional cases of complicated sinusitis, and uncommon cases of endophthalmitis or brain abscesses.

**BACTEREMIA** *E. coli* bacteremia can arise from primary infection at any extraintestinal site. In addition, primary *E. coli* bacteremia can arise from percutaneous intravascular devices or can result from the increased intestinal mucosal permeability seen in neonates and in the settings of neutropenia and chemotherapy-induced mucositis, trauma, and burns. Roughly equal proportions of bacteremia cases originate in the community and in the hospital. *E. coli* and *Staphylococcus aureus* are the most common clinically significant blood isolates; *E. coli*, which is isolated in 17 to 37% of cases, is the gram-negative bacillus most often isolated from the blood in the ambulatory setting as well as in most long-term-care and hospital settings. Isolation of *E. coli* from the blood is almost always clinically significant and typically is accompanied by the sepsis syndrome, severe sepsis (sepsis-induced dysfunction of at least one organ or system), or septic shock ( Chap. 254). Calculations based on a conservative estimate for severe *E. coli* sepsis (i.e., 17% of all cases of severe sepsis) translate into an estimated 40,000 deaths among the affected patients in the United States in 2001.

The urinary tract is the most common source of *E. coli* bacteremia, accounting for two-thirds of episodes. Bacteremia from a urinary tract source is particularly common with pyelonephritis, urinary tract obstruction, or instrumentation in the presence of infected urine. The abdomen is the second most common source, accounting for 25% of episodes. Although obstructive biliary tract disease (stones, tumor), and overt disruption of bowel are responsible for many of these cases, some abdominal sources (e.g., abscesses) are remarkably silent clinically and require identification via imaging studies (e.g., computed tomography). Therefore, the physician should be cautious in designating the urinary tract as the source of *E. coli* bacteremia in the absence of appropriate signs and symptoms. Soft tissue, bone, and pulmonary infections are the next most common sources for bacteremia.

**Diagnosis** Strains of *E. coli* that cause extraintestinal infections usually grow both aerobically and anaerobically within 24 h on standard diagnostic media and are easily identified by the clinical microbiology laboratory according to standard biochemical criteria. More than 90% of ExPEC strains are rapid lactose fermenters.

### Treatment

In the past, *E. coli* has typically been highly susceptible to antibiotics and readily eradicated with antibiotic therapy. Unfortunately, this situation has changed. In general, the frequency of ampicillin resistance precludes its empirical use, even in community-acquired infections. Rates of resistance to first-generation cephalosporins and TMP-SMX are increasing among community-acquired strains in the United States (with current rates of 10 to 40%) and are even higher in Europe and developing countries. Until recently, TMP-SMX was the drug of choice for the treatment of uncomplicated cystitis in many locales. Although continued empirical use of TMP-SMX will predictably result in ever-diminishing cure rates, a wholesale switch to alternative agents (e.g., fluoroquinolones) will just as predictably accelerate the widespread emergence of resistance to these antimicrobial classes, as has already occurred in some areas. It is not surprising that rates of resistance among isolates from long-term-care facilities and hospitals are particularly high. Significant resistance (30 to 40%) to amoxicillin/clavulanic acid and piperacillin has been increasingly reported. Fortunately, rates of resistance to cephalosporins (second-, third-, and fourth-generation), quinolones, monobactams (e.g., aztreonam), carbapenems (e.g., imipenem), and aminoglycosides are generally <10%.

### Klebsiella Infections

*K. pneumoniae* is the most important *Klebsiella* species from a medical standpoint, causing community-acquired, long-term-care, and nosocomial infections. *K. oxytoca* is primarily a pathogen in long-term-care and hospital settings. *K. rhinoscleromatis* and *K. ozaenae* are usually isolated from patients in tropical climates. *Klebsiella* species are broadly prevalent in the environment and colonize mucosal surfaces of mammals. In healthy humans, *K. pneumoniae* colonization rates range from 5 to 35% in the colon and from 1 to 5% in the oropharynx; the skin is usually colonized only transiently. In long-term-care facilities and hospitals, colonization occurs with *K. oxytoca* as well, and carriage rates are significant among both workers and patients. Person-to-person spread is thought to be the predominant mode of acquisition. Classically, *Klebsiella* is associated with CAP, primarily in alcoholics. However, the majority of *Klebsiella* infections now occur in long-term-care facilities and hospitals. *Klebsiella* causes a spectrum of extraintestinal infections similar to that caused by *E. coli*. However, extraintestinal infections due to *Klebsiella* occur at a lower incidence in all sites except the respiratory tract. These variances in infection rates are probably due to differences in colonization and site-specific virulence traits. Antibiotic-resistant strains have been responsible for a number of nosocomial outbreaks of infection in intensive care units (ICUs) and neonatal nurseries. The most common clinical syndromes are pneumonia, UTI, abdominal infection, surgical site infection, soft tissue infection, and subsequent bacteremia. *K. rhinoscleromatis* is the causative agent of rhinoscleroma, a slowly progressive (months to years) mucosal upper respiratory infection that causes necrosis and occasional obstruction of the nasal passages. *K. ozaenae* has been implicated as a cause of chronic atrophic rhinitis.

### Infectious Syndromes

**PNEUMONIA** *K. pneumoniae* causes only a small proportion of cases of CAP ( Chap. 239). This infection occurs primarily in hosts with underlying disease, such as alcoholics, diabetics, and individuals with chronic lung disease. As in all pneumonias due to enteric GNB, purulent sputum production and “airspace” disease on x-ray are typical. Presentation with earlier, less extensive infection is more common than that with the classic lobar infiltrate with a bulging fissure. Pulmonary necrosis, pleural effusion, and empyema occur with progression. Pulmonary infection in residents of long-term-care facilities and in hospitalized patients is especially frequent because of increased oropharyngeal colonization rates. Mechanical ventilation is an important risk factor.

**UTI** The incidence of *K. pneumoniae* UTI among healthy adults is only 1 to 2%. However, in complicated UTIs (including those associated with indwelling bladder catheters), the incidence of *Klebsiella* infection increases to 5 to 17%.

**ABDOMINAL INFECTION** *Klebsiella* causes a spectrum of abdominal infections similar to that caused by *E. coli* but is less frequently isolated from these infections.

**OTHER INFECTIONS** *Klebsiella* cellulitis or soft tissue infection occurs most frequently in devitalized tissue (e.g., decubitus ulcers, diabetes, burn sites) or in immunocompromised hosts. *Klebsiella* causes a significant minority of surgical site infections, hematogenously derived endophthalmitis cases, and nosocomial sinusitis cases as well as occasional cases of osteomyelitis contiguous to soft tissue infection, temporomandibular joint disease, and neonatal meningitis or meningitis associated with neurosurgery.
**BACTEREMIA**  Klebsiella infection at any site can result in bacteremia. Infections of the urinary tract, respiratory tract, and abdomen each account for 15 to 30% of Klebsiella bacteremias. Intravascular device-related infection is another important source (5 to 15%). Surgical site infection and other miscellaneous infections account for the rest. Klebsiella is one of the agents that causes sepsis neonatorum and bacteremia with fever and neutropenia. Like enteric GNB in general, Klebsiella rarely causes endocarditis or endovascular infection.

**Diagnosis**  Except for K. rhinoscleromatis and K. ozaenae, klebsiellae are readily isolated and identified by the laboratory and usually ferment lactose.

**TREATMENT**  

*K. pneumoniae* and *K. oxytoca* have similar antibiotic resistance profiles. They are intrinsically resistant to ampicillin and ticarcillin. NNIS data from 1998 indicated that 10.7% of ICU patients were infected with strains resistant to third-generation cephalosporins. This increasing degree of resistance is primarily mediated by plasmids containing genes that encode ESBLs. In addition, these plasmids usually possess linked resistance determinants for aminoglycosides, tetracyclines, and TMP-SMX. In specific hospitals or geographic locales (e.g., Brooklyn, NY), the prevalence of ESBL-containing isolates is significantly higher. Resistance to β-lactam/β-lactamase inhibitor combinations and second-generation cephalosporin's independent of ESBL-containing plasmids has also been increasingly described. Up to 50% of ESBL-containing strains have displayed associated fluoroquinolone resistance. At this time, rates of resistance to quinolones, cefepime, and amikacin can be generally less than 10%, but these rates will probably increase. Carbapenems (e.g., imipenem) remain the most active antibiotic class against Klebsiella.

**PROTEUS INFECTIONS**  *P. mirabilis* causes 90% of Proteus infections. These infections occur in the community, in long-term-care facilities, and in hospitals. *P. vulgaris* and *P. penneri* are isolated primarily from infections contracted in long-term-care facilities or hospitals. Proteus species are part of the colonic flora of a wide variety of mammals, birds, fish, and reptiles. Their ability to generate histamine from contaminated fish has implicated these GNB in the pathogenesis of scombroid (fish) poisoning (Chap. 378). *P. mirabilis* colonizes healthy humans (prevalence, 50%), but *P. vulgaris* and *P. penneri* are isolated primarily from individuals with underlying disease. The urinary tract is overwhelmingly the favored site of Proteus infection, with abscesses, flagella, IgA protease, and urease the important virulence factors. *Proteus* is commonly responsible for neonatal meningitis/sepsis (particularly in premature infants); contaminated formula has been implicated as a source of this infection, which is often complicated by brain abscess or ventriculitis. Bacteremia can result from infection at any of these sites. In the setting of Enterobacter bacteremia, contamination of intravenous fluids or medications, blood components or plasma derivatives, catheter-flushing fluids, pressure monitors, and dialysis equipment should always be considered, particularly with epidemic infection. Enterobacter can also cause bacteremia in patients with fever and neutropenia. Enterobacter

**ENTEROBACTER INFECTIONS**  *E. cloacae* and *E. aerogenes* are responsible for most Enterobacter infections (65 to 75% and 15 to 25%, respectively); *E. agglomerans*, *E. sakazakii*, and *E. gergoviae* are less commonly isolated (5%, 1%, and <1%, respectively). These organisms cause primarily health care-related or hospital-related infections. They are widely prevalent in foods, environmental sources (including health care facility equipment), and a wide variety of animals. Only a minority of healthy humans are colonized, but the percentage increases significantly in the setting of long-term care or hospitalization. Although colonization is an important prelude to infection, direct introduction via intravenous lines (e.g., contaminated intravenous fluids, pressure monitors) also occurs. Significant antibiotic resistance has developed in Enterobacter species and has contributed to their emergence as prominent nosocomial pathogens. Individuals who have received prior antibiotic treatment, who have comorbid disease, and who are patients in ICUs are at greatest risk for infection. Enterobacter causes a spectrum of extraintestinal infections similar to that described for other GNB in this chapter.

**INFECTION SYNDROMES**

**Enterobacter infections**  Pneumonia, UTI (particularly catheter-related), intravascular device-related infection, surgical site infection, and abdominal infection (primarily postoperative or device-related—e.g., biliary stents) are the most common syndromes encountered. Nosocomial sinusitis, meningitis related to neurosurgical procedures (including use of pressure monitors), osteomyelitis, and endophthalmitis after eye surgery are less frequent. *E. sakazakii* is commonly responsible for neonatal meningitis/sepsis (particularly in premature infants); contaminated formula has been implicated as a source of this infection, which is often complicated by brain abscess or ventriculitis. Bacteremia can result from infection at any of these sites. In the setting of Enterobacter bacteremia, contamination of intravenous fluids or medications, blood components or plasma derivatives, catheter-flushing fluids, pressure monitors, and dialysis equipment should always be considered, particularly with epidemic infection. Enterobacter can also cause bacteremia in patients with fever and neutropenia. Enterobacter

**OTHER INFECTIONS**  Although the majority of Proteus infections arise from the urinary tract, these bacteria occasionally cause pneumonia (primarily in long-term-care or hospitalized patients), nosocomial si-
endocarditis is rare, occurring primarily in association with intravenous drug abuse or prosthetic valves.

**Diagnosis** Enterobacter is readily isolated and identified by the laboratory. Most strains are lactose positive.

**TREATMENT**

Significant antimicrobial resistance exists among Enterobacter strains. Ampicillin and the first- and second-generation cephalosporins have little or no activity. The extensive use of third-generation cephalosporins has resulted in the selection of strains that produce high levels of AmpC \( \beta \)-lactamase, which confers resistance to second- and third-generation cephalosporins, monobactams (e.g., aztreonam), and (frequently) \( \beta \)-lactam/\( \beta \)-lactamase inhibitor combinations. Resistant isolates may emerge during therapy; their presence should be considered a possibility when clinical deterioration follows several days of improvement. A 34% resistance rate to third-generation cephalosporins was reported in ICU isolates in 1998 (NNIS data). Imipenem, fourth-generation cephalosporins (e.g., cefepime), aminoglycosides (amikacin > gentamicin), TMP-SMX, and quinolones have retained excellent activity (90 to 99%). However, increasing resistance to quinolones, in conjunction with the increased use of these agents, is a concern.

**ACINETOBACTER INFECTIONS** A. baumannii is responsible for the majority of Acinetobacter infections; a minority are due to A. calcoaceticus, A. junii, and Acinetobacter genospecies 3 and 13TU. Acinetobacter is highly prevalent in the environment. It is found in most water and soil samples and has a wide habitat. Acinetobacter has been cultured from the moist skin of healthy humans; increased colonization of the skin and the respiratory and gastrointestinal tracts occurs in individuals in long-term-care facilities and hospitals. Reservoirs for acquisition in these settings include health care personnel, medical equipment, food, and the surrounding environment. The overwhelming majority of infections are acquired in the hospital or in long-term-care facilities. The spectrum of extraintestinal infections caused by Acinetobacter is similar to that caused by other GNB. Acinetobacter species account for 1 to 2% of nosocomial infections. The affected hosts are usually immunocompromised or have comorbid disease. ICUs are a prominent site of Acinetobacter infection. In some centers, the incidence of Acinetobacter infections, particularly those due to antibiotic-resistant strains, is increasing. Both sporadic and epidemic infections occur, usually after the first week of hospitalization.

**Infectious Syndromes** The respiratory tract, the genitourinary tract, intravascular devices, and surgical wounds are the most common sites of Serratia infection and sources of Serratia bacteremia. Soft tissue infections, including myositis, osteomyelitis, abdominal and biliary tract infection (postprocedural), contact lens–associated keratitis, endophthalmitis, septic arthritis (primarily with intraarticular injections), and infusion-related bacteremias occur less commonly. Serratiae are uncommon causes of neonatal or postsurgical meningitis and bacteremia associated with fever and neutropenia. Endocarditis is rare.

**TREATMENT**

A high proportion of Serratia strains (>80%) are resistant to ampicillin and the first-generation cephalosporins. Although derepression of inducible chromosomal AmpC \( \beta \)-lactamases may be preexistent or may develop during therapy, >90% of isolates are susceptible to other GNB-appropriate antibiotics.

**CITROBACTER INFECTIONS** C. freundii and C. koseri (former C. diversus) cause the majority of human Citrobacter infections, which are similar epidemiologically and clinically to Enterobacter and Acinetobacter infections. Citrobacter organisms are commonly present in water, food, soil, and the intestinal tracts of animals. Citrobacter is part of the normal fecal flora in a minority of healthy humans, but colonization rates increase in long-term-care facilities and hospitals—the settings in which nearly all infections occur. Citrobacter species account for 1 to 2% of nosocomial infections. The affected hosts are usually immunocompromised or have comorbid disease. Citrobacter causes extraintestinal infections whose spectrum is similar to that described for other GNB.

**Infectious Syndromes** The urinary tract is the site of 40 to 50% of infections due to Citrobacter. Less commonly infected sites include the biliary tree (particularly with stones or obstruction), the respiratory tract, surgical sites, soft tissue (e.g., decubitus ulcers), the peritoneum, and intravascular devices. Osteomyelitis (usually contiguous), neurosurgery-related infection, and myositis occur rarely. Citrobacter is also an uncommon cause of neonatal meningitis; C. koseri accounts for 90% of cases due to this genus. A frequent and devastating complication of this infection (occurring in 50 to 80% of cases) is the development of brain abscesses. Bacteremia is most commonly due to UTI, biliary or abdominal infection, or intravascular devices. Citrobacter is an uncommon cause of bacteremia in the setting of fever and neutropenia. Endocarditis or endovascular infection is rare.
Diagnosis  Citrobacter species are readily isolated and identified, often as part of a polymicrobial culture; 35 to 50% of isolates are lactose positive.

TREATMENT  C. freundii is generally more resistant to antibiotics than C. koseri. Ampicillin and the first- and second-generation cephalosporins display poor activity against Citrobacter. Resistance is variable but increasing to ticarcillin, mezlocillin, piperacillin, aztreonam, quinolones, gentamicin, and third-generation cephalosporins; such resistance may evolve during therapy. The β-lactamase inhibitors usually do not improve susceptibility to β-lactam agents. Imipenem, amikacin, and the fourth-generation cephalosporins are most active, with >90% of strains sensitive.

MORGANELLA AND PROVIDENCIA INFECTIONS  M. morgani (formerly Proteus morganii), P. stuartii, and (less frequently) P. rettgeri (formerly Proteus rettgeri) are the members of these genera that are responsible for human infections. The epidemiologic, pathogenic, and clinical manifestations of these organisms are similar to those of Proteus species; however, Morganella and Providencia are almost exclusively pathogens of persons in long-term-care facilities and, to a lesser degree, hospitalized patients.

Infectious Syndromes  These species are primarily urinary tract pathogens, most often associated with long-term (>30-day) catheterization. UTI in uncatheterized or short-term-catheterized individuals is uncommon. Biofilm formation or encrustation of the catheter usually develops and may lead to catheter obstruction. Likewise, infection may result in the development of struvite bladder or renal stones, which, in turn, may lead to renal obstruction and serve as foci for relapse. Other infectious syndromes occur less commonly but include surgical site infection, soft tissue infection (primarily decubitus and diabetic ulcers), burn site infection, pneumonia (particularly ventilator-associated), intravascular device infection, and intraabdominal infection. Rarely, the other extraintestinal infections described for GNB also occur. Bacteremia is uncommon; although any infected site can serve as the source, the urinary tract accounts for the majority of cases, with surgical site and soft tissue infections less frequently responsible.

Diagnosis  M. morgani and Providencia are readily isolated and identified. Nearly all isolates are unable to ferment lactose.

TREATMENT  Morganella and Providencia may be highly resistant to antimicrobial agents. Ampicillin and the first-generation cephalosporins exhibit poor activity against these organisms. Of Providencia isolates, 40% are resistant to fluoroquinolones. Variable resistance is emerging (and may evolve during therapy) against ticarcillin, mezlocillin, piperacillin, aztreonam, gentamicin, and third- and fourth-generation cephalosporins. The β-lactamase inhibitor tazobactam (but not sulbactam or clavulanic acid) somewhat improves susceptibility to β-lactam agents. Imipenem, amikacin, and the fourth-generation cephalosporins are most active, with >90% of strains susceptible. Removal of an infected catheter or stones is critical for eradication of the organisms from the urinary tract.

EDWARDSIELLA INFECTION  E. tarda is the only member of this genus associated with human disease. This organism is found predominantly in both freshwater and marine environments and in the animals that live in these environments. Human acquisition occurs primarily during interaction with these reservoirs. E. tarda infection is rare in the United States; most recently reported cases are from Southeast Asia. This pathogen shares some of the clinical features of both Salmonella species and Vibrio vulnificus.

Infectious Syndromes  Gastroenteritis is the predominant infectious syndrome reported (50 to 80% of infections). Self-limiting watery diarrhea is most frequent; however, cases of severe colitis responding to therapy have also been described. The most common extraintestinal infection is wound infection due to direct inoculation, which is often associated with freshwater, marine, or snake-related injuries. Other infectious syndromes appear to be due to invasion of the gastrointestinal tract and subsequent bacteremia. The majority of afflicted hosts have either liver disease or an iron-overload state (e.g., sickle cell disease). A primary bacteremic syndrome, sometimes complicated by meningitis, has been described and has a 40% case-fatality rate. Visceral (primarily hepatic) or intraperitoneal abscesses have also been reported.

Diagnosis  Although E. tarda can readily be isolated and identified, most laboratories do not routinely identify it from stool.
DEFINITION Helicobacter pylori persistently colonizes the human stomach and is of etiologic importance in peptic ulcer disease (Chap. 274) and gastric malignancy (Chap. 77). Other gastric Helicobacter species colonize animals, some with a narrow range and others with a broad range of host species specificity. Those with broad specificity are occasionally found in humans, probably as zoonoses. The two most common of these species among isolates from humans are Helicobacter bizzozeronii (formerly known as Helicobacter heilmannii) or Gastrospirillum hominis and Helicobacter felis. It is unclear whether these helicobacters cause human disease. Numerous species of non-gastric helicobacters are found in humans and animals and have been increasingly recognized as causes of human disease, especially in immunocompromised hosts.

ETIOLOGIC AGENT H. pylori is a gram-negative, spiral, flagellated bacillus that has naturally colonized humans for at least tens of thousands of years. It is noninvasive, living in gastric mucus; a small proportion of the bacterial cells are adherent to the mucus. Its spiral shape and flagella render H. pylori motile in the mucus environment. This organism has several acid-resistance mechanisms, most notably a highly expressed urease that catalyzes urea hydrolysis to produce buffering ammonia. In vitro, H. pylori is microaerophilic and slow-growing and requires complex growth media. Publication of the complete genomic sequence of H. pylori in 1997 led to significant advances in the understanding of the organism’s biology.

EPIDEMIOLOGY The prevalence of H. pylori is ~30% in the United States and other developed countries as opposed to >80% in most developing countries. In the United States, prevalence varies with age: ~50% of 60-year-old persons and 20% of 30-year-old persons are colonized. H. pylori is usually acquired in childhood. The age association is due mostly to a birth-cohort effect whereby current 60-year-olds were more commonly colonized as children than current 30-year-olds. Spontaneous acquisition or loss of the bacterium in adulthood is uncommon. Other than age, the main risk factor for H. pylori positivity is low socioeconomic status; crowding and markers of poor hygiene in childhood are particularly strong risk factors. Thus, the falling incidence among children is likely due, at least in part, to improvements in living standards and increased use of antibiotics.

Humans are the only important reservoir of H. pylori. Members of a family may carry the same strain, and colonization is particularly common in childhood institutions. These findings imply direct person-to-person spread, but whether transmission takes place by the fecal-oral or the oral-oral route is unknown. H. pylori is easily cultured from vomitus and gastroesophageal reflex and is less easily cultured from stool.

PATHOLOGY AND PATHOGENESIS H. pylori colonization induces chronic superficial gastritis, which includes both mononuclear and polymorphonuclear cell infiltration of the mucosa. (The term gastritis should be used specifically to describe histologic features; it also has been used to describe endoscopic appearances and even symptoms, which do not correlate closely with microscopic findings or with the presence of H. pylori.) The immune response to H. pylori includes both the production of antibody (local and systemic) and a cell-mediated response but is ineffective in clearing the bacterium. The pattern of gastric inflammation is associated with disease risk: antral-predominant gastritis is most closely linked with duodenal ulceration, whereas pan-gastritis is linked with gastric ulceration and adenocarcinoma. This probably explains why patients with duodenal ulceration rarely develop gastric adenocarcinoma later, despite being colonized by H. pylori. Longitudinal analyses of gastric biopsy specimens taken years apart from the same patient show that inflammation may progress stepwise through atrophy, intestinal metaplasia, and dysplasia to carcinoma. Continuous proton pump inhibitor (PPI) therapy—for example, for gastroesophageal reflux disease (GERD)—may slow progression to atrophy when H. pylori is present, but it remains unclear whether this situation increases cancer risk.

Most H. pylori–colonized persons do not develop clinical sequelae. That some persons develop overt disease whereas others do not is probably due to a combination of bacterial strain differences, host susceptibility to disease, and environmental factors. Several H. pylori virulence factors are more common in disease-associated strains. The cag PaI is a group of genes including those that encode a secretion system through which a specific protein, CagA, is translocated into epithelial cells. CagA interferes with host cell signaling, causing proliferation and cytoskeletal changes. The secretion system also induces a proinflammatory cytokine response, which results in enhanced inflammation. The CagA protein is highly immunogenic, and patients with peptic ulcer disease or gastric adenocarcinoma are more likely than persons without these conditions to have antibodies to CagA. However, patients with severe reflux esophagitis, the premalignant condition Barrett’s esophagus, or esophageal adenocarcinoma are less likely to harbor cag+ strains than are persons with a normal esophagus. The H. pylori vacuolating cytotoxin VacA occurs in several forms that exhibit different levels of toxicity. Strains with the more toxic forms are more commonly isolated from patients with peptic ulcer disease or gastric carcinoma than from persons without these conditions. BabA, an adhesin expressed by only some strains, is associated with increased gastric inflammation and with increased risk of peptic ulceration and gastric adenocarcinoma.

The best-characterized host determinant of disease is the possession of genetic polymorphisms leading to enhanced H. pylori–stimulated secretion of the proinflammatory cytokine interleukin 1β. If they are H. pylori–positive, individuals with these polymorphisms are at increased risk of hypochlorhydria and gastric adenocarcinoma. Environmental cofactors are also important in pathogenesis. Smoking increases ulcer and cancer risk in H. pylori–positive individuals. Diets high in salt and preserved foods increase cancer risk, whereas diets high in antioxidants and vitamin C are protective.

The pathogenesis of duodenal ulceration is becoming clearer. Antral H. pylori colonization diminishes the number of somatostatin-producing cells. Since somatostatin inhibits gastrin release, gastrin levels are higher than normal in H. pylori–positive persons. Individuals with antral-predominant gastritis (and thus a normally functioning acid-producing gastric corpus) develop increased acid secretion, which induces protective gastric metaplasia in the duodenum; the duodenum becomes colonized by H. pylori, inflamed, and then ulcerated. The pathogenesis of gastric ulceration is less well understood. These ulcers usually occur at the junction of antral and corpus-type mucosa, and this region is particularly inflamed. Gastric cancer probably stems from progressive DNA damage and the survival of abnormal epithelial cell clones. The DNA damage is thought to be due principally to reactive oxygen and nitrogen species arising from inflammatory cells and perhaps from other bacteria that survive in the achlorhydric stomachs in which gastric malignancies occur.

CLINICAL MANIFESTATIONS Essentially all H. pylori–colonized persons have gastric inflammation, but fewer than 10% of these individuals develop associated illnesses such as peptic ulceration, gastric adenocarcinoma, or gastric lymphoma (Fig. 135-1).

More than 80% of duodenal ulcers and 60% of gastric ulcers are related to H. pylori colonization (Chap. 274), most of the remainder being due to aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). The main lines of evidence for an ulcer-promoting role of H. pylori are (1) that the presence of the organism is a risk factor for the development of ulcers, (2) that (non-NSAID-induced) ulcers rarely develop in the absence of H. pylori, (3) that eradication of H. pylori markedly reduces rates of ulcer relapse, and (4) that experimental H. pylori infection of gerbils causes gastric ulceration. Prospective nested case-control studies have shown that H. pylori colonization is a risk factor for adenocarcinomas of the distal stomach (Chap. 77). Long-term experimental infection of gerbils also may re-
sult in gastric adenocarcinoma. The presence of H. pylori is strongly associated with gastric lymphoma, although this is a rarer condition. Many low-grade gastric B cell lymphomas arising from mucosa-associated lymphoid tissue (MALT) are driven by T cell stimulation, which in turn is driven by H. pylori antigen stimulation; H. pylori antigen–driven tumors may regress either fully or partially after H. pylori eradication.

Many patients have upper gastrointestinal symptoms but normal results in upper gastrointestinal endoscopy (so-called functional or nonulcer dyspepsia; Chap. 274). Because H. pylori is common, some of these patients will be positive for the organism. H. pylori eradication leads to symptom resolution more commonly than does placebo treatment, but only by a little (<10%). Whether such patients have peptic ulcers in remission at the time of endoscopy or whether a subgroup of patients with true functional dyspepsia respond to H. pylori treatment is unclear.

Much interest has focused on a possible protective role for H. pylori against GERD (Chap. 273) and adenocarcinoma of the esophagus and gastric cardia (Chap. 77). The main lines of evidence for this role are (1) that there is a temporal relationship between a falling prevalence of H. pylori colonization and a rising incidence of these conditions; (2) that in most studies, the prevalence of H. pylori colonization (especially with proinflammatory cagA+ strains) is significantly among patients with these esophageal diseases than among control subjects; and (3) that in some studies, eradication of H. pylori leads to the development or worsening of GERD. The mechanism underlying this protective effect appears to be H. pylori–induced hypochlorhydria. Since— at the individual level—GERD symptoms may decrease, worsen, or remain unchanged after H. pylori treatment, concerns about GERD should not affect treatment decisions where a definite indication exists.

H. pylori has a less-well-established role in other gastric pathologies. H. pylori may be one initial precipitant of autoimmune gastritis and pernicious anemia and also may predispose to iron deficiency in some patients through hypochlorhydria and reduced iron absorption. In addition, several extragastrointestinal pathologies have been linked epidemiologically with H. pylori colonization, the most notable being ischemic heart disease and cerebrovascular disease. However, the strength of these associations is reduced if confounding factors are considered, and most authorities consider them to be noncausal.

**DIAGNOSIS** Tests for H. pylori can be divided into two groups: invasive tests, which require upper gastrointestinal endoscopy and are based on the analysis of gastric biopsy specimens, and noninvasive tests (Table 135-1). Endoscopy often is not performed in the initial management of young dyspeptic patients without worrying symptoms but is commonly used in older people to exclude malignancy. If endoscopy is performed, the most convenient biopsy-based test is the biopsy urease test, in which one large or two small antral biopsies are placed into a gel containing urea and an indicator. The presence of H. pylori urease elicits a color change, which often occurs within minutes but can require up to 24 h. Histologic examination of biopsy specimens is accurate, provided that a special stain (e.g., a modified Giemsa or silver stain) permitting optimal visualization of H. pylori is used. If biopsies from both antrum and corpus are obtained, histologic study yields additional information, including the degree and pattern of inflammation, atrophy, metaplasia, and dysplasia. Microbiologic culture is most specific but may be insensitive because of difficulty with H. pylori isolation. Once cultured, the identity of H. pylori can be confirmed by its typical appearance on Gram’s stain and its positive reactions in oxidase, catalase, and urease tests. Moreover, the organism’s antibiotic sensitivities can be determined. The occasional biopsy specimens containing the less common non-pylori Helicobacters give only weakly positive results in the biopsy urease test.

comparative studies. The urea breath test, the stool antigen test, and biopsy-based tests can all be used to assess the success of treatment. However, because these tests are dependent on *H. pylori* load, their use <4 weeks after treatment may lead to false-negative results. These tests are also unreliable if performed within 4 weeks of intercurrent treatment with antibiotics or bismuth compounds or within 2 weeks of the discontinuation of PPI treatment. In the assessment of treatment success, noninvasive tests are normally preferred; however, after gastric ulceration, endoscopy should be repeated to ensure healing and to exclude gastric carcinoma by further histologic sampling.

The simplest tests for ascertaining *H. pylori* status are serologic assays measuring specific IgG levels in serum by enzyme-linked immunosorbent assay (ELISA) or immunoblot. The best of these tests are as accurate as other diagnostic methods, but many commercial tests, especially rapid office tests, perform poorly. In quantitative tests, a defined drop in antibody titer between matched serum samples taken before and 6 months after treatment (no sooner because of the slow decline in titer) accurately indicates that *H. pylori* has been eradicated. However, serologic tests are not commonly used in this context because of the inconvenient wait and the logistics. Although serology can distinguish between *cag*+ and *cag*− strains, this technique is not yet commercially available in the United States.

</tbody>
</table>

* For first-line therapy, many practitioners prefer Regimen 1 to Regimen 2, as it avoids the use of metronidazole—an important constituent of second-line therapy.
† Omeprazole may be replaced with any protein pump inhibitor at an equivalent dosage or, in Regimens 1 and 2, with ranitidine bismuth citrate (400 mg).
‡ An alternative to this second-line therapy is to culture *H. pylori* and to be guided by antibiotic susceptibility data. Patients in whom second-line therapy fails should undergo endoscopy for *H. pylori* culture and antibiotic susceptibility testing.
§ Data supporting this regimen come mainly from Europe and are based on the use of bismuth subcitrate and metronidazole (400 mg tid).

The most clear-cut indications for treatment are *H. pylori*–related duodenal or gastric ulceration and low-grade gastric B cell lymphoma. *H. pylori* should be eradicated in patients with documented ulcer disease, whether or not the ulcers are currently active, to reduce the likelihood of relapse. Many guidelines now recommend *H. pylori* treatment in uninvestigated simple dyspepsia following noninvasive diagnosis; others also recommend treatment in functional dyspepsia, in case the patient is one of the perhaps 5 to 10% to benefit (beyond placebo effects) from such treatment. People with a strong family history of gastric cancer should be treated for *H. pylori* in the hope that this therapy will reduce their risk. For many reasons, widespread community screening for and treatment of *H. pylori* as primary prophylaxis for gastric cancer and peptic ulcers are not currently recommended. It is unclear whether treatment of *H. pylori* (as opposed to never having acquired the organism) reduces cancer risk, except in certain high-risk populations. Treatment has side effects, which are severe in rare cases. Antibiotic resistance may arise in *H. pylori* or other incidentally carried bacteria. Otherwise healthy people may become anxious, especially if treatment is unsuccessful. Finally, there is a possible risk of provoking or worsening GERD.

Although *H. pylori* is susceptible to a wide range of antibiotics in vitro, monotherapy has been disappointing in vivo, probably because of inadequate antibiotic delivery to the full locus of colonization. Failure of monotherapy has led to the development of multidrug regimens, the most successful of which are triple and quadruple combinations that produce *H. pylori* eradication rates of >90% in many trials and >75% in clinical practice. Current regimens consist of a PPI or ranitidine bismuth citrate and two or three antimicrobial agents given for 7 to 14 days (Table 135-2).

The two most important goals in *H. pylori* eradication are to obtain the patient’s close compliance with the dosing regimen and to use drugs to which *H. pylori* has not acquired resistance. Treatment failure following minor lapses in compliance is common and often leads to acquired resistance to metronidazole or clarithromycin. To stress the importance of compliance, written instructions should be given to the patient, and minor side effects of the regimen should be explained. Resistance to metronidazole and clarithromycin is of growing concern. Clarithromycin resistance is less prevalent but, if present, usually results in treatment failure. Metronidazole-resistant strains of *H. pylori* are more common, but infections with these strains may still respond to metronidazole-containing regimens. Assessment of antibiotic susceptibilities before treatment would be optimal but is not usually undertaken. In the absence of susceptibility information, a history of antibiotic use should be obtained, and, even if only distant exposure is identified (e.g., previous metronidazole consumption for giardiasis or trichomoniasis), use of the agent should be avoided if possible. If initial *H. pylori* treatment fails, two strategies are commonly used. One is re-treatment with a quadruple drug regimen (Table 135-2). The second is endoscopy and biopsy culture plus treatment based on documented antibiotic sensitivities. If re-treatment fails, susceptibility testing should always be performed.

Clearance of non-*pylori* gastric helicobacters following the use of bismuth compounds alone or triple-therapy regimens has been described. However, in the absence of trials, it is unclear whether this result represents successful treatment or natural clearance of the bacterium.

### PREVENTION

Carriage of *H. pylori* has considerable public health significance in developed countries, where it is associated with peptic ulcer disease and gastric adenocarcinoma, and in developing countries, where gastric adenocarcinoma is an even more common cause of cancer death late in life. However, given that *H. pylori* has co-evolved with its human host over millennia, preventing or eliminating colonization on a population basis may have distinct disadvantages. For example, absence of *H. pylori* has been reported to increase the risk of diarrheal diseases and, as has been mentioned, appears to increase the risk of GERD and esophageal adenocarcinoma. If mass prevention were contemplated, vaccination would be the most obvious method, and experimental immunization of animals has given promising results. However, in the United States and other developed countries, rates of *H. pylori* carriage, peptic ulceration, and gastric adenocarcinoma are falling. Thus, prevention of colonization in these countries may be unnecessary or even unwise.

### FURTHER READING

**136 INFECTIONS DUE TO PSEUDOMONAS SPECIES AND RELATED ORGANISMS**

Christopher A. Ohl, Matthew Pollack

*Pseudomonas* species and phylogenetically related bacteria are ubiquitous, free-living, opportunistic gram-negative pathogens. *Pseudomonas aeruginosa*, the most common human pathogen in this group, is the primary subject of this chapter. Also discussed are *Burkholderia cepacia* (formerly *Pseudomonas cepacia*), *Stenotrophomonas maltophilia* (formerly *Xanthomonas maltophilia*), and *Burkholderia pseudomallei* and *Burkholderia mallei* (the causative agents of melioidosis and glanders, respectively).

**INFECTIONS DUE TO P. AERUGINOSA**

**MICROBIOLOGY** *P. aeruginosa* is a small, nonsporulating, aerobic gram-negative rod belonging to the family Pseudomonadaceae. It is motile by virtue of its single polar flagellum. More than half of all clinical isolates produce the blue-green pigment pyocyanin; this pigment is helpful in the identification of the organism and accounts for the species name *aeruginosa*, which refers to the distinctive color of copper oxide. The organism, which can easily be identified in culture by the clinical laboratory, is differentiated from enteric gram-negative bacilli by its ability to oxidize indophenol and its inability to ferment lactose.

**EPIDEMIOLOGY** *P. aeruginosa* is widespread in nature, inhabiting soil, water, plants, and animals (including humans). It has a predilection for moist environments. This organism occasionally colonizes the skin, external ear, upper respiratory tract, or large bowel of healthy humans. Rates of carriage are relatively low, however, except among patients who have serious underlying disease, whose host defenses have been naturally or iatrogenically compromised, who have previously received antibiotic therapy, and/or who have been exposed to the hospital environment. Under these circumstances, colonization with *P. aeruginosa* frequently precedes infection, and factors that predispose to the former also increase the likelihood of the latter.

**DISRUPTION OF NORMAL BACTERIAL FLORA**

Exposure to the hospital environment will undoubtedly increase our understanding of the pathogenicity and virulence of *P. aeruginosa*.

The production and secretion of many of the extracellular virulence factors of *P. aeruginosa* as well as the assembly and maturation of its biofilm are under the regulatory control of a complex cell-to-cell signaling system termed *quorum sensing*. Through lactones and other signal molecules secreted by each individual bacterium, the entire population of *P. aeruginosa* in a biofilm, colonized mucosa, or infected tissue senses its environment, communicates, and discerns its own cell density. This regulatory system may conceivably allow the bacteria to produce extracellular virulence factors in a coordinated manner that depends on cell density and thus may give the pathogen an appreciable advantage over host defense mechanisms.

Some of the exotoxins produced by *P. aeruginosa* (ExoS, ExoT, ExoU, and ExoY) are introduced directly from the bacterial cytosol into the host cell cytoplasm via a complex array of transmembrane proteins that together make up the type III secretion apparatus. This

system requires direct cell contact and allows the injection of virulence factors from the bacterium into host cells without interference from humoral immune defenses.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

**Respiratory Tract Infections**

Primary pneumonia or nonbacteremic pneumonia results from the aspiration of upper respiratory tract secretions and often develops in patients with previous antibiotic use who are exposed to the hospital environment, particularly the ICU. It is a common cause of ventilator-associated pneumonia and is noted especially often in patients with chronic lung disease, congestive heart failure, or AIDS. Community-acquired pneumonia due to *P. aeruginosa* is uncommon among normal hosts. Fever, chills, severe dyspnea, cyanosis, productive cough, apprehension, confusion, and other signs of severe systemic toxicity characterize this acute, often life-threatening infection. Chest roentgenograms typically show bilateral bronchopneumonia with nodular infiltrates and small areas of radiolucency; pleural effusions are common; empyema is relatively uncommon; and lobar consolidation is occasionally seen. Cavitory lesions are unusually common among AIDS patients with *P. aeruginosa* pneumonia. Pathologic lesions include alveolar necrosis, focal hemorrhages, and microabscesses.

Bacteremic pneumonia due to *P. aeruginosa* begins as a respiratory infection. However, unlike primary pneumonia, it is typically associated with neutropenia, subsequent bloodstream invasion, and metastatic spread that produces characteristic lesions in the lungs and other viscera. Alveolar hemorrhage and necrosis are common. The signs and symptoms of this fulminant disease include those described for nonbacteremic pneumonia caused by this organism as well as those associated with gram-negative sepsis. Chest roentgenograms characteristically demonstrate a rapid progression from pulmonary vascular congestion to interstitial edema, then to alveolar edema, and finally to diffuse necrotizing bronchopneumonia with cavity formation. The patient typically dies 3 or 4 days after initial presentation.

Chronic infection of the lower respiratory tract with *P. aeruginosa* is caused almost exclusively by mucoid strains that produce alginate and is prevalent among older children and young adults with cystic fibrosis as well as in some patients with bronchiectasis or AIDS. In patients with cystic fibrosis, mucoid strains invariably colonize and infect patients with increasing prevalence over time and contribute to the acute exacerbations and chronic progression that characterize pulmonary disease in these individuals. Airway obstruction appears to begin with bronchiolitis, which causes mucus plugging and predisposes to *P. aeruginosa* infection. The latter produces more mucus plugging, chronic suppuration, bronchiectasis, atelectasis, and ultimately fibrosis. This process progresses to pulmonary insufficiency, hypoxemia, and alterations in cardiopulmonary dynamics resulting in pulmonary hypertension and cor pulmonale.

Clinical manifestations of lower respiratory tract infections due to *P. aeruginosa* in patients with cystic fibrosis vary with the severity and duration of underlying lung disease, the frequency and intensity of acute episodes, and the presence of co-infecting pathogens such as *B. cepacia* (Chap. 241). Early in the disease, patients may experience recurrent upper respiratory symptoms followed by a lingering cough. Episodes of pneumonia develop later, with persistent cough between acute episodes. Eventually, patients exhibit a chronic productive cough, wheezing, diminished appetite, weight loss, growth retardation, and decreased activity. Acute exacerbations are typically accompanied by low-grade fever and heightened respiratory symptoms. Physical signs include evidence of malnutrition, an increase in anteroposterior diameter, intercostal retractions, cyanosis, inspiratory and expiratory wheezing, rhonchi, moist rales, abdominal distention, and clubbing of the fingers and toes. Laboratory abnormalities include leukocytosis with a left shift and hypoxemia with or without hypercarbia. Tests of pulmonary function demonstrate obstructive and restrictive defects. Chest roentgenograms reveal overaeration, patchy atelectasis, peribronchial fibrosis, and patchy infiltrates associated with pneumonia. In more advanced disease, there may be evidence of severe overaeration, depressed diaphragm, further increased anteroposterior diameter, extensive peribronchial infiltration, generalized bronchiectasis, and cyst formation.

**Bacteremia**

*P. aeruginosa* remains an important cause of life-threatening bloodstream infection in immunocompromised patients, particularly those with hematologic malignancies complicated by neutropenia. Bacteremia is frequently iatrogenic and is usually seen in hospitalized patients with various comorbid conditions (Table 136-1). Bloodstream infection may be primary (with no identifiable source) or secondary to a discrete focus of infection. Common primary sites of infection include the urinary and gastrointestinal tracts, lungs, skin and soft tissues, and intravascular foci, including indwelling central venous catheters.

The clinical features of *P. aeruginosa* bacteremia are similar to those of other forms of bacteremia. Fever, tachypnea, tachycardia, and prostration are common. Disorientation, confusion, or obtundation may be evident. Hypotension can progress to refractory shock. Renal failure, adult respiratory distress syndrome, disseminated intravascular coagulation, and other manifestations of SIRS occur as complications. Pathognomonic skin lesions termed “erythema gangrenosum” (Fig. 136-1) develop in a relatively small minority of patients with *P. aeruginosa* bacteremia. The lesions begin as small hemorrhagic vesicles.

</table>
surrounded by a rim of erythema and undergo central necrosis with subsequent ulceration. They occur singly or in small numbers on the perineum, buttocks, and extremities; in the axillae; and elsewhere. Bacterial invasion of blood vessels, documented histologically, is the sine qua non of ecthyma lesions. Bacteria are visible on Gram’s staining or are recoverable by culture of aspirated material from lesions.

**Endocarditis** (See also Chap. 109) *P. aeruginosa* infects the native heart valves of intravenous drug users as well as prosthetic heart valves. The source of *P. aeruginosa* strains infecting heart valve users appears to be standing water contaminating drug paraphernalia. Foreign materials mixed with heroin may cause injury to valve leaflets or mural endocardium, with resulting fibrosis and an increased risk for valve infection. Exposure of the tricuspid valve to both trauma and bacteria apparently accounts for the high incidence of tricuspid involvement in association with intravenous drug use.

The tricuspid, pulmonic, mitral, or aortic valve and the mural endocardium of either atrium may be affected in *P. aeruginosa* endocarditis. Multiple-valve infections are common. Tricuspid or right-sided involvement is often associated with septic pulmonary emboli. Right-sided *P. aeruginosa* endocarditis usually presents subacutely, while the appearance of left-sided disease is likely to be more acute or even fulminant. Fever is virtually invariable, and murmurs are usually detectable at initial presentation or shortly thereafter. Septic pulmonary emboli associated with right-sided disease result in cough, pleuritic chest pain, sputum production, pulmonary infiltration (with or without abscess formation), and pleural effusion. Left-sided infections may present as intractable heart failure or large systemic emboli. Mycotic aneurysms, cerebritis, or brain abscess may occur; septic foci are occasionally found in the spleen. Skin and soft tissue manifestations, including Janeway lesions, Osler’s nodes, and ecthyma gangrenosum, are relatively uncommon.

The diagnosis of *P. aeruginosa* endocarditis is based on positive blood culture in the absence of an extracardiac source; an indication of valvular dysfunction or vegetation on an echocardiogram; evidence of septic pulmonary lesions on a chest roentgenogram (in right-sided disease); and the actual demonstration of infected heart valves at the time of surgery.

**Central Nervous System Infections** *P. aeruginosa* infections of the central nervous system include meningitis and brain abscess. These infections follow extension from a contiguous parameningeal structure such as the ear, mastoid, or paranasal sinus; direct inoculation into the subarachnoid space or brain through head trauma, surgery, or diagnostic procedures; or bacteremic spread from infection at a distant site. Like *P. aeruginosa* infections at other anatomical sites, central nervous system infections are documented almost exclusively in patients with compromised local or systemic immune-defense mechanisms. Mortality rates from these infections are high.

The clinical signs of *P. aeruginosa* meningitis, like those of other forms of acute bacterial meningitis, include fever, headache, stiff neck, confusion, and obtundation. The onset of illness may be acute or even fulminant, particularly in bacteremic patients, with a precipitous downhill course, shock, coma, and early death. In nonbacteremic patients, *P. aeruginosa* meningitis or brain abscess may present more insidiously, with a paucity of systemic symptoms. This presentation is especially common in infections resulting from recent neurosurgery, cancer of the head and neck, or direct extension from a parameningeal focus of chronic infection. Occasionally, *P. aeruginosa* meningitis runs a subacute or relapsing course that is thought to be related to compromised local or systemic immune-defense mechanisms. Morbidity associated with meningitis may result from even minor corneal injury, which interrupts the integrity of the superficial epithelial surface and permits bacterial access to the underlying stroma. Corneal ulcer may complicate contact lens use, particularly when extended-wear soft contact lenses are involved. Contact lens solutions or the lenses themselves may be the source of the organism, which is probably inoculated into the eye at sites of minor lens-induced corneal damage. Patients who have sustained serious burns, have undergone ocular irradiation or tracheostomy, have been exposed to the intensive care environment, and/or are in a coma are also susceptible to *P. aeruginosa*–associated corneal ulcers. Contaminated eye medications are occasionally implicated in these infections. *P. aeruginosa* keratitis usually starts as a small central ulcer; spreads concentrically to involve a large portion of the cornea, sclera, and underlying stroma; and in some cases progresses to posterior corneal perforation.

The clinical manifestations of *P. aeruginosa* keratitis include a rapidly expanding, necrotic stromal infiltrate in the bed of an epithelial injury; surrounding epithelial edema; an anterior chamber reaction; and mucopurulent discharge adherent to the ulcer’s surface. Corneal ulcer due to *P. aeruginosa* may advance rapidly to involve the entire cornea in ≤2 days or may evolve subacutely over several days. Systemic symptoms are uncommon. Complications include corneal perforation, anterior chamber involvement, and endophthalmitis.

*P. aeruginosa* endophthalmitis is typically a rapidly progressive,
sight-threatening condition that demands immediate therapeutic intervention. It may complicate penetrating injuries of the eye, intraocular surgery, hematogenous spread from other sites of Pseudomonas infection, or posterior perforation of corneal ulcers. Clinical manifestations may include eye pain, conjunctival hyperemia, chemosis, lid edema, decreased visual acuity, hypopyon, severe anterior uveitis, and signs of possible vitreous involvement. Panophthalmitis may result from this intraocular infection.

**Bone and Joint Infections**

Sternoclavicular pyarthrosis caused by P. aeruginosa is often a complication of injection drug use and is rarely associated with P. aeruginosa endocarditis. Joint involvement is usually monarticular, with the sternoclavicular joint more often affected than sternochondral joints. Patients present with acute or chronic pain in the anterior chest wall, often associated with fever and restricted movement of the homolateral shoulder. Physical examination reveals tenderness, erythema, and swelling over the affected joint. Leukocytosis is common, and the ESR is almost invariably elevated. Roentgenograms show soft tissue edema, bone demineralization, lytic lesions, and periosteal elevation of the clavicular head, rib, or sternum. Material obtained by arthrocentesis or synovial biopsy yields P. aeruginosa in culture.

P. aeruginosa infections of the symphysis pubis are associated with pelvic surgery and injection drug use. The symphysis pubis, like other fibrocartilaginous joints, exhibits a peculiar susceptibility to bloodstream infection with P. aeruginosa. Affected patients report pain in the groin, hip, thigh, and/or lower abdomen that is made worse by walking. Fever is variable, and the duration of symptoms before diagnosis ranges from days to months. The ESR is markedly elevated. Roentgenograms or CT scans show irregularities of the pubic margins, separation of the symphysis pubis, and osteomyelitic abnormalities of the pubic rami that may be extensive. Bone scans are usually positive. Needle aspiration or biopsy is necessary to obtain material for culture. A positive culture is particularly important for the discrimination of P. aeruginosa infections and other pyogenic infections from osteitis pubis, which is thought to be a noninfectious condition complicating pelvic surgery, childbirth, or trauma.

P. aeruginosa is the most common cause of osteochondritis of the foot following plantar puncture wounds. This infection is seen primarily in children and is usually acquired via the direct inoculation of P. aeruginosa that inhabits the moist environment found in the soles of shoes. The organism infects the small joints and bones, including the proximal phalanges, metatarsals, metatarsophalangeal joints, tarsal bones, and calcaneus. On average, local pain and swelling last for several weeks, and systemic symptoms are usually lacking. There may be plantar callosities under the involved area or tenderness upon deep palpation. Results of roentgenograms and bone scans are generally positive. Aspiration of the affected joint frequently yields purulent material in which P. aeruginosa can be demonstrated by Gram’s staining and by culture.

Vertebral osteomyelitis due to P. aeruginosa is associated with complicated urinary tract infection, genitourinary instrumentation or surgery, and injection drug use. Vertebral infections that are associated with a urinary tract source most often develop in the elderly and usually affect the lumbarosacral spine. Presumably the route of infection in these patients is a shared venous plexus between the pelvis and spine. Drug use–related infections typically occur in younger patients and may affect the cervical or lumbarosacral spine. P. aeruginosa vertebral osteomyelitis is usually an indolent disease. Accordingly, symptoms may develop weeks or even months before diagnosis. Back or neck pain is generally reported, while fever and systemic symptoms are relatively uncommon. Local tenderness and decreased range of motion of the affected spine are typical. Leukocytosis may be noted, the ESR is almost always markedly elevated, and blood cultures are sometimes positive. Roentgenograms reveal loss of bone density, narrowed intervertebral space, destruction of vertebral end plates, lytic lesions of vertebral bodies, sclerosis, and possible osteophyte formation. MRI or CT is the most sensitive and specific means of defining lesions. Technetium bone scans and gallium scans usually yield positive results but have lower specificity. An etiologic diagnosis requires the culture of material obtained by needle aspiration or biopsy of the affected spine under fluoroscopic guidance; open biopsy is occasionally needed. P. aeruginosa is one of the most common causative agents in a variety of other, less specific syndromes involving nonhematogenous infections of bones and joints and collectively referred to as chronic contiguous osteomyelitis. These infections may result, for example, from compound fractures, contamination associated with open reduction and fixation of closed fractures, sternotomy performed in conjunction with cardiac surgery, contiguous spread from infected ischial ulcers related to peripheral vascular disease or diabetes mellitus, and cellulitis in general. The chronicity, indolence, and heterogeneity of these infections explain their varied clinical manifestations and the frequent need for complicated long-term management.

**Urinary Tract Infections**

P. aeruginosa is one of the most common causes of complicated and nosocomial infections of the urinary tract. These infections may result from urinary tract catheterization, instrumentation, surgery (including renal transplantation), or obstruction; they may arise from persistent foci (e.g., the prostate or stones) and may be chronic or recurrent. The urinary tract may be a target for bloodstream infection in patients with P. aeruginosa bacteremia but more often is the source of bacteremia. Chronic P. aeruginosa infections of the urinary tract are relatively common among patients with indwelling bladder catheters, altered urinary tract anatomy secondary to diversionary procedures, and paraplegia. Chronic or recurrent urinary tract infection caused by Pseudomonas often involves multidrug-resistant (MDR) strains.

The clinical features of urinary tract infections due to P. aeruginosa are usually indistinguishable from those of other bacterial infections. However, P. aeruginosa infections exhibit a propensity for persistence, chronicity, and recurrence. More unusual forms of urinary tract involvement peculiar to P. aeruginosa include (1) ulcerative lesions of the renal pelvis, ureters, and bladder that cause sloughing of vesical membranes in the urine; and (2) erythema-like lesions of the renal cortex that are seen in association with Pseudomonas sepsis.

**Skin and Soft Tissue Infections**

(See also Chap. 110) As indicated above, P. aeruginosa bacteremia may be associated with the disseminated skin lesions of erythema gangrenosum (Fig. 136–1). Less common skin manifestations of P. aeruginosa sepsis include vesicular or pustular lesions, bullae, subcutaneous nodules, deep abscesses, and cellulitis. Metastatic lesions of the skin or mucous membranes complicate Pseudomonas sepsis and occasionally produce massive necrosis or gangrene of the extremities, perineum, face, or oropharynx.

Primary P. aeruginosa pyoderma occurs when the skin breaks down secondary to surgery, trauma, burn injury, dermatitis, or ulcers related to peripheral vascular disease or pressure sores. Moist conditions and neutropenia may predispose to this condition. The clinical appearance of primary P. aeruginosa pyoderma, which frequently includes hemorrhage and necrosis, resembles that of metastatic P. aeruginosa skin lesions. Histologic studies document vascular invasion by bacteria in both diseases. A rare distinguishing feature of P. aeruginosa pyoderma is its association with a characteristic fruity odor and an exudate of blue-green hue (due to pyocyanin) that is occasionally noted on dressings or bandages rather than on the wound itself. P. aeruginosa wound infection complicating extensive third-degree burn injuries typically occurs at least 1 to 2 weeks after the injury and results from colonization of the burn site or burn eschar. Invasion of the subeschar space and underlying dermis, vascular invasion, and systemic spread may occur and are associated with an elevated mortality rate. The development and progression of P. aeruginosa burn wound sepsis are facilitated by the injury-associated breakdown of normal skin, selection of antibiotics with inadequate coverage for this pathogen, and burn-related immune defects. Local manifestations include black, dark brown, or violaceous discoloration of the burn es-
The susceptibility of the isolate from a particular case should guide definitive antibiotic therapy (see below).

In most severe or life-threatening infections due to *P. aeruginosa*, two antipseudomonal antibiotics to which the infecting strain is (or is likely to be) sensitive should be administered together. The putative benefits of this combined therapy, as determined by in vitro studies, are to increase efficacy, to achieve additive or synergistic killing, and to prevent the emergence of antibiotic resistance. Despite widespread acceptance of combination therapy for *P. aeruginosa* infections, there are few clinical data collected since the advent of newer β-lactam antibiotics to document that combination therapy is in fact more efficacious than monotherapy or that it actually forestalls the acquisition of antimicrobial resistance. Nevertheless, combination therapy continues to be recommended—at least as initial treatment—for most fulminant infections, as outlined in Table 136-4.

The appropriate duration of antibiotic therapy for disease caused by *P. aeruginosa* depends on the type, location, and severity of infection. In general, chronic infections associated with extensive tissue injury, disruption of normal anatomy, foreign or prosthetic material, or suboptimal antibiotic accessibility require therapy for weeks or even months rather than days. More acute infections may be treated aggressively but for shorter periods.

*P. aeruginosa* infections of the lower respiratory tract in cystic fibrosis pose a special challenge because of their long-standing nature (Chap. 241). In general, antibiotic therapy for acute exacerbations results in short-term clinical improvement, while periodic expectant courses of antimicrobial therapy may limit disease progression. The clinical response to antimicrobial therapy may have little relation to the identity and antimicrobial susceptibility of cultured sputum isolates. A more novel approach to antimicrobial treatment—the use of intermittent, cyclical inhaled tobramycin—has been shown to improve pulmonary function, decrease the risk of hospitalization, and reduce the density of *P. aeruginosa* in sputum of older patients with cystic fibrosis. In addition, lung transplantation has been employed with good results in selected cystic fibrosis patients with severe, progressive lower respiratory tract infections due to *P. aeruginosa*.

**Antimicrobial Resistance**

Antibiotic resistance in *P. aeruginosa* is both intrinsic (as reflected by the relative paucity of antibiotics with inherent activity against wild-type strains) and acquired (as defined by high-level resistance to agents that normally would be expected to exhibit antimicrobial activity). Acquired resistance is rapidly increasing among isolates of *P. aeruginosa*, particularly those associated with cystic fibrosis and with ICUs. Escalating resistance among ICU isolates is especially alarming. Data from NNIS and the Intensive Care Antimicrobial Resistance Epidemiology (ICARE) project on the resistance of *P. aeruginosa* between 1998 and 2002 show that the pooled mean figures for resistance to piperacillin, ceftazidime, imipenem, and ciprofloxacin increased from previous years and represented 14.3, 10.5, 13.7, and 28.9% of ICU-associated isolates, respectively. Factors responsible for this increase may include the expanding use of immunosuppressive therapies, the increased severity of illness in hospitalized patients, inadequate infection-control procedures, and growing antibiotic use. Resistant organisms can be transmitted directly to patients from the hospital staff, other patients, or the environment, or they may arise de novo during therapy with any given agent. The emergence of MDR strains has been associated with increases in secondary bacteremia and mortality and has led in some cases to longer hospital stays and increased hospitalization costs. Therapy for resistant *P. aeruginosa* infections should consist of antimicrobial agents selected on the basis of extended susceptibility testing and may involve increased treatment duration as well as surgical drainage or removal of infected tissues. Infections due to strains resistant to all commonly available antimicrobial agents may respond to parenteral or inhaled therapy with the relatively toxic antibiotics polymyxin B and colistin.

infections and occasional nosocomial outbreaks. An opportunistic pathogen that is implicated in both sporadic endemic and nosocomial outbreaks, B. cepacia is actually a complex of closely related bacteria, and the species is now divided into nine distinct genomovars based on molecular sequencing and biochemical analysis. Hospital epidemics are most frequently associated with a liquid reservoir or a moist environmental surface. Colonization by this organism precedes infection, and distinction between the two is often difficult. B. cepacia has been reported to cause pneumonia, urinary tract infections, meningitis, peritonitis, surgical and burn wound infections, bacteremia, and endocarditis related to injection drug use. In addition, B. cepacia has been implicated as a cause of chronic lower respiratory tract infections in patients with chronic granulomatous disease, in patients with sickle cell hemoglobinopathies, and— together with P. aeruginosa—in patients with cystic fibrosis. For cystic fibrosis patients, chronic B. cepacia respiratory infection (especially that involving genomovar III) is of special concern, as it portends an unusually rapid decline in pulmonary function and a poor clinical prognosis. Moreover, in some patients with cystic fibrosis, B. cepacia has been associated with fulminant necrotizing pneumonia, bacteremia, and a rapid downhill course.

* Indicated dosages are for the treatment of infections due to P. aeruginosa in adults. Doses should be adjusted in renal insufficiency. Higher doses may be required in patients with cystic fibrosis, and lower doses may be adequate for the treatment of uncomplicated urinary tract infections.
* Some strains of P. aeruginosa may rapidly develop resistance to these agents during therapy.
* Ertaopenem, an additional drug in this class, has less in vitro activity and should not be used for the treatment of Pseudomonas infections.
* Trovafloxacin, an additional fluoroquinolone with antipseudomonal activity, has limited usefulness because of its hepatotoxicity. Gatifloxacine and moxifloxacine have in vitro activity against P. aeruginosa (albeit less than ciprofloxacin and levofloxacin), but there are no clinical studies to support their use in Pseudomonas or nosocomial infections.

Abbreviations: MD, multidose; ODD, once-daily dosing; CNS, central nervous system.

**TREATMENT**

The treatment of B. cepacia infections typically is complicated by intrinsic resistance of the organism to several antimicrobial drugs, including many $\beta$-lactam agents, the aminoglycosides, colistin, and polymyxin B. Trimethoprim-sulfamethoxazole (TMP-SMX; 15 to 20 mg/kg per day for patients with normal renal function) is preferred for the treatment of B. cepacia infections, although acquired resistance to this agent has been reported. Carbapenems, third-generation cephalosporins, fluoroquinolones, monocyline, and chloramphenicol may offer activity against sensitive strains. For infections with MDR strains or those not responding to a single antibiotic, combinations of agents may display in vitro synergy and clinical efficacy. Some cystic fibrosis centers segregate patients infected with B. cepacia in an attempt to reduce horizontal transmission to uninfected patients. In addition, many centers consider lung transplantation contraindicated in patients with chronic infection due to genomovar III because of an unacceptably high mortality rate following surgery.

**Stenotrophomonas maltophilia** A ubiquitous free-living opportunistic bacterium, S. maltophilia has emerged as an important pathogen among hospitalized patients, particularly at cancer centers and in ICUs. Most infections are sporadic; however, nosocomial outbreaks of S. maltophilia infection have been linked to contaminated respiratory and inhalational equipment and water faucets. As with P. aeruginosa and B. cepacia, infection can be difficult to discriminate from colonization. Risk factors for either include prolonged hospitalization, malignancy, chemotherapy-induced mucositis and neutropenia, instrumentation (e.g., urinary, peritoneal, and central venous catheterization), and prior administration of broad-spectrum antibiotics. Intrinsinc antibiotic resistance of S. maltophilia, based on both low outer-membrane permeability and inducible $\beta$-lactamases, is at least partly responsible for the emergence of this organism as a nosocomial pathogen under the selective pressure of antibiotic treatment.

---

*S. maltophilia* has most commonly been associated with pneumonia but also causes bacteremia, urinary tract infection, wound infection, peritonitis, cholangitis, meningitis, and (rarely) endocarditis. Acute *S. maltophilia* pneumonia, an uncommon but devastating disease associated with bacteremia, is usually seen in debilitated patients in ICUs. Bacteremia is most often related to central venous catheter infection, although it may arise secondary to any focal *S. maltophilia* infection.

**TREATMENT**

TMP-SMX is the drug of choice for the treatment of most *S. maltophilia* infections. Other agents include ticarcillin/clavulanate, minocycline, or doxycycline, either alone or in combination with TMP-SMX. The third-generation cephalosporins cefoperazone and ceftazidime and the fluoroquinolones are occasionally active against *S. maltophilia*, but in vitro susceptibility data may not reflect the clinical efficacy of these agents. The aminoglycosides and carbapenems are almost always inactive. Indwelling catheters or appliances that are associated with infection should be removed.

*Melioidosis* □ *ETOLOGY AND EPIDEMIOLOGY* Infections caused by *B. pseudomallei* (formerly *P. pseudomallei*) constitute a broad spectrum of acute and chronic, local and systemic, clinical and subclinical disease processes collectively called melioidosis. *B. pseudomallei* and the infections it causes are found mainly in the tropics and are endemic in Southeast Asia, northern Australia, and—to a lesser extent—southern Asia and southern China. Melioidosis is sometimes seen outside of these regions, however, in immigrants or travelers arriving from endemic areas. *B. pseudomallei* is a free-living, small, motile, aerobic gram-negative bacillus saprophyte normally found in soil, ponds, and rice paddies and on produce from endemic areas. It is occasionally a pathogen for animals, but zoonotic transmission to humans is rare. Humans con-
tract the disease during contact with *B. pseudomallei*—contaminated soil or water through exposure of abraded skin, percutaneous inoculation, nasal instillation, inhalation, or possibly ingestion. Unlike *B. cepacia*, *B. pseudomallei* does not cause colonization without infection and is only rarely transmitted from person to person. *B. pseudomallei* is listed as a category B biological agent by the Centers for Disease Control and Prevention (CDC) because of its potential to cause considerable morbidity and mortality if deliberately disseminated as a weapon of mass destruction.

**MANIFESTATIONS** Melioidosis presents in different forms. The infection may be acute, subacute, or chronic. High rates of seropositivity in endemic areas such as Vietnam, Thailand, and Malaysia suggest that many infections are clinically inapparent. The occasional diagnosis based solely on abnormal routine chest roentgenogram represents asymptomatic pneumonitis. Acute pulmonary infections are the most common manifestation of melioidosis and may result from hematogenous spread or originate in the respiratory tract; these infections vary from mild bronchitis to extensive necrotizing pneumonia. Their onset may be gradual or sudden. Fever, rigor, productive cough, and marked tachypnea are common. More chronic pulmonary infections may present as productive cough, hemoptysis, and indolent fever with night sweats mimicking tuberculosis. Chest roentgenograms typically reveal upper-lobe infiltrates, occasionally with thin-walled cavities. Another common manifestation of melioidosis is an acute, localized skin infection with ulceration or abscess that is associated with nodular lymphangitis and regional lymphadenitis. Melioidosis may also present as suppurrative parotitis, particularly in children. More rarely, *B. pseudomallei* may cause liver or splenic abscesses, septic arthritis, osteomyelitis, or genitourinary or central nervous system infection. Recrudescence disease arising from inactive sites of infection and perhaps triggered by intercurrent illness or other events may present in an acute or chronic form.

Either acute suppurrative infections or pulmonary disease may give rise to hematogenous dissemination and the acute septicemic form of melioidosis. This progression is more likely in chronically debilitated patients, such as those with diabetes mellitus, chronic renal disease, or alcoholism. Septicemic patients may present with severe tachypnea, confusion, headache, pharyngitis, diarrhea, and pustular lesions of the head, trunk, and extremities. The skin may be flushed or cyanotic, signs of meningitis or arthritis may be apparent, the liver and spleen may be enlarged, and muscle tenderness may be striking. Chest roentgenograms show diffuse nodular densities that may expand, coalesce, and finally cavitate. The acute septicemic form of melioidosis usually follows a rapid downhill course, ending in early death. Mortality rates remain high despite optimal therapy.

**DIAGNOSIS** The diagnosis of melioidosis should be entertained when a febrile patient who has been in an endemic area presents with an acute lower respiratory tract illness, parotitis, lymphadenitis, or unusual skin or subcutaneous lesions or has a chest roentgenogram suggesting tuberculosis in the absence of sputum-associated tubercle bacilli. An etiologic diagnosis is suggested by the microscopic demonstration in exudate material of small, bipolar, irregularly staining, gram-negative rods with a characteristic “safety-pin” appearance and is confirmed by a culture positive for *B. pseudomallei* and/or a fourfold or greater rise in the titer of serum antibody to the organism.

**TREATMENT** The mainstay of treatment for melioidosis is antibiotic administration combined with appropriate surgical drainage of abscesses and aggressive support for patients with septicemic forms of the disease. The guidelines for antibiotic therapy are somewhat imprecise. Cefazidime or carbapenems such as imipenem or meropenem appear to be the agents of choice for clinical disease, including severe infections. TMP-SMX, cefotaxime, and amoxicillin/clavulanate are possible alternatives. Fluoroquinolones are not active against *B. pseudomallei* and have no role in the treatment of melioidosis. Combination therapy with cefazidime or imipenem plus TMP-SMX may be indicated in severe forms of melioidosis, including septicemia. Unfortunately, the increasing resistance of many strains of *B. pseudomallei* to TMP-SMX, particularly in Southeast Asia, is of concern. Patients with acute pulmonary infections who are treated with either cefazidime or carbapenems should receive antibiotics until they show definite evidence of clinical improvement (often in 10 to 30 days), at which time they can be switched to oral maintenance or eradication therapy with a combination of chloramphenicol, TMP-SMX, and doxycycline or with the single agent amoxycillin/clavulanate for 12 to 20 weeks. Chronic disease associated with persistently positive sputum cultures and extrapulmonary suppurrative disease may require treatment for up to 1 year.

**Glanders**

**ETIOLOGY AND EPIDEMIOLOGY** Glanders is primarily a systemic equine disease that is caused by *B. mallei*. Once widespread, glanders was eradicated from North America in 1938 through the extensive culling of infected or exposed horses. The disease still occurs sporadically, however, in Africa, Asia, and South America. Historically, glanders was occasionally transmitted to humans during close contact with infected horses, mules, or donkeys. *B. mallei* is believed to have been used deliberately as an agent of biological warfare during World War I, an effort resulting in the infection of large numbers of Russian horses and mules. Research on *B. mallei* as an agent of biological warfare may have continued into more recent times, including work to develop an antibiotic-resistant aerosolized form of the bacterium. The first human case of glanders since 1949 was reported in the United States in 2001 and was acquired through laboratory exposure to *B. mallei* during the course of research on defense against agents of biological warfare and terrorism. Like *B. pseudomallei*, *B. mallei* has been classified by the CDC as a category B biological agent.

**MANIFESTATIONS** Glanders can assume the following forms in humans: acute localized suppurrative infection, acute pulmonary infection, acute septicemic infection, and chronic suppurrative infection. Disease develops several days or weeks after the inoculation of *B. mallei* into the skin, usually of the hand or arm. A localized skin nodule or suppurative focus is associated with regional lymphadenitis, fever, malaise, and prostration. Mucous membrane infection results in the production of a mucopurulent discharge from the eye, nose, or lips, with the subsequent development of granulomatous ulcers. Inhalation of the organism is accompanied by the typical symptoms and signs of pneumonia. The acute septicemic form of the infection may follow local infection and is characterized by signs of sepsis frequently associated with shock and multiorgan system failure. Evidence of acute *B. mallei* dissemination may include lymphadenopathy, splenomegaly, lung abscesses, lobar consolidation, liver and splenic abscesses, and a diffuse papular or pustular eruption resembling smallpox. Mortality rates from septicemic and acute disseminated disease are high. Chronic suppurrative glanders presents as multiple subcutaneous, intramuscular, and visceral abscesses. Any form of glanders could follow aerosolized dissemination of the organism—e.g., in a bioterrorist event.

**DIAGNOSIS** The diagnosis of glanders may be suggested by the epidemiology and clinical setting of the infection together with evidence of irregularly staining, small, bipolar, gram-negative rods in suppurrative exudates. *B. mallei* can be cultured and identified with standard bacteriologic media but may be misidentified as *Pseudomonas fluorescens* or *P. putida* by automated identification systems. Molecular methods, such as 16S rRNA gene sequencing, can be used for rapid identification of *B. mallei* from culture and can discriminate this organism from closely related organisms, including *B. pseudomallei*. A single high titer of serum antibody or a fourfold increase in titer suggests recent infection. A diagnosis of glanders in the absence of close contact with an infected equine should raise suspicion regarding the deliberate, bioterrorism-related dissemination of *B. mallei*. 
TREATMENT

Treatment of glanders includes appropriate supportive measures for sepsis and the surgical drainage of abscesses. Optimal antimicrobial therapy for glanders has not been adequately defined because of a lack of human infections in the antibiotic era. Cefazidime, gentamicin, imipenem, doxycycline, and ciprofloxacin all have in vitro activity against B. mallei. A recent laboratory-acquired case of human glanders responded to a combination of imipenem and doxycycline, and experimental glanders in primates responds to a combination of sulfa-monomethoxime (not available in the United States) and trimethoprim. It has been suggested that rational therapy for glanders should consist of the same antibiotics recommended for the treatment of melioidosis, with the specific agent chosen on the basis of in vitro susceptibility testing. As in melioidosis, long-term antimicrobial therapy is probably necessary. The antimicrobial susceptibilities of B. mallei organisms disseminated in the context of bioterrorism or biowarfare may not be predictable, given the possibility of bioengineered antimicrobial resistance.

Other Species P. fluorescens occasionally causes human disease; it is implicated particularly often in infections related to the administration of contaminated (stored) blood products and in pseudoinfections. Additional bacterial species that are associated only rarely with human infections include P. putida, Pseudomonas luteola, Pseudomonas stutzeri, Pseudomonas alcaligenes, Pseudomonas pseudalcaligenes, and (all formerly Pseudomonas species) Burkholderia gladioli, Burkholderia pickettii, Comamonas acidovorans, Comamonas testosteroni, Brevundimonas diminuta, and Brevundimonas vesicularis.

secretion). These bacterial proteins mediate alterations in the actin cytoskeleton that are required for Salmonella uptake.

After crossing the epithelial layer of the small intestine, S. typhi and S. paratyphi, which cause enteric (typhoid) fever, are phagocytosed by macrophages. Once internalized, the salmonellae are protected from polymorphonuclear leukocytes (PMNs), the complement system, and the acquired immune response (antibodies). However, these bacteria must survive the antimicrobial environment of the macrophage, which includes the production of reactive oxygen and nitrogen species, antimicrobial peptides, and hydrolytic enzymes. Environmental signals within the macrophage trigger alterations in regulatory systems of the phagocytosed bacteria. The best-characterized regulatory system is PhoP/PhoQ, a two-component system that senses changes in bacterial location and alters bacterial protein expression. For example, PhoP/PhoQ triggers the expression of outer-membrane proteins and mediates modifications in LPS so that the bacteria’s outer surface can resist microbicidal activities and potentially alter host cell signaling. In addition, salmonellae encode a second type III secretion system that directly delivers bacterial proteins from the phagosome into the macrophage cytoplasm. This secretion system is essential for survival within macrophages.

Once phagocytosed, salmonellae disseminate throughout the body in macrophages via the lymphatics and colonize reticuloendothelial tissues (liver, spleen, lymph nodes, and bone marrow). Patients have relatively few or no signs and symptoms during this initial incubation stage. Signs and symptoms, including fever and abdominal pain, probably result from secretion of cytokines by macrophages when a critical number of organisms have replicated. For example, the development of hepatosplenomegaly is likely to be related to the recruitment of mononuclear cells and the development of a cell-mediated immune response to S. typhi colonization. The recruitment of additional mononuclear cells and lymphocytes to Peyer’s patches during the several weeks after initial colonization/infection can result in marked enlargement and necrosis of the Peyer’s patches.

In contrast to enteric fever, which is characterized by an infiltration of mononuclear cells into the small-bowel mucosa, nontyphoidal Salmonella gastroenteritis is characterized by massive PMN infiltration into both the large- and the small-bowel mucosa. This response appears to depend on the induction of interleukin (IL) 8, a strong neutrophil chemotactic factor, which is secreted by intestinal cells. The degranulation and release of toxic substances by neutrophils may result in damage to the intestinal mucosa, causing the inflammatory diarrhea observed with nontyphoidal gastroenteritis.

It is not yet known why S. typhi and S. paratyphi cause systemic disease and are host restricted, whereas the vast majority of pathogenic Salmonella strains cause gastroenteritis in a broad range of hosts. Recently generated genome sequences show that S. typhi contains more than 200 pseudogenes, which appear to be functional genes in S. typhimurium. These pseudogenes may have been dispensable for S. typhi growth in humans.

**ENTERIC (TYPHOID) FEVER**

Typhoid fever is a systemic disease characterized by fever and abdominal pain caused by dissemination of S. typhi or S. paratyphi. The disease was initially called typhoid fever because of its clinical similarity to typhus. However, in the early 1800s, typhoid fever was clearly defined pathologically as a unique illness on the basis of its association with enlarged Peyer’s patches and mesenteric lymph nodes. In 1869, given the anatomical site of infection, the term enteric fever was proposed as an alternative designation to distinguish typhoid fever from typhus. However, to this day, the two designations are used interchangeably.

**EPIDEMIOLOGY** In contrast to other Salmonella serotypes, the etiologic agents of enteric fever—S. typhi and S. paratyphi—have no known hosts other than humans. Thus, enteric fever is transmitted only through close contact with acutely infected individuals or chronic carriers. While direct person-to-person transmission through the fecal-oral route has been documented, it is quite rare. Rather, most cases of disease result from ingestion of contaminated food or water. Health care workers occasionally acquire enteric fever after exposure to infected patients, while laboratory workers can acquire the disease after laboratory accidents.

Over the past four decades, with the advent of improvements in food handling and water/sewage treatment, enteric fever has become a rare occurrence in developed nations. Over the past 10 years, ~400 cases of typhoid fever and even fewer cases of paratyphoid fever have been reported annually in the United States. In contrast, enteric fever continues to be a global health problem, with an estimated 13 to 17 million cases worldwide resulting in ~600,000 deaths per year. Children <1 year of age appear to be most susceptible to initial infection and to the development of severe disease.

Enteric fever is endemic in most developing regions, especially the Indian subcontinent, South and Central America, and Asia, and is related to rapid population growth, increased urbanization, inadequate human waste treatment, limited water supply, and overburdened health care systems. These conditions most likely account for the recent epidemics of typhoid fever in Eastern Europe. Antibiotic resistance among salmonellae is also a rising concern and has been linked to antibiotic use in livestock. Many S. typhi strains contain plasmids encoding resistance to chloramphenicol, ampicillin, and trimethoprim—antibiotics that have long been used to treat enteric fever. In addition, resistance to ciprofloxacin, either chromosomally or plasmid encoded, has been observed in Asia (India and Vietnam). Morbidity and mortality are increased in outbreaks associated with antibiotic-resistant strains, presumably because of inadequate or delayed treatment.

The high worldwide prevalence of enteric fever serves as a reservoir for cases in the United States. More than 70% of U.S. cases are related to international travel within 30 days before onset. Only 3% of travelers diagnosed with enteric fever give a history of vaccination against S. typhi within the previous 2 years. Of U.S. cases of internationally acquired enteric fever, 80% can be linked to travel in six countries: Mexico (28%), India (25%), the Philippines (10%), Pakistan (8%), El Salvador (5%), and Haiti (4%). While the percentage of cases associated with travel to Mexico is declining, travel to the Indian subcontinent is becoming much riskier, with an incidence 18 times higher than for any other area. The trend toward an increased incidence of multidrug-resistant (MDR) Salmonella (see “Treatment,” below) in developing countries is reflected by the increase in the proportion of U.S. cases caused by MDR strains from 0.6% in 1985–1989 to 12% in 1990–1994.

Almost 30% of the reported cases of enteric fever in the United States are domestically acquired. Although the majority of these cases (80%) are sporadic, large outbreaks do occur. In 1993, 47 culture-proven and 24 potential cases were linked to contaminated orange juice at a resort in New York. Evaluation of this outbreak led to the identification of a previously unknown chronic carrier. Similarly, evaluation of 25% of the 571 cases of domestically acquired enteric fever reported between 1985 and 1994 led to the identification of previously unknown chronic carriers.

**CLINICAL COURSE** Enteric fever is a misnomer, in that the hallmark features of this disease—fever and abdominal pain—are variable. While fever is documented at presentation in more than 75% of cases, abdominal pain is reported in only 20 to 40%. Thus, a high index of suspicion for this potentially lethal systemic illness is necessary when a person presents with fever and a history of recent travel to a developing country.

The incubation period for S. typhi ranges from 3 to 21 days. This variability is most likely related to the size of the initial inoculum and the health and immune status of the host. The most prominent symptom is the systemic illness, which is characterized by a persistent low-grade fever (38.8° to 40.5°C or 101.8° to 104.9°F). A prodrome of nonspecific symptoms often precedes fever and includes chills, headache, anorexia, cough, weakness,
sore throat, dizziness, and muscle pains. Gastrointestinal symptoms are quite variable. Patients can present with either diarrhea or constipation; diarrhea is more common among patients with AIDS and among children <1 year of age. As stated above, only 20 to 40% of patients present with abdominal pain, although the majority have abdominal tenderness over the course of the disease. In general, the symptoms associated with \textit{S. typhi} are more severe than those associated with \textit{S. paratyphi}.

Early physical findings of enteric fever include rash (“rose spots”), hepatosplenomegaly, epistaxis, and relative bradycardia. Rose spots (Fig. 137-1) make up a faint, salmon-colored, blanching, maculopapular rash located primarily on the trunk and chest. The rash is evident in ~30% of patients at the end of the first week and resolves after 2 to 5 days without leaving a trace. Patients can have two or three crops of lesions, and \textit{Salmonella} can be cultured from punch biopsies of these lesions. The faintness of the rash makes it difficult to detect in dark-skinned patients. On occasion, patients who remain toxic manifest neuropsychiatric symptoms described as a “muttering delirium” or “coma vigilt,” with picking at bedclothes or imaginary objects.

Late complications, occurring in the third and fourth weeks of infection, are most common in untreated adults and include intestinal perforation and/or gastrointestinal hemorrhage. These complications can develop despite clinical improvement and presumably result from necrosis at the initial site of \textit{Salmonella} infiltration at the Peyer’s patches of the small intestine. Both complications are life-threatening and require immediate medical and surgical interventions, with broadened antibiotic coverage for polymicrobial peritonitis (Chap. 112) and treatment of gastrointestinal hemorrhages, including bowel resection.

Rare complications whose incidences are reduced by prompt antibiotic treatment include pancreatitis, hepatic and splenic abscesses, endocarditis, pericarditis, orchitis, hepatitis, meningitis, nephritis, myocardiitis, pneumonia, arthritis, osteomyelitis, and parotitis. Despite prompt antibiotic treatment, relapse rates remain at ~10% in immunocompetent hosts.

Approximately 1 to 5% of patients with enteric fever become long-term, asymptomatic, chronic carriers who shed \textit{S. typhi} in either urine or stool for >1 year. The incidence of chronic carriers is higher among women and among persons with biliary abnormalities (e.g., gallstones, carcinoma of the gallbladder) and gastrointestinal malignancies. The anatomical abnormalities associated with these conditions presumably allow prolonged colonization.

**DIAGNOSIS** Since the clinical presentation of typhoid fever is relatively nondescript, the diagnosis needs to be considered in any febrile traveler returning from a developing country, especially the Indian subcontinent, the Philippines, or Latin America. Other diagnoses that should be considered in this patient population include malaria, hepatitis, bacterial enteritis, dengue fever, rickettsial infections, leptospirosis, amebic liver abscesses, and acute HIV infection (Chap. 108).

Other than a positive culture, no specific laboratory test is diagnostic for enteric fever. In 15 to 25% of cases, leukopenia and neutropenia are detectable. In the majority of cases, the white blood cell count is normal despite high fever. However, leukocytosis can develop in typhoid fever (especially in children) during the first 10 days of the illness, or later if the disease course is complicated by intestinal perforation or secondary infection. Other nonspecific laboratory results include moderately elevated values in liver function tests (aminotransferases, alkaline phosphatase, and lactate dehydrogenase). In addition, nonspecific ST and T wave abnormalities can be seen on electrocardiograms.

The diagnostic “gold standard” is a culture positive for \textit{S. typhi} or \textit{S. paratyphi}. The yield of blood cultures is quite variable: it can be as high as 90% during the first week of infection and decrease to 50% by the third week. A low yield is related to low numbers of \textit{Salmonella} (<15 organisms per milliliter) in infected patients and/or to recent antibiotic treatment. Centrifugation to isolate and culture the buffy coat, which contains abundant blood mononuclear cells associated with the bacteria, decreases time to isolation but does not affect culture sensitivity.
